Publication information: *Journal of Hepatology* (ISSN 0168-8278). For 2018, volumes 68 and 69 are scheduled for publication. Subscription prices are available upon request from the Publisher or from the Elsevier Customer Service Department nearest you or from this journal's website (http://www.elsevier.com/locate/jhep). Further information is available on this journal and other Elsevier products through Elsevier's website: (http://www.elsevier.com). Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by standard mail (surface within Europe, air delivery outside Europe). Priority rates are available upon request. Claims for missing issues should be made within six months of the date of dispatch.

Orders, claims, and journal enquiries: Please visit our Support Hub page https://service.elsevier.com for assistance.

Advertising information: Advertising orders and enquiries can be sent to: **USA, Canada and South America:** Elsevier Inc., 360 Park Avenue, Suite 800, New York, NY 10169-0901, USA; phone: (+1) (212) 989 5800. **Europe and ROW:** Robert Bayliss, Pharma Solutions, Elsevier Ltd., 125 London Wall, London EC2Y 5AS, UK; phone: (+44) 207 424 4454; e-mail: r.bayliss@elsevier.com.

Author enquiries: You can track your submitted article at http://www.elsevier.com/track-submission. You can track your accepted article at http://www.elsevier.com/trackarticle. You are also welcome to contact Customer Support via http://service.elsevier.com.

Funding body agreements and policies: Elsevier has established agreements and developed policies to allow authors whose articles appear in journals published by Elsevier, to comply with potential manuscript archiving requirements as specified as conditions of their grant awards. To learn more about existing agreements and policies please visit http://www.elsevier.com/fundingbodies.

♾ The paper used in this publication meets the requirements of ANSI/NISO Z39.48-1992 (Permanence of Paper).

Registration of Clinical Trials
The *Journal of Hepatology* endorses the policy of the WHO and the International Committee of Medical Journal Editors (ICMJE) on the registration of clinical trials. Therefore, any trial that starts recruiting on or after July 1, 2005 should be registered in a publicly owned, publicly accessible registry and should satisfy a minimal standard dataset. Trials that started recruiting before that date will be considered for publication if registered before September 13, 2005.
More detailed information regarding clinical trials and registration can be found in New Engl J Med 2004; 351:1250–1251 and New Engl J Med 2005; 352:2437–2438.

Background and Aims: Bacterial infections are common and life-threatening in patients with cirrhosis. However, the epidemiology and the outcome of bacterial infections across the world is poorly known. Thus, the International Club of Ascites promoted this multicenter intercontinental study aimed to investigate the epidemiology and the outcome of bacterial/fungal infections in hospitalized patients with cirrhosis across the world.
Method: Hospitalized patients with cirrhosis and bacterial infection were prospectively included at 46 centers across the world. Demographic, clinical, microbiological and treatment data were collected at the diagnosis of infection and during the hospitalization. Patients were followed till death, transplantation or discharge. Multi drug resistant (MDR) bacteria were defined as bacteria resistant to at least one antibiotic in >2 classes
Results: From October 2015 to September 2016, 1302 patients were included, 25% from North or South America, 32% from Asia and 43% from Europe. The most common infections were SBP (27%), UTI (22%) and pneumonia (19%). 740 patients (57%) had at least 1 positive culture and 959 microorganisms were isolated (58% Gram neg; 38% Gram pos; 4% Fungi). The global prevalence of MDR across the world was 34% (95% CI = 31–37%). Independent risk factors for MDR infections were an infection in Asia (OR = 2.79; p = 0.017), particularly in India (OR = 7.94; p < 0.001) or in South America (OR = 2.23; p = 0.053), the use of antibiotics in the previous 3 months before the hospitalization (OR = 1.92; p = 0.001), the category of infection (nosocomial [OR = 2.65; p < 0.001] and healthcare associated [1.62; p = 0.032])and the site of infection (pneumonia [OR = 3.20;p < 0.001], UTI [OR = 2.48; p < 0.001] and skin and soft tissue infection [OR = 2.92; p = 0.004]). Infections due to MDR bacteria were associated with a lower rate of response to empirical antibiotic treatment (40 *vs.* 68%; p < 0.001), a higher incidence of shock (27 *vs.* 15%; p < 0.001) and new organ failures (42 *vs.* 31%; p = 0.001), a lower rate of resolution of infection (82 *vs.* 72%; p = 0.003), and a higher in-hospital mortality (31 *vs.* 21%; p = 0.004) than those due to non-MDR bacteria.
Conclusion: The relevant differences in the etiology of bacterial/fungal infections across the world, particularly as regard to prevalence of MDR bacteria, highlight the need to develop different empirical antibiotic strategies across different continents and countries. In addition, while waiting for new antibiotics, any effort should be done to reduce the spread of MDR bacteria in cirrhosis.

GS-002

Cenicriviroc treatment for adults with non-alcoholic steatohepatitis: Year 2 analysis of the Phase 2b CENTAUR study

V. Ratziu[1], A. Sanyal[2], S. Francque[3], W. Sun, V. Wong[4], R. Loomba[5], Z. Goodman[6], E. Lefebvre[7], G. Aithal[8], S. Harrison[9], M. Abdelmalek[10], S. Friedman[11], F. ELSEVIER

Background: Cenicriviroc (CVC) is an oral CCR2/5 antagonist under treatment evaluation for liver fibrosis in adults with non-alcoholic steatohepatitis (NASH). CVC had significant antifibrotic benefit over placebo (PBO) at the 1 year (Y1) primary endpoint; herein, we report year 2 (Y2) data of the Phase 2b CENTAUR study (NCT02217475).
Method: Adults with histologically-confirmed NASH, non–alcoholic fatty liver disease activity score (NAS) ≥ 4, and liver fibrosis (NASH Clinical Research Network stage 1–3) were randomized 2:1:1 to CVC 150 mg once daily or PBO. Arms A and C received CVC or PBO, respectively, for 2 years; Arm B received PBO in Y1 and crossed over to CVC in Y2. Fibrosis, NASH, and NAS status were assessed in liver biopsies at baseline (BL), Y1, and Y2 by a central pathologist. All analyses were prespecified.
Results: 289 adults were randomized: 52% diabetes, mean BMI 34 kg/m^2, and 67% fibrosis stage 2–3 (F2-3). 242 subjects continued after Y1 (121, 61, and 60 per Arm A, B, and C); 213 had paired BL and Y2 biopsies, with missing data for 42, 12, and 16 subjects per arm. For Y1 PBO nonresponders (i.e., those who did not achieve ≥1-stage fibrosis improvement and no worsening of NASH at Y1), fibrosis improvement without worsening of NASH was seen in subjects crossing over to CVC vs. remaining on PBO (24% [10/41] in Arm B vs. 17% [6/35] in Arm C; p = 0.36), while 16/41 (39%) on CVC and 10/35 (29%) on PBO achieved ≥1-stage fibrosis reduction. Over 2 years, a similar proportion on CVC or PBO achieved ≥1-stage fibrosis improvement and no worsening of NASH (15% [15/99] in Arm A vs. 17% [9/54] in Arm C); however, a greater proportion on CVC achieved ≥2-stage fibrosis improvement and no worsening of NASH (11% [7/65] in Arm A vs. 3% [1/34] in Arm C). For those with biopsies at BL, Y1, and Y2, a greater proportion on CVC achieving ≥1-stage fibrosis improvement at Y1 maintained benefit at Y2 (60% [18/30] in Arm A vs. 30% [3/10] in Arm C); in CVC subjects with BL F3 that improved, upto 86% (12/14) maintained benefit at Y2. Greater reductions in hs-CRP and fibrinogen, but no effect on NASH or liver enzymes were observed with CVC. Adverse events were comparable for CVC and PBO and no deaths occurred.
Conclusion: CVC was well tolerated and provided antifibrotic activity in adults with NASH and liver fibrosis, confirming the Year 1 primary endpoint. A majority of subjects achieving ≥1-stage fibrosis improvement at Year 1 maintained benefit at Year 2 with CVC, with greater effect in those with advanced fibrosis.

GS-003
Sorafenib with versus without concurrent conventional transarterial chemoembolization (*c*TACE) in patients with advanced hepatocellular carcinoma (HCC): Results from a multicenter, open-label, randomized, controlled phase III STAH trial

J.-W. Park[1], Y.J. Kim[2], D.Y. Kim[3], S.H. Bae[4], S.W. Paik[5], Y.-J. Lee[6], D. Lee[7], H.C. Lee[8], S.Y. Han[9], J.Y. Cheong[10], O.S. Kwon[11], J.E. Yeon[12], B.H. Kim[1], J.-S. Hwang[13]. *[1]National Cancer Center, Korea; [2]Seoul National University Hospital; [3]Severance Hospital; [4]The Catholic University of Korea, Seoul St. Mary's Hospital; [5]Samsung Medical Center; [6]Inje University Busan Paik Hospital; [7]SNU Boramae Medical Center; [8]Asan Medical Center; [9]Dong-A University Hospital; [10]Ajou University Hospital; [11]Gachon University Gil Medical Center; [12]Korea University Guro Hospital; [13]Keimyung University Dongsan Medical Center*
Email: jwpark@ncc.re.kr

Background and Aims: Sorafenib is the standard first-line therapy for patients (pts) with advanced HCC (aHCC). *c*TACE is an effective treatment for unresectable HCC. A previous phase II study revealed that sorafenib combined with concurrent *c*TACE (SOR+T) tended to improve outcomes. Herein, we present the results from an investigator-initiated phase III trial that evaluated the effects of SOR+T in pts with aHCC.
Method: Pts were randomly assigned (1:1) into one of two arms, to receive sorafenib with *c*TACE (Arm C) or without *c*TACE (Arm S) according to modified International Union Against Cancer tumor stage, extent of vascular invasion, Child-Pugh score and serum alpha fetoprotein level. All eligible pts received 800 mg sorafenib within 3 days (Arm S and C) and *c*TACE within 7-21 days after randomization, and repeating *c*TACE on demand (Arm C). The study continued until progression or unacceptable toxicities were observed. The primary endpoint was overall survival (OS), and secondary endpoints included time to progression (TTP), progression-free survival (PFS), tumor response rate (TRR), and safety profile.
Results: Between January 2013 and December 2015, 339 pts were enrolled from 13 hospitals in South Korea, and the last pt completed the trial on June 2017. Pts baseline characteristics were well balanced. For Arm C and S, respectively, median OS was 12.8 vs. 10.8 months (m) (hazard ratio [HR], 0.91; 95% confidence interval [CI] 0.69–1.21; p = 0.290); median TTP was 5.3 vs. 3.5 m (HR, 0.67; 95% CI, 0.53–0.85; p = 0.003); median PFS was 5.2 vs. 3.6 m (HR, 0.73; 95% CI, 0.59–0.91; p = 0.01); TRR was 60.6% vs. 47.3% (p = 0.005).
For Arm C and S, respectively, serious adverse events (AE) were 33.3% vs. 19.8% (p = 0.006), and grade ≥ 3 AE were increased alanine aminotransferase (20.3% vs. 3.6%), hyperbilirubinemia (11.8% vs. 3.0%), ascites (11.8% vs. 4.2%), thrombocytopenia (7.2% vs. 1.2%), anorexia (7.2% vs. 1.2%), hyponatremia (5.2% vs. 0%) (p < 0.05); hand-foot skin reaction (10.5% vs. 11.4%), encephalopathy (5.2% vs. 1.2%) and diarrhea (5.2% vs. 4.2%).
Subgroup analysis showed a survival benefit in pts (46.4%) of Arm C who received ≥2 *c*TACE sessions when compared to pts in Arm S (18.6 vs. 10.8 m; HR, 0.58; 95% CI, 0.40-0.82; p = 0.006).
Conclusion: SOR+T therapy did not improve OS versus sorafenib alone in pts with aHCC. However, SOR+T therapy significantly improved TTP, PFS, and TRR, and a survival benefit was observed in the pts who received SOR+T ≥2 *c*TACE sessions.

GS-004
Integrative molecular classification of extrahepatic cholangiocarcinoma

Email: romontal@clinic.cat

Background and Aims: Cholangiocarcinoma (CCA) is a malignancy of the biliary tree that can be divided into intrahepatic (iCCA) or extrahepatic (eCCA), with differences in pathogenesis and clinical management. There are no effective systemic molecular therapies for eCCA and no comprehensive molecular profiling of this cancer has been performed in western patients. Thus, understanding the main molecular classes and drivers of this tumor will lead to a more precise therapeutic approach.
Method: A total of 189 FFPE primary eCCA treated by resection were retrospectively collected at seven international centers from 1995 to 2015. Median survival of the cohort was of 48.5mo. Whole gene-expression profiling (Affymetrix) was performed and data was

submitted to unsupervised clustering by NMF consensus. Clusters were characterized by Gene Set Enrichment Analysis and Ingenuity Pathway Analysis and correlated with clinico-pathological data. Screening of most prevalent somatic mutations and copy number aberrations is currently ongoing.
Results: We have identified four distinct molecular subtypes of eCCA (NMF cophenetic coefficient = 0.995). Tumors classified within the *metabolic class* *(18.7%) were enriched in gene signatures defining bile- and fatty-acid ($p < 0.001$) metabolism and presented over-expression of classic hepatocyte markers with HNF4A as the major activated upstream transcription factor ($p < 0.001$). The *proliferation class* (22.5%) was associated with papillary histology ($p < 0.01$) and presented enrichment of MYC ($p < 0.001$) and mTOR ($p < 0.05$) signaling, as well as iCCA proliferation subclass ($p < 0.001$). The *mesenchymal class* (47.3%) was associated with signatures defining epithelial-mesenchymal transition ($p < 0.001$) and stromal activation ($p < 0.001$), which was in accordance with higher desmoplasia at pathological study ($p < 0.05$). Moreover, tumors belonging to the mesenchymal class were significantly associated with poor prognosis in terms of OS (median survival 33.2 vs 55.5mo, HR = 2.02, p = 0.022). Finally, tumors classified as *immune class* (11.5%) were characterized by enrichment of PD-1 signaling ($p < 0.01$) and presented increased tumor-infiltrating lymphocytes when compared to the other three subtypes ($p < 0.001$).
Conclusion: Transcriptome-based classification of eCCA identifies four distinct molecular subtypes (metabolic, proliferation, mesenchymal and immune) that correlate with clinico-pathological characteristics. These molecular findings enhance the understanding of this cancer and pave the way for more precise therapeutics.

GS-005
Final results of a multicenter, open-label phase 2b clinical trial to assess safety and efficacy of Myrcludex B in combination with Tenofovir in patients with chronic HBV/HDV co-infection

Email: Katrin.Schoeneweis@med.uni-heidelberg.de

Background and Aims: Currently there is no approved drug for hepatitis D virus (HDV) infection. Myrcludex B (MyrB) is a first-in-class entry inhibitor blocking the HBV/HDV receptor NTCP. We previously reported end-of-treatment data of a Phase 2 clinical trial in chronic HDV infection (Wedemeyer et al.; Hepatology 2017, DOI: 10.1002/hep.29500). Here we present follow up data after stopping MyrB therapy.
Methods: 120 patients with chronic Hepatitis D were randomized in four treatment arms. Treatment with TDF 245 mg/day started not less than 12w prior to MyrB. MyrB was administered s.c. once daily at 2 (A), 5 (B) or 10 mg (C) for 24w followed by a 24w period continuing TDF. Patients in arm D received TDF alone. The primary endpoint was HDV RNA reduction by 2log or negativity.
Results: At abstract submission, virology data from 41 patients who completed the week 12 of follow up, and ALT data from 94 patients are available. **Safety:** MyrB was very well tolerated. Apart from bile acids increase, no specific AE pattern could be identified for MyrB. After MyrB cessation, two hepatitis exacerbations after stopping MyrB were reported as SAEs. The ALT flairs were not associated with bilirubin increases and resolved without intervention. Bile acid levels returned to baseline at the follow up week 1. **Efficacy:** At end of treatment, the primary endpoint was reached by 46.4%, 46.8%, 76.6%, and 3.3% of patients of arms A, B, C, and D. Median HDV RNA declined by −1.75 log, −1.60 log, −2.70 log and −0.18 log. Plasma HDV RNA decline correlated with intrahepatic decrease of HDV RNA replication. ALT normalization was achieved in 42.8%, 50%, 40% and 6.6%. Mean liver stiffness values significantly declined in all MyrB groups from baseline to treatment week 24 but not in the control group.
At follow up week 12, an HDV RNA relapse occurred in 60%, 80% and 83% of HDV RNA responders. Median HDV RNA increased by 1.26 log, 0.62 log, 1.85 log, 0 log in arms A, B, and C and D. HDV RNA levels remained −0.77 log, −1.27 log, −0.99 log, and 0 log below BL levels. Median ALT increased from 44.0 U/l, 40.5 U/l, 43.0 U/l and 76.0 U/l to 79 U/l, 63 U/l, 93 U/l and 64 U/l.
Conclusion: Myrcludex B shows a dose-dependent antiviral efficacy against HDV associated with improvements of biochemical activity and liver stiffness. Sustained HDV control after 24 weeks of therapy is possible in single patients but longer treatment durations or even maintenance therapy need to be investigated in future trials.

GS-006
Efficacy and safety of 8 weeks of elbasvir/grazoprevir in HCV GT4-infected treatment-naïve participants

Email: barbara.haber@merck.com

Background and Aims: Approximately 15–20% of HCV infections worldwide are due to genotype 4 (GT4). HCV GT4 is endemic in the Middle East and Africa, and increasing in prevalence in Europe as a result of immigration and injecting drug use. Shorter DAA treatment durations may expand access and facilitate treatment of more people infected with HCV GT4, in particular, those actively injecting drugs. Currently, a minimum of 12 weeks of the fixed-dose combination of elbasvir (EBR) 50 mg and grazoprevir (GZR) 100 mg once daily is approved for treatment of chronic HCV GT4 infection.
Methods: Protocol MK-5172-096 is a phase 4 study evaluating 8 or 12 weeks of EBR/GZR across multiple subgroups of HCV GT4 infected participants in France where 2 of the 4 study arms are to include 75 treatment-naïve participants with stage 0–2 fibrosis (FibroScan® score <8.0 kPa or demonstration of stage F0-F2 fibrosis from liver

biopsy specimen) randomized 2:1 to receive 8 or 12 weeks of EBR/GZR. Here we report interim results from those who received 8 weeks of EBR/GZR (target n = 50). The primary efficacy endpoint is sustained virologic response 12 weeks after the end of therapy (SVR12), defined as HCV RNA < 15IU/ml as measured by COBAS® AmpliPrep/COBAS® Taqman® HCV test (v. 2.0). HCV GT4 subtyping was determined by HCV NS5B miniamplicon sequence analysis.

Results: To date, 31 GT4 participants have been enrolled in the 8-week treatment arm and their demographics and baseline characteristics are summarized in the Table. Of the participants with available data, 18/18 had HCV RNA <15 IU/ml at the end of the 8-week treatment with EBR/GZR and 12/12 participants had no detectable HCV RNA at follow up week 4 (SVR4). There were no treatment discontinuations due to adverse events or serious adverse events.

Demographics and Baseline Characteristics		All patients (n = 31)
Sex, n (%)	Female	16 (52%)
	Male	15 (48%)
Race (self-reported), n (%)	White	17 (55%)
	Black	10 (32%)
	Asian	1 (3%)
	Not disclosed	3 (10%)
Age, years, mean (range)	54 (29–80)	
Baseline HCV RNA, n (%)	<800,000 IU/ml	9 (29%)
	>800,000 IU/ml	22 (71%)
	<2,000,000 IU/ml	19 (61%)
	>2,000,000 U/ml	12 (39%)
Fibrosis Stage	F0-F1 (by biopsy or FibroScan® score <7.0 kPA)	28 (90%)
	F2 (by biopsy or FibroScan® score > 7.0 and <8.0 kPa	3 (10%)
Samples with Completed NS5B Sequencing for GT4 Subtype Analysis, n (%); GT4 subtype, (n)	17 (55%)	4a (5), 4c (2), 4d (3), 4f (3), 4k (2), 4r (1), 4t (1)

Conclusion: Preliminary data suggest that 8 weeks of EBR/GZR may be effective, safe and well tolerated in treatment-naïve HCV GT4-infected individuals with minimal fibrosis. Interim results including SVR12 data from all enrolled participants receiving 8 weeks of EBR/GZR will be presented.

Background and Aims: BEZURSO is the first ever placebo-controlled trial of a fibrate (i.e. an agonist of the peroxisome proliferator-activated receptor alpha) for the treatment of primary biliary cholangitis (PBC). It was a 24-month phase 3 study assessing the efficacy of bezafibrate (BZF) 400 mg daily in association with standard of care ursodeoxycholic acid (UDCA) in PBC patients with an inadequate response to UDCA. The trial reached the primary endpoint, which was a complete biochemical response at 24 months defined by normal levels of total bilirubin, alkaline phosphatases, transaminases, albumin and prothrombin index. However, the study duration was too short to observe a difference in liver-related complications or death. The UK-PBC and Global PBC risk scores are validated prognostic models based on data from >6,000 UDCA-treated patients with PBC. The aim of the present study was to assess the predicted reduction in the risk of death or liver transplantation (LT) of patients in BEZURSO using the UK-PBC and Global PBC risk scores.

Method: A total of 100 patients with an inadequate response to UDCA were randomized to receive BZF (n = 50) or placebo (n = 50), in association with UDCA, for 24 months. Baseline, Month 12, and Month 24 data were entered into the UK-PBC and Global PBC risk score calculations, to assess the risk of an endpoint (liver-related death or LT for UK-PBC score; death or LT for Global PBC score) at 5, 10, and 15 years in the two groups.

Results: The UK-PBC predicted changes in the risk of events from baseline following 12 months of treatment was on average −34.5% (IQR: −49.4%; −7.6%) in the BZF group and +25.4% (−10.9%; +57.9%) in the placebo group ($p < 0.0001$). The Global PBC predicted changes in this risk was −41.3% (−50.0%; −22.5%) in the BZF group and +15.4% (−4.6%; +51.2%) in the placebo group ($p < 0.0001$). Similar results were obtained after 24 months of treatment. Figure 1 shows the UK-PBC (A) and Global PBC (B) predicted percentages of events at 5, 10, and 15 years according to treatment group and time point (baseline vs. Month 12). While the percent risk did not differ within groups at baseline, it was significantly lower in the BZF group than in the placebo group after 12 months of treatment in both models ($p = 0.0037$ and $p = 0.0002$, respectively). Similar results were obtained after 24 months of treatment.

Conclusion: Compared to placebo and UDCA, BZF and UDCA combined treatment was associated with a significant reduction in estimated risk of LT and (liver-related vs. all-cause) mortality with both UK-PBC and Global PBC risk scores.

	5 years	10 years	15 years
UDCA + placebo Baseline	1.35	4.44	8.11
UDCA + placebo 12 mo.	1.89	6.18	11.2
UDCA + bezafibrate Baseline	2.17	7.08	12.77
UDCA + bezafibrate 12 mo.	1.18	3.90	7.14

	5 years	10 years	15 years
UDCA + placebo Baseline	5.66	14.53	24.53
UDCA + placebo 12 mo.	6.49	16.52	27.65
UDCA + bezafibrate Baseline	7.57	19.10	31.62
UDCA + bezafibrate 12 mo.	3.53	9.21	15.91

Email: a-tanaka@med.teikyo-u.ac.jp

Background and Aims: It is crucial to stratify the risk for progression in patients with primary biliary cholangitis (PBC). Although the Globe and UK-PBC scores have been established for this purpose, these are not validated in patients treated with other drugs in addition to ursodeoxycholic acid (UDCA). We have used bezafibrate (BF) for patients who were refractory to UDCA in Japan, and herein performed a validation study of these scores in Japanese patients treated with UDCA and/or BF.
Method: We took advantage of a large-scale retrospective database in Japan consisting of 9,919 patients with PBC diagnosed between 1985 and 2014. We selected patients for the current study according the following criteria: (1) treated with UDCA and/or BF, (2) followed up at least 2 years after initiating treatment, and (3) biochemical treatment responses at 1 year of treatment and outcomes were clearly recorded. When patients were consecutively treated with both UDCA and BF, the treatment response at baseline and at 1 year of the secondary added drug was used for calculating the scores.
Results: We identified 727 patients who met the above criteria (M/F = 109/618, 58.4 ± 11.3 yo at diagnosis). Among them, 542, 183 and 3 patients were treated with UDCA only (74.5%), UDCA + BF (25.2%), and BF only (0.4%). Observation period was 8.3 ± 5.5 years. Liver transplantation (LT)-free survival rates at 5-, 10- and 15-years was 98.0%, 95.5% and 89.3%, respectively. The average estimated LT-free survival rates at 5-, 10- and 15-years using the Globe score were 81.9%, 62.9% and 47.5%, respectively, which were significantly lower than the real outcomes at each point ($p < 0.001$). AUROC of the Globe score was 0.811 for LT-free survival. Meanwhile, the estimated LT-free survival rates using the UK-PBC score were 96.9%, 91.8% and 86.6%, respectively, which were significantly lower as well ($p < 0.05$). AUROC of the UK-PBC score for LT-free survival was 0.899.
Conclusion: The risk predictive values of the Globe and UK-PBC scores were diminished when BF was additionally used for patients who were refractory to UDCA, while performance of the UK-PBC score was better. It is warranted to develop a new scoring system for predicting outcomes in patients treated with a new drug such as obeticholic acid in addition to UDCA.

PS-003

Sub-cutaneously delivered mesenchymal stromal cells and down-regulation of activated vascular endothelium – a novel, clinically ready, therapeutic approach to treating cholestatic liver disease

V. Vigneswara[1], N.-T. Luu[1], M. Alfaifi[1], L. O'flynn[2], C. Baan[3], M. Hoogduijn[3], M. Gargesha[4], D. Roy[4], S. Elliman[2], G. Hirschfield[1], P. Newsome[1]. *[1]National Institute for Health Research Birmingham Biomedical Research Centre at University Hospitals Birmingham NHS Foundation Trust and the University of Birmingham, United Kingdom; [2]Orbsen Therapeutics; [3]Erasmus Medical Center; [4]BioInVision*
Email: p.n.newsome@bham.ac.uk

Background and Aims: Human mesenchymal stromal cells represent a potential novel therapy for inflammatory liver diseases. We set out to define the mechanism of action, and specifically remote effects, of MSC in a murine pre-clinical model of PSC.
Method: Umbilical cord (UC) derived MSC (OrbCel™) were injected intravenously (IV) or subcutaneously (SC) into 6–7 week old male Mdr2$^{(-/-)}$ mice (FVB/N background) and subsequent impact on liver damage was determined by liver histology, serum analysis and FACS

analysis of liver digest. Bio-distribution of Q-dot labelled MSC was determined by whole mouse cryo-imaging. Effect of MSC or MSC-conditioned media (CM) on adhesion of peripheral blood mononuclear cells (PBMC) to hepatic sinusoidal endothelial cells (HSEC) over flow conditions were studied. HSEC activation markers (VCAM/ICAM) were studied *in vitro* and *in vivo* after MSC/MSC-CM treatment.
Results: MSC administered SC were as effective as IV, versus control (Con), in reducing liver injury *in vivo* with reductions in serum ALT (SC 493 iu vs Con 707 iu; $p < 0.05$) and bile acids (SC 38 mmol/l vs Con 75 mmol/l; $p < 0.05$). Numbers of CD4 and CD8 cells infiltrating the liver were also reduced after SC MSC administration. There was also an increase in the M2/M1 macrophage ratio after SC administration (SC 0.97 vs Con 0.71; $p < 0.05$). A cryo-imaging seven day time-course indicated MSC were cleared rapidly with no migration of SC administered cells. MSC and MSC-CM pre-treatment of HSEC reduced subsequent adhesion and trans-migration of PBMC under conditions of sinusoidal flow. In addition, this was associated with reduced expression of activation markers VCAM and ICAM on HSEC (flow cytometry and confocal fluorescent staining – Figure 1). SC MSC-treated Mdr2$^{(-/-)}$ mice demonstrated reduced VCAM/ICAM expression at the gene and protein level versus Con mice. MSC-CM also reduced senescence and increased proliferation of biliary epithelial cells *in vitro*.

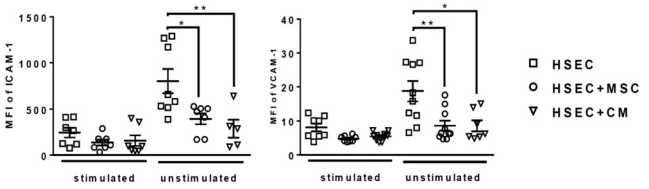

Figure 1: VCAM/ICAM expression on HSEC after treatment with MSC or MSC CM.

Conclusion: Remote sub-cutaneous MSC administration demonstrates a retained potent anti-inflammatory action in murine model of cholestatic liver injury. This effect is mediated through secreted factors that down-regulate endothelial cell activation reducing inflammatory cell ingress to the liver. MSC are cleared rapidly after infusion with no hepatic homing and induce significant M2 polarisation of hepatic monocytes.

PS-004
The gut-liver axis is essential for disease progression in the Mdr2−/− mouse model of primary sclerosing cholangitis

L. Liao[1,2], K.M. Schneider[1], M. Frissen[1], T. Strowig[3], H.-U. Marschall[4], A. Wahlström[5], G. Eric[3], A. Mohs[1], P. Jin[1], J. Jung[1], J. Reissing[1], H. Sun[1], C. Elfers[1], V. Bieghs[1], F.J. Cubero[6], C. Trautwein[1]. [1]*University Hospital, Department of Internal Medicine III, Aachen, Germany;* [2]*Renji Hospital, Shanghai Jiao Tong University, Department of Pain Management, Shanghai, China;* [3]*Helmholtz Centre for Infection Research, Braunschweig, Germany;* [4]*University of Gothenburg, Wallenberg Laboratory, Gothenburg;* [5]*University of Gothenburg, Wallenberg Laboratory, Gothenburg, Sweden;* [6]*Complutense University School of Medicine, Department of Immunology, Madrid, Spain*
Email: liaolijunxiao@gmail.com

Background and Aims: Primary sclerosing cholangitis (PSC) is strongly associated with inflammatory bowel disease. The gut-liver axis plays a critical role in PSC onset and progression. However, the functional implications of intestinal microbiota and inflammasome mediated innate immune response for PSC is unclear. Here, we investigated gut-liver crosstalk and NLRP3 inflammasome activation in the murine Mdr2 knockout (Mdr2$^{-/-}$) model resembling PSC.
Method: Mdr2$^{-/-}$, WT control mice, Mdr2$^{-/-}$/Casp8$^{\Delta hepa}$ and Mdr2$^{-/-}$/Casp8$^{f/f}$ were housed for 8w or 52w. Only male mice were used in this study. The relevance of Mdr2 deletion on liver injury as well as gut microbiota and bile acid profile were studied. NLRP3 inflammasome and caspase activation in the gut-liver axis were comprehensively analyzed. Pan-caspase inhibitor (IDN-7314) was treat to block caspase activation, and the effect of IND-7314 on gut-liver axis was detected.
Results: Mdr2$^{-/-}$ mice displayed significantly increased serum transaminases and liver peridutular inflammation compared to WT mice. Mdr2$^{-/-}$ liver was characteristic presenting a strong induction of apoptotic cell death, progressive bile duct proliferation and periportal fibrosis development over time (52 weeks). The abnormal bile acid composition in Mdr2$^{-/-}$ mice was associated with an altered intestinal microbiota composition. This was linked to an impaired intestinal barrier, including colonic mucus layers, reduction of tight junction expression and increased permeability evidenced by an in-vivo FITC-dextran assay. Intestinal dysbiosis in Mdr2$^{-/-}$ mice urged increased translocation of endotoxin and bacterial, further augmented the hepatic innate immune response. Mechanistically, enhanced hepatic NLRP3 inflammasome activation via caspase-1 triggered macrophage and neutrophil infiltration and caspase-3, -8 and -9 mediated apoptotic cell death. However, by introducing Mdr2$^{-/-}$/Casp8$^{\Delta hepa}$ animals the Mdr2$^{-/-}$ phenotype could not be rescued indicating that hepatocytic caspase-8 activation is a downstream consequence and dispensable for the inflammatory response. Strikingly, a pan-caspase (IDN-7314) dampened inflammasome activation and ameliorated liver injury, periportal inflammation, serum bile acid profile as well as intestinal dysbiosis.
Conclusion: Our data demonstrate that Mdr2 associated cholestasis triggers intestinal dysbiosis, with translocation of endotoxin and bacterial in the portal vein and subsequent NLRP3 inflammasome activation, which contributes to higher liver injury. This process can be blocked by pancaspase, but not hepatocytic caspase-8 inhibition.

Email: michael.trauner@meduniwien.ac.at

Background and Aims: Primary sclerosing cholangitis (PSC) is a progressive immune-mediated liver disease, currently lacking effective medical therapy. In a recent European multicenter phase II clinical study for primary sclerosing cholangitis (PSC), nor-ursodeoxycholic acid (*nor*UDCA), a side chain-shortened derivative of UDCA improved cholestasis irrespective of previous response to UDCA. However, potential immunomodulatory mechanisms of *nor*UDCA are still poorly understood. Since CD8 T-cell trafficking along the gut-liver axis is an important pathophysiological factor in PSC, we aimed to explore how *nor*UDCA impacts on CD8 T-cell immunity.
Method: The potential modulatory effects of *nor*UDCA on CD8 T-cell immunity were assessed in vitro by proliferation and differentiation assays as well as in vivo, in lymphocytic choriomeningitis virus (LCMV) model of CD8 T-cell driven hepatic immunopathology and in Mdr2 (Abcb4) KO mouse model of PSC.
Results: In vitro, *nor*UDCA but not UDCA reduced CD8 T-cell proliferation and lymphoblast formation by 53% compared to untreated controls ($p < 0.05$). Mechanistically, mTOR(Ser2448) phosphorylation of CD8 T-cells was suppressed by *nor*UDCA by 40% ($p <$

0.005). In line, *nor*UDCA reduced mTORC1 and mTORC2 kinase activities as reflected by lower phosphorylation level of P70 S6 Kinase (Thr421/Ser424) and AKT(Ser473) by 41% ($p < 0.05$) and 53% ($p < 0.05$), respectively. Additionally, *nor*UDCA strongly reduced mean fluorescence intensity of mTOR dependent Granzyme B and IFNγ by 73% and 56%. Moreover, similar to rapamycin, glycolysis but not oxidative phosphorylation in activated CD8 T-cells was inhibited by *nor*UDCA as shown by a reduction in extracellular acidification rate without a change in oxygen consumption rate. In vivo, *nor*UDCA ameliorated hepatic injury and inflammation induced by LCMV as shown by lower ALT (*nor*UDCA + LCMV 88U/L vs LCMV 209.6U/L, $p < 0.005$) and decreased liver expression of Granzyme B by 41% ($p < 0.005$) and Cxcl10 by 40% ($p < 0.005$). Supporting our in vitro finding, *nor*UDCA remarkably reduced CD8 effector T-cell frequency in the liver of LCMV infected mice. Notably, this reduction led to improved control of inflammation without compromising quality of viral-specific CD8 T-cell immunity. Additionally, *nor*UDCA (but again not UDCA) had similar impact on reducing liver CD8 T-cell number in Mdr2 KO mice.

Conclusion: Overall, we unraveled novel anti-inflammatory mechanisms of *nor*UDCA impacting mTOR signaling and distinct from UDCA, indicating that *nor*UDCA may represent a promising immunometabolic drug for treatment of T-cell based inflammatory liver diseases.

Background and Aims: Autoantibodies are key parameters in the diagnostic of autoimmune hepatitis (AIH) among those with chronic liver diseases. However, conventional autoantibodies such as anti-nuclear (ANA), anti-smooth muscle (SMA), anti-liver kidney microsomal antibodies (LKM) and antibodies against soluble liver antigen (SLA) either lack high sensitivity or high specificity. We screened for alternative autoantibodies with a better clinical performance.

Method: Antibodies against Huntingtin-interacting protein 1-related protein (HIP1R) were identified via a protein macroarray in patients with AIH. Next, antibodies against a HIP1R fragment, measured with an ELISA, were compared to conventional autoantibodies in three independent adult cohorts: a training and internal validation cohort from Hannover/Germany and an external validation cohort from Bologna/Italy. In total 208 AIH samples (untreated: n = 164; under therapy: n = 44), 350 samples with other chronic liver diseases and 46 healthy controls were analyzed.

Results: Patients with untreated AIH (type I and II) had the highest anti-HIP1R antibody concentrations compared to non-AIH liver diseases and healthy controls ($p < 0.001$). Baseline anti-HIP1R concentrations in AIH patients decreased to background levels of non-AIH liver diseases during therapy.

With the receiver operating characteristic the optimal cut-off for the distinction between untreated AIH and other liver diseases was identified (52.7 arbitrary units; AUC: 0.86; 95% confidence interval: 0.81–0.91). With this cut-off anti-HIP1R antibodies (OR: 12.8; 6.9–23.7) achieved a significantly higher sensitivity (0.77; 0.67–0.85) compared to SMA, LKM and SLA, a significantly higher specificity (0.80; 0.72–0.85) compared to ANA and SMA and the highest overall accuracy [0.79 (0.73–0.83); ANA: 0.71 (0.65–0.77); SMA: 0.57 (0.51–0.63), LKM: 0.64 (0.58–0.70); SLA: 0.64 (0.58–0.70)] for the diagnosis of untreated AIH in the retrospective training cohort from Hannover (n = 251).

Comparable results [anti-HIP1R: OR: 7.2 (3.5–14.9); sensitivity: 0.71 (0.56–0.83); specificity: 0.75 (0.68–0.81)] with a significantly higher overall accuracy (0.74; 0.68–0.79) than ANA and SMA were found in the prospective validation cohort from Hannover (n = 238). In the external validation cohort with only untreated AIH (n = 25) from Bologna, anti-HIP1R antibodies achieved the highest sensitivity (0.89; 0.68–0.97) from all tested autoantibodies.

Diagnostic anti-HIP1R concentrations were even found in 85% (11/13) of patients with untreated AIH negative for classical autoantibodies.

Conclusion: Anti-HIP1R autoantibodies seem superior to conventional autoantibodies (ANA, SMA, LKM) by a better clinical prediction of AIH and by a simpler ELISA assay compared to the demanding immunofluorescence titration on rodent tissue section.

PS-007

Intestine-specific deletion of Abcg5/g8 leads to hepatobiliary cholesterol overload: pathophysiology of biliary lipid secretion

R. Charlotte, B. Annika, M. Krawczyk, F. Lammert, S.N. Weber. *Saarland University Medical Center, Department of Medicien II, Homburg, Germany*
Email: susanne.weber@uks.eu

Intestine-specific deletion of *Abcg5/g8* leads to hepatobiliary cholesterol overload.

Charlotte Rebholz, Annika Bohner, Marcin Krawczyk, Frank Lammert, Susanne N. Weber.

Background and Aims: Gallstone disease is one of the most common disorders worldwide and is primarily caused by cholesterol supersaturation of bile. Cholesterol is secreted into bile by the ATP-dependent hepatobiliary sterol transporter ABCG5/G8, which also transports phytosterols and is expressed in liver and small intestine. Our aim now was to determine the role of intestinal ABCG5/G8 on biliary lipid secretion and cholesterol homeostasis, using mice in which the transporter is inactivated in the intestine but functional in the liver.

Methods: Using BAC-based recombineering, we generated conditional *Abcg5/g8* knock-out mice allowing tissue-specific deletion of the first 2 exons of *Abcg5* and the first exon of *Abcg8*, respectively, by cre-mediated recombination. *Abcg5/g8* fl/fl mice were crossed to *Villin*-cre mice expressing cre in the intestine under the control of the *Villin* promoter (*Abcg5/g8-Vil*). Hepatic bile was collected via cannulation of the common bile duct, and bile flow and biliary lipid secretion rates were measured in the first hour of an acute bile fistula in *Abcg5/g8-Vil* mice and controls.

Results: All animals developed normal, were fertile, and showed no macroscopic abnormalities. Total bile flow remained stable for three hours and did not differ between the strains. In hepatic bile from the intestine-specific *Abcg5/g8* knock-out mice, total lipid (1.1 ± 0.1 vs. 1.5 ± 0.1 g/dl) and bile acid concentrations (69.5 ± 3.3 vs. 78.4 ± 1.5 mole%) were significantly ($p < 0.05$) reduced as compared to controls. The mean cholesterol saturation index (CSI) exceeded 1 in knock-out mice only (2.1 ± 0.3 vs. 0.9 ± 0.1, $p < 0.05$). In the first hour of the acute bile fistula, cholesterol secretion rates were significantly higher ($0.30 + 0.07x$ vs. $0.15 + 0.03x$ μmol/h/100 g), and phosphatidylcholine secretion rates were significantly lower in *Abcg5/g8-Vil* mice than in controls. Upon feeding lithogenic diet (15% butter fat, 1% cholesterol, 0.5% cholic acid) for 12 weeks, 89% of *Abcg5/g8-Vil* mice vs. 58% of wild-type controls developed gross fatty liver disease, and 65% vs. 44% presented with cholesterol monohydrate crystals and gallstones, respectively. CSIs were ≥1 in both groups (2.4 ± 0.8 vs. 1.9 ± 0.2; $p < 0.05$).

Conclusions: Our results show that the intestine-specific deletion of *Abcg5/g8* leads to hepatobiliary overload and consecutive hypersecretion of cholesterol, resulting in marked cholesterol supersaturation of bile in the conditional knock-out mice without dietary

challenge. This is accompanied by decreased bile acid, phosphatidylcholine and total lipid concentrations. Further studies are needed to determine the adaptive responses to the selective lack of cholesterol and phytosterol efflux in the intestine.

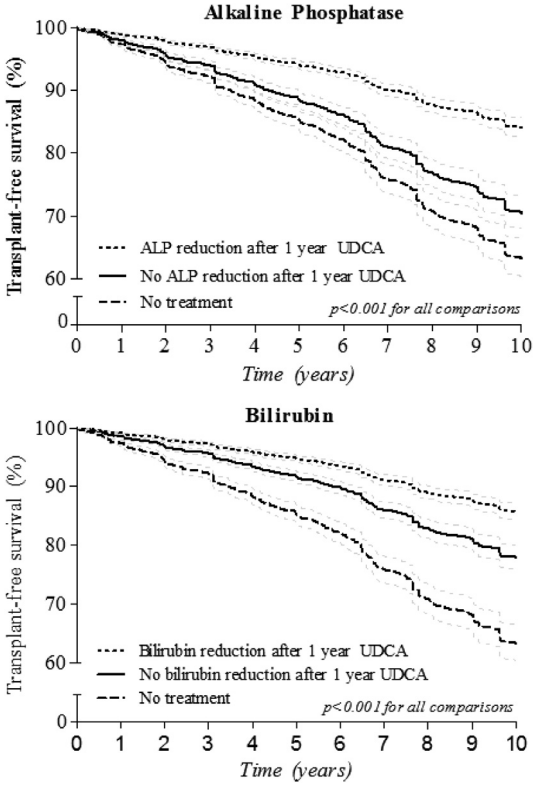
Email: m.h.harms@erasmusmc.nl

Background and Aims: Treatment with ursodeoxycholic acid (UDCA) is associated with a prolonged liver transplant (LT) free survival in primary biliary cholangitis (PBC). The effect of UDCA is primarily evaluated through improvements in alkaline phosphatase (ALP) and/or bilirubin. In this study, we aimed to assess the association between UDCA and LT-free survival among PBC patients without improvements of these surrogate markers after 1 year of treatment.

Method: An international cohort study including PBC patients from 14 large hepatology centers was performed. The association between UDCA therapy and LT-free survival was assessed with Cox survival analyses and inverse probability of treatment weighting, and was adjusted for sex, age, year of diagnosis, and baseline biochemistry including ALP, total bilirubin, albumin, platelet count, aspartate aminotransferase and alanine aminotransferase.

Results: We included 3902 patients with PBC, who were followed for a median of 7.8 (IQR 4.1–12.1) years. Mean age was 54.3 (SD 11.9) years, 3552 (94%) were female, and 3529 (90.4%) received UDCA treatment. In the overall cohort, UDCA was associated with a reduced risk of LT/death (adjusted HR 0.46, 95%CI 0.40–0.52, $p < 0.0001$) as opposed to no treatment. 624/3529 (17.7%) UDCA-treated patients showed no reduction in ALP after 1 year of UDCA. In these patients, UDCA was independently associated with a significantly lower risk of LT/death (adjusted HR 0.61, 95%CI 0.46–0.81, $p = 0.0008$). In patients who did show a reduction of ALP after 1 year (n = 2905, 83.3%), the adjusted HR was 0.37 (95%CI 0.31–0.44, $p < 0.0001$). In the 1484/3529 (42.1%) UDCA-treated patients that experienced no reduction of bilirubin after 1 year of treatment, UDCA was also associated with a significantly reduced risk of LT/death (adjusted HR 0.55, 95%CI 0.45–0.67, $p < 0.0001$), as opposed to a HR of 0.34 (95%CI 0.27–0.41, $p < 0.0001$) for patients that did show a reduction of bilirubin. In 337/3529 (9.5%) treated patients with neither ALP nor bilirubin improvement, UDCA treatment still showed a trend towards a lower risk of LT/death (HR 0.76, 95%CI 0.55–1.07, $p = 0.113$).



Conclusion: UDCA therapy was independently associated with a prolonged LT-free survival among PBC patients. Although the association was strongest in case of a biochemical improvement, it remained in those without any reduction of the commonly used surrogate markers. This finding supports the hypothesis that UDCA might have additional mechanisms of action.

Cirrhosis and its complications: Experimental and pathophysiology

Stem cells as a new therapeutic strategy for portal hypertension and cirrhosis

A. Fernández-Iglesias[1,2], G. Pietrosi[3], M. Pampalone[4], O. Parolini[5], G. Vizzini[3], P.G. Conaldi[3], A. Luca[3], J. Bosch[2,1,6], J. Gracia-Sancho[1,2,6]. *[1]IDIBAPS Biomedical Research Institute, Liver Vascular Biology Research Group, Barcelona, Spain; [2]CIBEREHD, Madrid, Spain; [3]Mediterranean Institute for Transplantation and Advanced Specialized Therapies, IRCCS-ISMETT, Palermo, Italy; [4]Ri.MED Foundation, Palermo, Italy; [5]Centro di Ricerca "E. Menni", Fondazione Poliambulanza- Istituto Ospedaliero, Brescia, Italy; [6]Inselspital - University of Bern, Hepatology, Bern, Switzerland*
Email: jordi.gracia@idibaps.org

Background and Aims: Liver cirrhosis still represents a serious health problem; indeed lack of treatments to promote its regression

requires the development of new therapies including pluripotent stem cells transplantation. We herein aimed at characterizing the effects of human-placenta derived stem cells in a pre-clinical model of cirrhosis.

Method: Mesenchymal (hMSCs) and epithelial (hAECs) stem cells were isolated from human amnion membranes. Cirrhotic rats (CCl_4 inhalation) received 4×10^6 hMSCs, 4×10^6 hAECs, or vehicle (NaCl 0.9%) (i.p.; n = 10). After 2 weeks the following parameters were analysed: (a) stem cells engraftment by human mitochondria detection; (b) hemodynamic: mean arterial pressure (MAP), portal pressure (PP), portal blood flow (PBF) and hepatic vascular resistance (HVR); (c) liver microcirculatory function as response to acetylcholine; (d) hepatic cellular phenotype (fibrosis and hepatic stellate cells [HSC], inflammatory and endothelial phenotypes).

Results: Livers from stem cells-transplanted cirrhotic animals showed positivity to human mitochondria. Interestingly, cirrhotic rats receiving stem cell therapy had significantly lower PP than vehicle animals (15.4 ± 0.7 mmHg Veh vs. 12.8 ± 0.7 hMSCS (−17%); 12.3 ± 1.0 hAECs (−20%); $p < 0.01$), without changes in PBF, thus indicating decreased HVR. This was associated with a marked amelioration in liver microcirculatory dysfunction (+166% hMSCS, p = 0.023/+109% hAECs, p = 0.083). Blood tests showed improvement in the hMSCs group (Bilirubin −85% p = 0.03; Albumin +18% p = 0.04; AST −40% p = 0.08), without changes in the hAECs group.

The underlying mechanisms for the amelioration in portal pressure and liver microcirculatory dysfunction were mainly associated with a marked de-activation of HSC; hMSCs: −90% αSMA, −60% PDGFRβ, −77% TGFβ, −50% TIMP1, −68% col1a1 and −80% desmin. hAECs: −75% αSMA, −32% PDGFRβ, −30% TIMP2, −50% col1a1, without changes in desmin. Hepatic fibrosis was not changed, however hMSCs treatment improved the hepatic inflammatory [−65% MCP-1, −74% TNFα] and endothelial phenotypes [−80% CD31, −87% ET-1]. All $p < 0.05$.

Conclusion: The present pre-clinical study demonstrates for the first time the effectiveness, and the mechanism of action, of transplantation of human pluripotent stem cells as a treatment for advanced cirrhosis and portal hypertension. The results obtained open the possibility of evaluating the possible beneficial effects of human stem cells in patients with chronic liver disease.

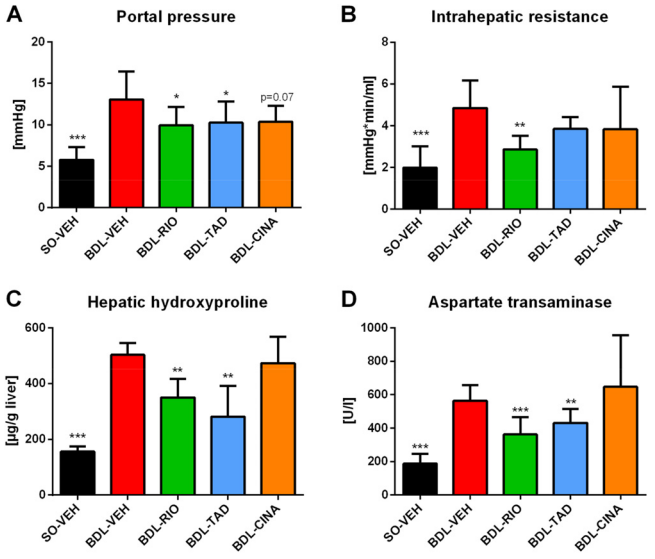
Targeting the nitric-oxide downstream pathway in bile-duct ligated rats to improve portal hypertension and liver fibrosis

K. Brusilovskaya[1,2], P. Königshofer[1,2], D. Lampach[1,2], A. Szodl[1,2], P. Supper[1,2], M. Trauner[1], T. Reiberger[1,2], P. Schwabl[1,2]. [1]*Medical University of Vienna, Div. of Gastroenterology and Hepatology, Dept. of Internal Medicine III, Vienna, Austria;* [2]*Medical University of Vienna, Vienna Hepatic Hemodynamic Lab, Vienna, Austria*
Email: philipp.schwabl@meduniwien.ac.at

Background and Aims: In cirrhotic livers the distorted nitric-oxide (NO) pathway worsens portal hypertension. We aimed to improve intrahepatic vasodilation and portal hypertension in cirrhotic rats by targeting the NO downstream pathway: soluble guanylate cyclase (sGC) – cyclic guanosine monophosphate (cGMP) – phosphodiesterase 5 (PDE5).

Method: 46 rats underwent bile-duct ligation (BDL) or sham operation. One week after surgery, animals received bidaily gavage of sGC-stimulator riociguat (RIO, 0.5 mg/kg), sGC-activator cinaciguat (CINA, 1 mg/kg), PFE5-inhibitor tadalafil (TAD, 1.5 mg/kg) or vehicle (VEH) for three weeks, respectively. Subsequently mean arterial pressure (MAP), heart rate (HR), portal pressure (PP), splanchnic blood flow, portal venous blood flow (PVBF) and intrahepatic resistance (PP/PVBF) were assessed and serum transaminases measured. Degree of hepatic fibrosis was quantified using chrome aniline blue (CAB) staining, hepatic hydroxyproline (HP) content and collagen expression. Intrahepatic cGMP levels and degree of inflammation (IL6, MCP-1) were assessed by PCR.

Results: BDL-VEH controls presented with portal hypertension (PP: 13.1 ± 3.3 mmHg) and liver cirrhosis. All treatments increased hepatic cGMP levels, especially RIO (+3.4-fold; p = 0.006). Both, RIO (9.9 ± 2.2 mmHg; p = 0.021) and TAD (10.2 ± 2.5 mmHg; p = 0.050) treated animals had significantly lower PP than BDL-VEH rats, whereas MAP and HR were not affected. In line, intrahepatic resistance decreased significantly in BDL-RIO animals (4.85 ± 1.3 vs. 2.86 ± 0.6; p = 0.005). Furthermore, livers of RIO (HP: 350 ± 66 vs. 503 ± 43 µg/g; p = 0.003/CAB: 2.1 ± 0.8 vs 4.2 ± 1.6%; p = 0.011) and TAD (HP: 281 ± 111 vs. 503 ± 43 µg/g; p = 0.003) treated rats had significantly less fibrosis compared to BDL-VEH controls. Hepatic collagen expression decreased by 50% in both groups. Significantly reduced levels of transaminases AST (RIO: −35%; TAD: −23%) and ALT (RIO: −32%; TAD: −27%) as well as less IL6 expression (RIO: −56%) indicated anti-inflammatory effects. In contrast, BDL-CINA rats suffered from toxic side effects. They presented with significant weight loss, increased lactate levels and a drop in MAP, without ameliorating hepatic hemodynamics, liver fibrosis or inflammation.



Conclusion: Increasing cGMP availability reduces intrahepatic resistance, decreases portal pressure and further improves liver fibrosis. sGC stimulators may be a potential treatment option for cirrhotic portal hypertension. Yet, pharmacokinetics in cirrhosis still need to be explored.

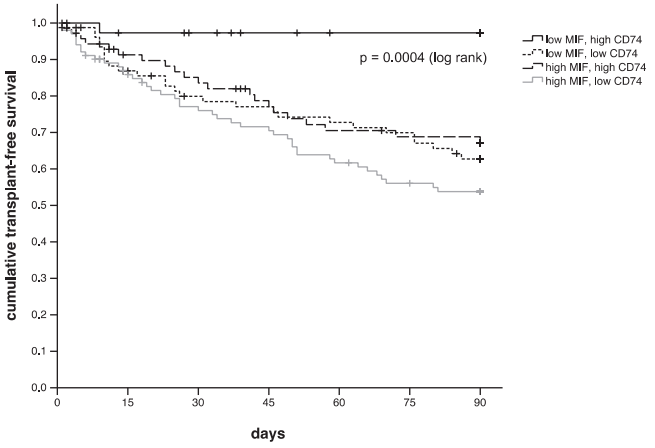
PS-011

Serum concentrations of Macrophage Migration Inhibitory Factor (MIF) and its soluble receptor CD74 predict transplant-free short-term survival in patients with acute decompensation of liver cirrhosis

T. Wirtz[1], N. Köse[2], B. Irina[1], B. Christina[3], P. Fischer[4], S. Stengel[2], Z.H. Wolfgang[3], K. Ingo[3], J. Bernhagen[5], C. Trautwein[4], A. Stallmach[2], M.-L. Berres[4], T. Bruns[2]. [1]*RWTH Aachen University Hospital, Medical Department III, Aachen, Germany;* [2]*Jena University Hospital, Department of Internal Medicine IV;* [3]*RWTH Aachen University Hospital, Institue of Human Genetics, Aachen, Germany;* [4]*RWTH Aachen University Hospital, Medical Department III;* [5]*University Hospital Munich, Institute for Stroke and Dementia Research*
Email: thwirtz@ukaachen.de

Background and Aims: Macrophage migration inhibitory factor (MIF) is a proinflammatory cytokine with chemokine-like functions and an important regulator of innate immune responses in different inflammatory diseases. We hypothesized that serum concentrations of MIF may indicate patients at risk of acute-on-chronic liver failure (ACLF) – a highly inflammatory multiple organ failure syndrome in decompensated cirrhosis.

Method: Concentrations of MIF and the shed form of its receptor (soluble CD74) were determined in sera from 292 German patients hospitalized for decompensation of cirrhosis with ascites, of which 78 (27%) had ACLF. Short-term mortality was prospectively assessed 90 days after inclusion. The MIF promoter polymorphisms G/C −173 and $(CATT)_{5-8}$ −794 were determined in DNA isolated from EDTA-blood using taqman genotyping PCR assays or fragment length analysis respectively.
Results: Although serum concentrations of MIF and sCD74 did not correlate with liver function parameters or ACLF, higher MIF (optimum cut-off >2300 pg/ml) and lower concentrations of sCD74 (optimum cut-off <66.5 ng/ml) both indicated poorer 90-days transplant-free survival in univariate Cox regression analyses (unadjusted HR 2.01 [1.26–3.22]; P = 0.004 for MIF; HR 0.59 [0.38–0.92]; P = 0.02 for sCD74) and after adjustment in multivariate models (Figure 1). Higher MIF concentrations correlated with higher surrogates of systemic inflammation (white blood cells, C-reactive protein). The investigated MIF promoter variants showed an association with sCD74 levels but did not correlate with short-term outcome.



Conclusion: Serum concentrations of Macrophage Migration Inhibitory Factor (MIF) and its soluble receptor CD74 increased 90-days transplant-free survival in patients with acute decompensation of cirrhosis. As this effect was independent of the investigated genetic predispositions and liver function but rather reflected systemic inflammation, MIF and sCD74 represent promising prognostic markers beyond classical scoring systems in patients at risk of ACLF.

PS-012
Oxidized albumin present in patients with decompensated cirrhosis triggers the inflammatory response in peripheral leukocytes through the p38 MAP kinase pathway

J.A. Quiles[1], M. Casulleras[1], K. Oettl[2], E. Titos[1,3], R. Flores-Costa[1], C. Lopez-Vicario[1], M. Duran-Güell[1], M. Pavesi[4], R.E. Stauber[5], V. Arroyo[4], J. Clària[1]. *[1]Hospital Clinic, Department of Biochemistry and Molecular Genetics; [2]Institute of Physiological Chemistry, Medical University of Graz, Center of Physiological Medicine, Graz, Austria; [3]CIBERehd; [4]EF-CLIF, Barcelona, Spain; [5]Division of Gastroenterology and Hepatology, Medical University of Graz, Department of Internal Medicine, Graz, Austria*
Email: jclaria@clinic.ub.es

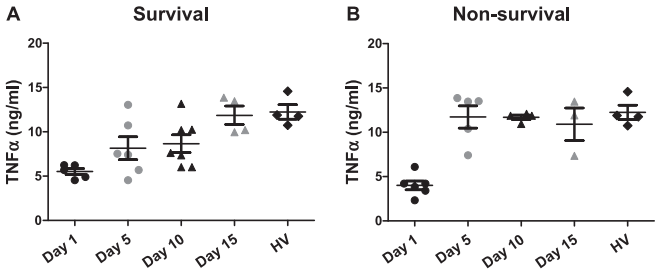
Background and Aims: Recent findings suggest that systemic inflammation characterized by increased levels of cytokines and oxidative stress plays a major role in the pathogenesis of ACLF in patients with decompensated cirrhosis. However, the endogenous factors triggering exacerbated inflammation in these patients remain unknown. Oxidation of circulating albumin to non-mercaptalbumin 1 (HNA1) and 2 (HNA2) is a common finding in cirrhosis. HNA1 and HNA2 have reduced binding capacity, lack the ability to effectively remove circulating toxic substances and are useful markers of oxidative stress in cirrhosis. Here, we examined whether in addition to these properties, HNA1 and HNA2 have the ability to activate innate immune cells and therefore to act as triggers of systemic inflammation in decompensated cirrhosis.
Method: The study included 48 healthy volunteers (HV), 41 patients with compensated cirrhosis and 153 patients with decompensated cirrhosis of whom 72 had ACLF. Levels and post-translational modifications of HNA1 and HNA2 were determined by HPLC and LC-qTOF/MS, respectively. Cell assays were performed in leukocytes, PBMCs and PMNs. Cytokine and eicosanoid levels in cell supernatants were measured by bead-based multiplex assays and LC-MS/MS, respectively. Gene expression was determined by real-time PCR. Kinase signaling pathways were determined by Proteome Profiler Human Phospho-Kinase Array Kit and validated by western blot.
Results: Plasma HNA1 and HNA2 levels increased in parallel with the severity of the disease and correlated very closely with markers of systemic inflammation (i.e. IL-6, IL-1β, TNF-alpha and IL-8) in patients with decompensated cirrhosis. Incubation of leukocytes with HNA1, which was characterized as a cysteinylated form of albumin, at concentrations in the range detected in patients with decompensated cirrhosis, resulted in increased IL-1beta, IL-6 and TNF-alpha mRNA and protein expression and enhanced release of eicosanoids (PGE_2, $PGF_{2\alpha}$, TXB_2 and LTB_4). Analysis of the Phospho-Kinase Array results revealed that HNA1 actions on leukocytes were associated with phosphorylation of the p38 MAP kinase.
Conclusion: Oxidized plasma albumin triggers inflammation in peripheral immune cells, providing a rationale for the removal and replacement of these oxidized albumin forms to efficiently prevent the development of organ failures in patients with decompensated cirrhosis.

PS-013
Lessons from ATTIRE feasibility study: differential inflammatory response profiles following treatment with albumin correlate with 6 months survival

N. Becares[1], S. Harmala[2], L. China[1], S.S. Skene[3], K. Bennett[3], Z. Shabir[3], A. O'brien[1]. *[1]University College London, Division of Medicine, London, United Kingdom; [2]University College London, Institute of Health Informatics, London, United Kingdom; [3]University College London, Comprehensive Clinical Trials Unit, London, United Kingdom*
Email: nbecares@gmail.com

Background and Aims: Infection is the most common cause of death in advanced liver disease secondary to immune suppression. We previously identified that circulating prostaglandin E2 (PGE2) was partly responsible for mediating immune suppression in acute decompensation/Acute-on-chronic liver failure (AD/ACLF) patients. Furthermore, albumin antagonised PGE2 effects and our single arm ATTIRE (Albumin to prevent infection in chronic liver failure) feasibility study of 79 patients at 10 sites demonstrated that 20% Human Albumin Solution (HAS) infusions improved immune function in AD/ACLF. Bacterial infections in AD/ACLF worsen 1 year mortality irrespective of liver disease severity and we therefore hypothesized that patients demonstrating a greater improvement in immune function following HAS would correlate with improved outcome.
Method: Immune function was assessed *ex-vivo* by treating human monocyte-derived macrophages (MDMs) with plasma samples randomly selected from the ATTIRE feasibility cohort corresponding to days 1 (pre-treatment), 5, 10 and 15 (end of trial) (n = 4–7) of participation, and measuring lipopolysaccharide-induced Tumour Necrosis Factor-alpha (TNFa) and Interleukin-10 production by ELISA. Plasma samples were divided *a priori* into two groups: those who died or survived during 6 months follow up at local NHS sites.
Results: There were no differences in clinical characteristics between groups pre-treatment; however, non-survivors developed increased nosocomial infections (36.7% vs 27.8%) and substantially

more renal dysfunction (26.7% vs 0%) during trial period. Our *ex-vivo* assay demonstrated worse immune function pre-treatment (day 1) in non-survivors (Fig. B) but unexpectedly showed a greater improvement at day 5 compared to survivors, with TNFa production reaching healthy levels (Fig. A). Moreover, PGE2 receptor antagonists improved immune function over the effect of HAS, irrespective of group (Fig. A,B). Lastly, non-survivors displayed significantly higher circulating C Reactive Protein (CRP) levels throughout trial period, consistent with an overall "hyper-inflammatory" phenotype.



Conclusion: Immune function was restored following HAS infusion to healthy levels by discharge in both survivors and non-survivors. Counter-intuitively, a more rapid improvement in immune function was associated with worse clinical outcome which was mirrored by a hyper-inflammatory phenotype in non-survivors, according to CRP levels. We have previously demonstrated lipid mediators profiling defined hyper/hypo-inflammatory profiles in AD/ACLF. This work is currently associative and future studies will investigate underlying molecular mechanisms and whether immune effects of HAS differ according to inflammatory profile.

PS-014

Acute-on-chronic liver failure is characterised by hepatocyte gasdermin D cleavage and release of the pro-inflammatory Damage Associated Molecular Pattern (DAMP) IL-α

U. Soffientini[1,2], N. Beaton[2], A. Habtesion[2], E. Weiss[3,4], V. Paradis[4], A. Nadar[2], N. Davies[2], R. Williams[1], S. Chokshi[1], R. Moreau[3,4], R. Jalan[2], G. Mehta[1,2]. [1]*Institute of Hepatology, Foundation for Liver Research, London, United Kingdom;* [2]*Institute for Liver and Digestive Health, UCL, London, United Kingdom;* [3]*INSERM, Centre de Recherche sur l'Inflammation, Paris, France;* [4]*Hôpital Beaujon, Assistance Publique-Hôpitaux de Paris, Clichy, France*
Email: gautam.mehta@ucl.ac.uk

Background and Aims: Acute-on-chronic liver failure (ACLF) displays systemic inflammation and non-apoptotic hepatocyte cell death. Gasdermin D (GSDMD) is a mediator of pyroptotic cell death. Upon cleavage, GSDMD forms pores in the cell membrane leading to cell death and release of DAMPs, such as IL-1α. The aim of this study was to determine if GSDMD cleavage and hepatocyte IL-1α release are features of ACLF in rodent models.
Method: Cirrhosis was induced in male C57BL mice by CCl4 gavage (0.5 ml/kg), and ACLF by LPS injection (2 mg/kg i.p). For validation experiments, cirrhosis was induced bile duct ligation (BDL) in Sprague-Dawley rats, and ACLF by LPS injection (0.03 mg/kg i.p). Experiments were terminated at baseline (control) or 4 hours (ACLF) following LPS injection (n = 7/group). Plasma ALT, creatinine and brain tissue water content were measured by standard techniques. GSDMD cleavage was assessed by Western blot (ratio cleaved:full-length). IL-1α expression was assessed by immunohistochemistry and ELISA. In vitro experiments were conducted on HepG2 cells, and immunofluorescence was performed using standard techniques.
Results: CCl4 + LPS mice show features of ACLF following LPS injection, with increased plasma ALT, creatinine and brain water at 4 hours compared to control. No positive immunostaining for IL-1α was seen at baseline, but following LPS multiple IL-1α positive hepatocytes are visible, consistent with cleavage of pro-IL-1α. A significant increase in hepatic mature IL-1α is noted in the CCL4 + LPS group at 4 hours compared to control (13.7 ± 3.5 *vs* 3.3 ± 0.3 pg/ml, $p < 0.05$). Importantly, no significant change in hepatic TNF-α or IL-1β was seen. A similar increase in mature IL-1α is seen in BDL + LPS at 4 hours compared to BDL control (21.7 ± 6.9 *vs* 0.2 ± 0.1 pg/ml, $p < 0.01$). Cleavage of hepatic GSDMD is seen in CCl4 + LPS at 4 hours compared to control (ratio: 7.7 ± 1.2 *vs* 2.1 ± 0.3, $p < 0.01$). Experiments in HepG2 cells demonstrate exposure to LPS in vitro also leads to GSDMD cleavage. Additionally, immunofluorescence demonstrates cytoplasmic IL-1α expression, which is reduced following LPS, consistent with GSDMD-mediated pore formation and IL-1α release.

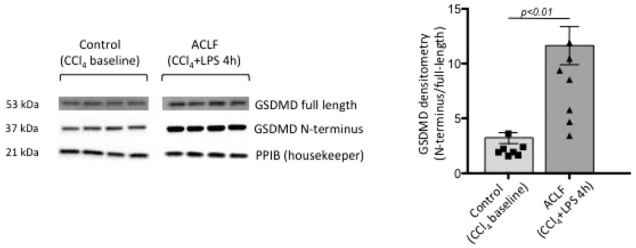


Figure: GSDMD cleavage in liver from control (CCl4 at baseline) and ACLF (CCl4+LPS) mice (n=7/group), presented as representative western blot *(left panel)* and densitometry of N-terminus:full-length GSDMD *(right panel)*.
Bar chart data are mean (SEM). Values compared with unpaired t-test.

Conclusion: This study demonstrates, for the first time, that ACLF is characterized by hepatocyte GSDMD cleavage, pore formation and release of the pro-inflammatory DAMP IL-1α. These findings suggest pyroptotic hepatocyte death as a key mechanism in ACLF, and support GSDMD and IL-1α as potential therapeutic targets in ACLF.

Email: csolem@clinic.ub.es

Background: Alterations in gut microbiome are common in human chronic diseases. Previous studies in patients with cirrhosis have shown a decreased gut microbial richness compared to healthy subjects. ACLF is the most severe clinical form of cirrhosis and is frequently associated with bacterial infections arising from endogenous flora. There is lack of information about gut microbiome alterations in ACLF using quantitative metagenomics.
Aims: To investigate the alterations in gut microbiome in a large series of patients with cirrhosis encompassing the whole spectrum of disease, from compensated (C), to acutely decompensated (AD) without ACLF, and ACLF.

Method: Stool samples were collected prospectively from 200 patients with cirrhosis: 35 C, 89 AD, and 76 ACLF. DNA extraction was performed using the Ion Proton sequencer for metagenomics characterization of complex microbial communities' composition. Microbial genes were grouped into clusters, denoted as metagenomic species (MGS), on the basis of their abundance profiles. Data was analyzed using non-parametric tests (Kruskal Wallis test or Dunn test), and Spearmans' correlations ($p < 0.01$).
Results: Overall, there was a significant loss of gene richness that correlated with disease stages. Gene richness was particularly low in patients with ACLF, independently of whether ACLF was present at hospital admission or developed during hospitalization. Reduced gene richness in ACLF appeared to be unrelated to antibiotic therapy. Two-hundred-and-ninety of the 1158 MGS detected contrasted between at least one disease stage. Interestingly, 44 MGS contrasted between AD and ACLF. The number of organ failures and MELD and Child-Pugh scores correlated positively with 3 MGS, basically from taxa that belong to *Enterococcus*. Unexpectedly, disease severity and organ failure also correlated with the finding of human DNA in stools.
Conclusion: Cirrhosis is characterized by marked alterations in gut microbiome that correlate with disease stage. Gene richness is strikingly reduced in the setting of ACLF. Enterococcus species correlate with disease severity, particularly with ACLF. The significance of the finding of homo sapiens DNA in stool samples of patients with cirrhosis, is uncertain but could be a marker of gut inflammation associated with disease severity, as shown by findings in inflammatory bowel disease.

PS-016
Diet affects gut microbiota and modulates hospitalization risk differentially in an international cirrhosis cohort

J.S. Bajaj[1], R. Idilman[2], L. Mabudian[3], M. Hood[3], A. Fagan[4], D. Turan[2], F. Karakaya[2], M. White[4], E. Gavis[4], D. Heuman[4], P. Hylemon[4], R. Atalay[5], R. Brown[3], M. Sikaroodi[3], P. Gillevet[3]. *[1]Virginia Commonwealth University and McGuire VAMC, Gastroenterology, Hepatology and Nutrition, Richmond, United States; [2]Ankara University School of Medicine, Gastroenterology, Ankara, Turkey; [3]George Mason University, Microbiome Analysis Center, Manassas, United States; [4]Virginia Commonwealth University and McGuire VAMC; [5]Middle East Technical University, Bioinformatics, Ankara, Turkey*
Email: jasmohan.bajaj@vcuhealth.org

Background and Aims: The relative ranking of cirrhosis-related deaths differs between high/middle-income countries. Gut microbiome is affected in cirrhosis and related to diet. However, analysis of differing dietary habits on gut microbiota and clinical outcomes is unclear.
Method: Outpatient compensated/decompensated cirrhotics and controls from Turkey and USA underwent dietary and stool microbiota analysis. Cirrhotics were followed till 90-day hospitalizations. Shannon diversity and multi-variable determinants of microbial diversity and hospitalizations were studied within/between groups.
Results: 296 subjects (157 USA:48 ctrls, 59 comp, 50 decomp, 139 Turkey:46 ctrls, 50 comp, 43 decomp) were included. Cirrhotics between cohorts had similar MELD scores (Table). American cirrhotics had more men, greater rifaximin/lactulose use and higher hepatitis C/alcohol etiologies. Coffee intake was higher in Americans while tea, fermented milk and chocolate intake were higher in Turkey ($p < 0.01$). The entire Turkish cohort had a significantly higher diversity than Americans, which did not change between their controls and cirrhotics (Figure). In contrast, diversity changed in the US-based cohort and was the lowest in decompensated patients. Coffee, tea, vegetable, chocolate and fermented milk intake predicted a higher diversity while MELD score, lactulose use and carbonated beverage use predicted a lower microbial diversity. The Turkish cohort had a lower risk of 90-day hospitalizations (Table). Coffee/tea and chocolate predicted lower 90-day hospitalization risk independent of cirrhosis severity (OR lactulose 3.84, MELD 1.15, coffee/tea 0.39, chocolate 0.33).

	USA (n = 157)				Turkey (n = 139)			
	All	Ctrl (n = 48)	Comp (n = 59)	Decomp (n = 50)	All	Control (n = 46)	Comp (n = 50)	Decomp (n = 43)
Age†		62 ± 14	61 ± 8	61 ± 7		42 ± 8	60 ± 10	60 ± 12*
Males†	121	27	48	46*	79	23	29	27
MELD		–	8.7 ± 2.9	12.6 ± 5.3*		–	8.4 ± 2.4	11.2 ± 3.5*
PPI Use	55	10	19	26*	46	8	17	31
Lactulose†	38	0	0	38	9	0	0	19
Rifaximin†	31	0	0	31	5	0	0	8
All-cause 90-day hospitalizations	29	0	9	20*	12	0	5	7*
Liver-related 90-day hospitalization	25	0	6	19*	10	0	3	7

†$p < 0.05$ between USA and Turkey, *$p < 0.05$ within same population

Conclusion: In this study of cirrhotic patients and healthy controls from USA and Turkey, a Mediterranean diet, along with coffee, tea and chocolate intake, is associated with a higher microbial diversity and an independently lower risk of 90-day hospitalizations.

Clinical management of hepatocellular carcinoma

Personalized T cell therapy against HBV-related hepatocellularcarcinoma

A. Tan[1], T. Krishnamoorthy[2], N. Yang[3], D. Low[4], Y.L. Tham[1], A. Khakpoor[1], E. Felinska[1], V. Oei[1], R. Giri[1], Z.Z. Ho[5], H.K. Tan[2], R. Kumar[2], W. Hwang[6], E. Guccione[7], W.C. Chow[6], A. Bertoletti[1,3]. *[1]Duke-NUS Medical School, Emerging Infectious Diseases, Singapore, Singapore; [2]Singapore General Hospital, Department of Gastroenterology & Hepatology, Singapore, Singapore; [3]Singapore Institute for Clinical Sciences (SICS), Singapore, Singapore; [4]Institute of Molecular and Cell Biology (IMCB), Singapore, Singapore; [5]Lion TCR Pte. Ltd., Singapore, Singapore; [6]Singapore General Hospital, Department of Haematology, Singapore; [7]Institute of Molecular and Cell Biology, Agency for Science, Technology and Research, Singapore*
Email: anthony.tan@duke-nus.edu.sg

Background and Aims: Short HBV-DNA fragments are frequently integrated in HBV-related hepatocellularcarcinoma (HCC). We hypothesized that the HBV transcriptomic profile detected in HCC can guide the correct selection of HBV-specific T cell receptors (TCR) used to engineer T cells for HCC targeted immunotherapy in patients.

Method: HBV-DNA integrants in HCC cell lines were characterized using targeted re-sequencing of the HBV transcriptome and HBV-specific Nanostring probes. TCRs specific for different HBV epitopes was introduced in lymphocytes through mRNA electroporation. These cells were tested in vitro for HCC recognition or adoptively transferred in a liver transplanted patient with HBV-related HCC metastases in the lungs. Clinical parameters and imaging of HCC were evaluated longitudinally.
Results: We first test whether short integrated HBV fragments can produce HBV epitopes recognized by CD8 T cells. Expression of short specific HBV regions was characterized in natural HBV-related HCC lines negative for serological markers of HBV infection. We demonstrated the functional presentation of the HBV epitope encoded within the integrated sequences. We then analyzed the profile of integrated HBV-DNA fragments in the primary HCC of a liver transplant patient with HBsAg negative HCC relapses in the lungs. We detected the presence of mRNA coding for a short region of the HBV envelope and we engineered the patient's lymphocytes with a HBV-specific TCR specific for this region. Multiple adoptive transfers of engineered HBV-specific TCR T cells were performed over a 6 months period as a therapy for HCC relapses. No therapy-related adverse events were observed. CT imaging performed before and during therapy showed an objective positive response with a volumetric reduction of nearly all lung lesions detected without new lesions in the lung or liver till date.
Conclusion: HCC cells serologically negative for HBV-antigen can be lysed in vitro by T cells engineered with HBV-TCR specific for HBV epitopes originating from short HBV-DNA fragments detected in the HCC. Thus HBV DNA integration profile of tumour cells can guide personalized T cell adoptive immunotherapy of patients with HBV-related HCC. Therapy with T cells engineered with HBV-specific TCRs selected with this criteria demonstrated objective signs of clinical effectiveness.

PS-018
Role of 99mTc-Macroaggregated Albumin SPECT/CT based dosimetry in predicting survival and tumor response of patients with locally advanced and inoperable hepatocellular carcinoma (HCC) treated by selective intra-arterial radiation therapy (SIRT) with yttrium-90 resin microspheres, a cohort from SARAH study

A.-L. Hermann[1], A. Dieudonné[2], R. Maxime[1], S. Manuel[2], P. Helena[3], C. Gilles[3], C. Laurent[4], L. Rachida[2], V. Vilgrain[1], S.T. Group[5]. *[1]Hôpital Beaujon, Radiology, Clichy, France; [2]Hôpital Beaujon, Nuclear Medicine, Clichy, France; [3]Hôpital Européen Georges Pompidou, URC-Biostatistical Unit, Paris Cedex 15, France; [4]Hôpital Beaujon, Hepatology, Clichy, France; [5]Hôpital Beaujon, Radiology, Paris, France*
Email: annelaure.hermann@gmail.com

Background and Aims: To assess the role of 99mTc-MAA SPECT/CT based dosimetry in predicting survival and tumour response of patients with locally advanced and inoperable HCC treated by SIRT with yttrium-90 resin microspheres.
Method: Among the 184 patients from the SARAH trial who received SIRT, 121 and 109 were included in the survival and tumour response analysis respectively, according to available dosimetric/tumour response data. All exams (baseline CT, MAA-SPECT/CT and Y90 SPECT/PET) were centralized and reviewed. Tumour-absorbed-dose was computed using MAA-SPECT/CT. Visual agreement between MAA and baseline CT, and between MAA and Y90 imaging were assessed with a 3-points scale (good, acceptable, and poor). Overall survival (OS) was evaluated using Kaplan-Meier tests. Tumour response was assessed on follow-up CT performed 6 months after the treatment, using RECIST 1.1. The predictive role of tumour-absorbed-dose on OS and tumour response was assessed.
Results: Median OS of the entire cohort was 9.3 months (95% CI 6.7–10.7). The median tumour-absorbed-dose was 112.2 Gy (IQR 67.8–220.0). Patients who received ≥100 Gy (n = 67) had significantly longer survival (median 14.1 months (95% CI 9.6–18.6) vs. 6.1 months (95% CI 4.9–6.8) in patients receiving <100 Gy, p < 0.0001). Among them, those with a good visual agreement (n = 24) had the longest median OS (24.9 months 95% CI 9.6–33.9). Objective response (OR) and disease control (DC) rates were 20.5% and 63.7%. DC was significantly associated with higher tumour-absorbed dose (median 121.4 Gy (IQR 86.0–189.8) vs. 85.1 Gy (IQR 58.4–164.3) in non-DC patients, p = 0.0204), while OR was not (median 133.4 Gy (IQR 76.2–238.1) vs. 103.6 Gy (IQR 72.0–174.7) in non-OR patients, p = 0.2). Among DC patients who received ≥100 Gy, those with a good visual agreement (m = 31 treatments) had the highest DC rate (70.5%).
Conclusion: Tumour-absorbed dose computed on MAA-SPECT/CT is significantly associated with overall survival and disease control. The best OS and DC rates were observed in patients who had both ≥100 Gy and good visual CT-MAA-Y90 agreement.

PS-019
Pattern of progression determines post-progression survival in patients with hepatocellular carcinoma treated with Radioembolization

C. Jordan[1], M. de la Torre[1], A.C. Gardini[2], J.I. Bilbao[3], M. Rodriguez-Fraile[4], L.S. Rodriguez[4], D. D'avola[5], M. Iñarrairaegui[5], J.I. Herrero[5], J. Quiroga[5], B. Sangro[5]. *[1]Liver Unit, Pamplona, Spain; [2]Medical Oncology, Meloda, Italy; [3]Radiology, Pamplona, Spain; [4]Nuclear Medicine, Pamplona, Spain; [5]Liver unit and CIBEREHD, Pamplona, Spain*
Email: mdalaez@unav.es

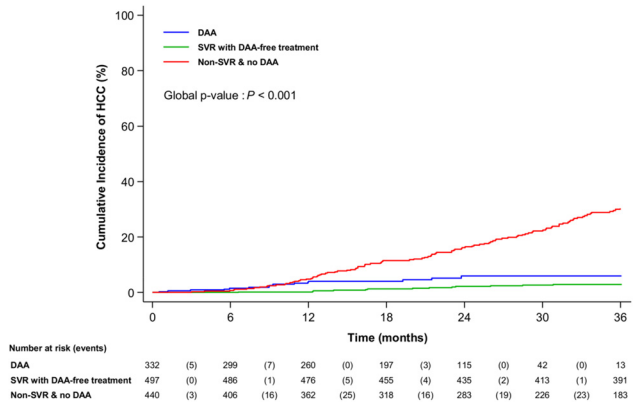
Background and Aims: In patients with hepatocellular carcinoma (HCC) treated with sorafenib, post-progression survival (PPS) is influenced by multiple variables, including the pattern of disease progression. Our objective was to assess the influence of patterns of progression in the PPS in patients with HCC treated with radioembolization (RE).
Method: Patients treated with RE between 1998 and 2015 were identified and those in BCLC-A stage with a nodule <5 cm or BCLC-C with metastasis to the lymph nodes were excluded. Patients were classified in 4 groups according to the pattern of progression: growth of treated lesions (gTL), growth of untreated lesions (gUTL), new intrahepatic disease (nIHD) or new extrahepatic lesions or vascular invasion (nEHD). Overall survival (OS, time from RE until death or last follow-up visit) and PPS (time from progression until death or last follow-up visit) were plotted using Kaplan-Meier method and compared by log-rank test. PPS and OS are expressed as median [95%CI]. A Cox regression was built to verify if pattern of progression was an independent prognostic factor.
Results: Out of 113 patients treated with RE that met the inclusion criteria, 77 had disease progression after a median follow-up of 14 months. Patterns of progression were gTL (n = 19), gUTL (n = 9), nIHL (n = 23) or nEHD (n = 26). OS in the entire cohort was 15.0 months [11.35–18.65] and PPS was 6.0 months [2.79–9.20]. PPS was similar in patients with nIHD (5.0 months [2.74–7.25]) or nEHD (4.0 months [1.20–6.79]), p = 0.42. Likewise, PPS was similar in patients with gTL (9 months [7.04–10.95]) or gUTL (15.0 months [12.34–17.65]), p = 0.74. Patients with growth of treated or untreated hepatic lesions (gHL) had a PPS of 12 months [7.10–16.89] that was significantly longer than the 4 months [2.20–5.79] of patients with new lesions inside or outside the liver (nL), p = 0.019. This classification of pattern of progression retained an independent prognostic value for PPS (HR: 2.96 95%CI: 1.6–5.47) in a multivariate model adjusted by ALBI grade and neutrophil to lymphocyte ratio. Time to progression in the gTL group (14.0 months [6.97–21.03] was significantly longer than that in the nEHD group (5.0 months [1.80–8.99]; p = 0.018) and the nIHD group (4.0 months [2.17–5.83], p = 0.48), while it was lowest for the gUTL group (2.0 months [0–4.77].
Conclusion: In a cohort of patients with HCC treated with RE, progression in the form of new intra- or extra-hepatic lesions was an independent prognostic factor of PPS.

PS-020

Lower compliance to prior HCC surveillance and liver function impairment explain the apparent higher HCC incidence under direct antivirals in HCV compensated cirrhotic patients: the French multicenter prospective ANRS CO12 CirVir cohort experience

P. Nahon[1], L. Richard[2], B. Valerie[1], C. Carole[3], M. Patrick[4], D. Guyader[5], P. Stanislas[6], D. Larrey[7], R. Francoise[2], E. Audureau[2]. *[1]APHP, Jean Verdier Hospital, Hepatology, Bondy, France; [2]APHP, Henri Mondor Hospital, Biostaisitcs, Créteil, France; [3]ANRS, Paris, France; [4]Hôpital Beaujon, Hépatologie; [5]Rennes Hospital, Hepatology, Renns, France; [6]APHP, Cochin Hospital, Hepatology, Paris, France; [7]Montpellier Hospital, Hepatology, Montpellier, France*
Email: pierre.nahon@jvr.aphp.fr

Background and Aims: This study aimed to accurately assess the incidence of HCC under and following DAAs therapy in patients with compensated cirrhosis included in the French prospective multicentre ANRS CO12 CirVir cohort as well as possible confounders.
Method: Data were collected from 1269 patients with compensated biopsy-proven HCV-cirrhosis recruited between 2006 and 2012 in 35 centres and currently prospectively followed-up, including clinical and biological features at baseline and achievement of a sustained virological response (SVR) during the study period. Patients were classified into 3 groups: patients who experienced DAAs (DAAs group, n = 332, T0 = date of DAAs treatment), patients who achieved SVR following interferon-based regimen (SVR-inf group, n = 497, T0 = date of interferon therapy treatment allowing SVR), non-SVR patients who never experienced DAAs (non-SVR group, n = 440, T0 = inclusion).
Results: During a median follow-up of 67.5 months, 749 (59%) patients achieved SVR. As compared to SVR-inf group, DAA patients were older (59.2 yrs vs 55.5 yrs, p < 0.0001), had higher rates of diabetes (24.9% vs 16.3%, p = 0.002), higher rates of baseline endoscopic portal hypertension (17.3% vs 35.5%, p < 0.0001) and lower platelet count (132/mm^3 vs 156/mm^3, p < 0.0001) and although compensated had a more impaired liver function [prothrombin time: 85% vs 91%, albuminemia: 40.2 g/l vs 43 g/l, bilirubin: 13 µmol/l vs 10 µmol/l, all p < 0.0001). During follow-up (fu), 200 (15.7%) patients developed HCC [DAAs group: 15 (4.5%), fu = 21.2 months), SVR-inf group: 30 (6.0%), fu = 63.0 months), non-SVR group: 155 (35.2%), fu = 42.5 months), p < 0.0001 for fu]. Corresponding HCC 3 yrs-cumulative incidences (CumI) were 6.0% vs 2.9% vs 30.3% respectively (global p < 0.0001, DAAs vs SVR-inf: HR = 2.46 [1.18; 5.11], P = 0.01, see Figure). Median rates of performed screening procedures were 81% in patients who developed HCC under DAAs vs 100% in the two other groups (p < 0.0001). In multivariate analysis DAAs intake was not associated with a higher risk of HCC occurrence. To account for indication biases and characteristics of patients, we used IPTW method. This approach confirmed the absence of deleterious effect of DAAs on HCC occurrence.



Conclusion: Although characterized by a shorter follow-up, compensated HCV cirrhotic patients experiencing DAAs have a lower HCC incidence as compared to non-SVR patients. An initial two-fold increase is observed as compared with patients who achieved SVR following interferon-based regimen, but can be explained by the phenotype of patients receiving DAAs encompassing older age, higher rates of comorbidities, impaired liver function and lower compliance to HCC surveillance prior to DAAs intake. These results do not support alarming reports suggesting higher risk of HCC following DAAs therapy.

PS-021

Post-treatment liver stiffness measurement is not useful to predict hepatocellular carcinoma in HCV patients who achieve SVR

S. Shili[1], S. Giovanna[2], J. Foucher[1], V. Anne[2], H. Jean-Baptiste[1], M. Francois[2], F. Chermak[1], P.-H. Bernard[1], V. De Ledinghen[1,3], C. Hezode[2,4]. *[1]Haut Leveque Hospital CHU Bordeaux, Hepatology, France; [2]CHU Créteil, Hepatology, France; [3]University of Bordeaux, France; [4]University of Créteil, France*
Email: sarah.shili@chu-bordeaux.fr

Background and Aims: The risk of development of hepatocellular carcinoma (HCC) persists in HCV patients who achieve a sustained virological response (SVR) after direct acting antiviral (DAA) treatment. Some predictors have been determined but the impact of the liver stiffness measurement (LSM) evolution between baseline and the post-treatment period on the occurrence of HCC is unknown. The aim of this study was to prospectively assess the role of LSM and its evolution for predicting the risk of HCC in HCV patients with SVR after DAA therapy.
Method: Patients were included in two French centers between May 2008 and November 2016. All consecutive patients treated with DAA and without prior history of HCC were included. LSM was assessed with the FibroScan® device before treatment and at least once during follow-up (12–24 and/or 48 weeks after the end of treatment). Delta-LSM was defined as LSM during follow-up – LSM at baseline. Patients were screened every six months for HCC using ultrasound and HCC occurrence during and after the treatment were considered.
Results: 849 patients (male 52.3%; median age: 61 years; genotype 3 14.7%; diabetes 15.9%; LSM ≥ 12 kPa 41.9%) were included. 799 of them (94.1%) achieved SVR. Median [Q1-Q3] LSM (kPa) was 10.9 [7.9–18]; 8.5 [5.5–16.6]; and 7.0 [5.0–13.9] at baseline, end of treatment, and the latest follow-up, respectively. Median decrease was −3.6 [−6.2- −1.1]kPa. For a median follow-up of 5 months [3–10], four patients died and 30 (3.5%) developed HCC in a median time of 5 [3–10] months. In the univariate analysis, delta LSM was associated with HCC (Hazard ratio [95% confidence interval] = 0.95 [0.91–0.99] per kPa, p = 0.01). In multivariate analysis, factors independently associated with the risk of HCC were age (1.05 [1.02–1.09] per year, p = 0.002), diabetes (3.03 [1.46–6.28], p = 0.003) and baseline LSM (1.05 [1.03–1.06] per kPa, p < 0.0001; HR = 2.5 [0.3–24] for patients with baseline LSM between 8 and 12 and HR = 14.0 [1.9–103.9] for patients with baseline LSM >12, compared to patients with baseline LSM < 8). After adjustment for baseline LSM, delta LSM was no longer associated with HCC (p = 0.50).
Conclusion: The risk of HCC is associated with age, diabetes and high LSM at baseline in patients with SVR after DAA. LSM decreases after SVR but its evolution is not independently associated with the risk of HCC. Post-treatment LSM should not be used to predict HCC in HCV patients with SVR.

Email: maria.varela.calvo@gmail.com

Background and Aims: Regorafenib (REGO) improves survival of hepatocellular carcinoma (HCC) in 2nd line after sorafenib (SOR). Patients with dermatological adverse effects >grade 2 in the first 60 days with SOR (DAE60) have greater survival (Reig et al., J Hepatol 2014). Finally, appearance of hand-foot syndrome (HFS) with REGO has a positive impact on survival (Merle et al., ILCA Congress 2017). AIMS: (1) to describe applicability, adverse effects (AE) and radiological response at 3 months of REGO in real life; (2) to asess if DAE60 with SOR is predictor of HFS with REGO.
Method: 65 patients (17 centres) were prospectively recruited: 58 with REGO indicated after SOR (group A); 3 after SOR and nivolumab (3rd line) (group B); 4 in post-transplant setting (group C).
Results: GROUP A: applicability 83%: 7 hasn't received REGO for symptomatic progression, 3 for lack of authorization. In the remaining 48: median age 64 yr, 79%men, etiology (%): 27 alcohol, 46 HCV, 10 HBV, 8 NAFLD. At diagnosis all were asymptomatic, Child A 89%, BCLC 0/A 39.6%, BCLC-B 39.6%, BCLC-C 20.8%. Tolerance to SOR estimated by final dose: full dose 70.8%, 600 mg 4.2%, 400 mg 25%. Median duration of REGO 3 months ($P_{25}P_{75}$ 1-6). 45.8% had DAE60, associated with non-significant greater survival from the start of SOR: mean 42.9 (95% CI 30.4–55.5) vs 28 months (95% CI 19.5–37.2), p = 0.052. The sensitivity, specificity, positive predictive value and negative predictive value of DAE60 to predict HFS with REGO were 89%, 80%, 73% and 92% respectively. Initial radiological evaluation was available in 28 cases: 35.7% (n = 10) presented absence of progression. Median survival from the start of SOR (SOR + REGO) was 15 months (P_{25}-P_{75} 10–22) and from diagnosis of HCC 28.4 months (P_{25}-P_{75} 20–43). Absence of symptoms at the beginning of SOR was the only predictor of higher survival: ECOG PS 0(n = 54) median 21 months, mean 41.9 (IC95% 26.1–57.7) vs ECOG PS 1(n = 4), mean 6.7 months (IC95% 0.0–14.8), p = 0.026. GROUP B: applicability 33%, scarce number of patients and short follow-up to draw conclusions. GROUP C: the most frequent AEs were asthenia, anorexia and diarrhea. None with HFS in the post-transplant setting.
Conclusions: In real life, REGO delays initial radiological progression of HCC in more than a third of patients. Absence of DAE60 with SOR predicts absence of HFS with REGO in 92% of cases, which can be useful when we have alternative 2nd line treatments.

PS-023

Pathological characteristics and early post-hepatic-resection outcome of patients with hepatocellular carcinoma occurred after hepatitis C treatment with new direct-acting antivirals: a multicenter cohort study

A. Vitale[1], F.P. Russo[1], C. Sposito[2], A. Cucchetti[3], G.B.L. Sandri[4], S. Gruttadauria[5], S. DI Sandro[6], D. Ghinolfi[7], D. Nicolini[8], F. Trevisani[3]. "Ospedali Riuniti", Ancona, Italy*
Email: alessandro.vitale@unipd.it

Background and Aims: There are no studies evaluating the pathological characteristics of recurrent or naïve hepatocellular carcinoma (HCC) occurring after anti-hepatitis-C (HCV) therapy with direct-acting antivirals (DAAs). Moreover, the early postoperative outcome of these HCC patients after hepatic resection is unknown.
Method: Prospectively collected data from 420 consecutive patients with HCC and HCV cirrhosis undergoing liver resection in 18 Italian hepato-biliary surgical units between January 2014 and December 2016 were analysed. Seventy-seven patients (18.3%) who develop recurrent or de novo HCC after DAAs therapy represented the study group, while the remaining 343 HCC patients formed the control group. The aim of this study was to compare these two groups in terms of pathological characteristics (primary endpoint) and early postoperative outcome (secondary endpoint). Inverse probability of treatment weighting (IPTW) was used to balance the preoperative characteristics of the two groups for the evaluation of the secondary endpoint.
Results: Primary endpoint (pathological characteristics): the study group showed significantly smaller tumors than the control group (25 mm vs. 35 mm), while no significant differences were found in terms of numbers of nodules, grading, micro and macro vascular invasion, and satellitosis. De novo/recurrent HCC and sustained viral response at resection variables did not influence this result.
Secondary endpoint (early postoperative outcome): after IPTW, the 2 groups became well-balanced for most baseline characteristics including patient's age, performance status, comorbidities, tumor radiological features, alpha-fetoprotein level, severity of underlying liver disease, and extension of liver resection. Patients in the study group showed a significantly lower incidence of severe (Clavien score >2) complications (3.4% vs. 9.3%) and early (within 6 months) postoperative mortality (2.0% vs 5.4%) than those in the control group. SVR patients in the study group (71%) reached a 0% postoperative mortality.
Conclusion: DAAs therapy doesn't seem to modify the biological aggressiveness of recurrent or de novo HCCs undergoing liver resection. Conversely, DAAs therapy significantly improves the early postoperative outcome of these patients. This benefit may be expected after all loco-regional therapies for HCC.

Email: t.meyer@ucl.ac.uk

Background and Aims: The majority of patients (pts) with advanced HCC (aHCC) progress on sorafenib (sor) therapy. Nivolumab (NIVO) is a fully human anti–PD-1 IgG4 mAb that demonstrated durable responses, manageable safety, and long-term survival in pts with aHCC in CheckMate-040 (El-Khoueiry AB, Sangro B, et al. *Lancet* 2017). Here we present updated hepatic safety and biomarker analyses in sor-experienced (sor-exp) pts with aHCC in CheckMate-040.

Method: Sor-exp pts with or without chronic viral hepatitis received NIVO 3 mg/kg Q2W in the dose-expansion phase (EXP) regardless of PD-L1 status. Primary endpoint was objective response rate (ORR) reported by blinded independent central review using RECIST v1.1 (EXP). Secondary endpoints included overall survival (OS), disease control rate (DCR), and safety. Exploratory analyses of on-treatment HCV and HBV viral kinetics and alpha-fetoprotein (AFP) levels were performed.

Results: Median duration of follow-up was 14.9 mo in sor-exp pts (N = 145), 132 (91%) of whom had progressed on sor. Baseline Child-Pugh scores of 5 or 6 and extrahepatic metastases were observed in 99% and 71% of pts, respectively. The ORR with NIVO was 14%; the DCR was 56%; median OS was 15.6 mo. Any-grade and grade 3–4 hepatic treatment-related AEs (TRAEs) occurred in 12 (8%) and 5 (3%) pts, respectively; 100% of grade 3–4 hepatic TRAEs resolved. Frequencies of grade 3–4 treatment-related ALT/AST elevations were 2–3%. No drug-related deaths due to hepatic AEs occurred, and no new safety signals were observed. Among HBV-infected pts, 8% (3 of 38) had a >1 log decrease in HBsAg, and 12% (5 of 41) had a >1 log increase in HBV DNA. HBV DNA increases did not result in changes in hepatic parameters or serious AEs. Among HCV-infected pts, 30% (8 of 27) had a >1 log decrease in HCV RNA. Median baseline AFP in responders (165 µg/L) and nonresponders (85 µg/L) was similar ($p = 0.5898$). For pts with baseline AFP ≥10 µg/L, on-treatment AFP declines >1 log occurred in 94% of responders and 10% of nonresponders. Updated data will be presented.

Conclusion: NIVO demonstrated long-term survival and objective responses across etiologies in sor-exp pts with aHCC. The manageable safety profile of NIVO, including immune-mediated and hepatic AEs, was consistent with other tumor types in which NIVO is approved. NIVO had limited impact on viral kinetics in HBV and HCV-infected pts. Responses occurred irrespective of baseline AFP levels, and AFP declines were associated with response.

HBV Cure: Pre-clinical studies

PS-025

Combinatorial RNAi/vaccination therapy for chronic hepatitis B achieves long-term functional cure in preclinical mouse model

T. Michler[1], A. Kosinska[1], T. Bunse[1], M. Heikenwälder[2], D. Grimm[2], S. Milstein[3], L. Sepp-Lorenzino[3], U. Protzer[1]. [1]*Virology, Technische Universität/Helmholtz Zentrum München;* [2]*Department of Infectious Diseases/Virology, Heidelberg University;* [3]*Alnylam Pharmaceuticals, Cambridge*
Email: thomas.michler@tum.de

Background and Aims: Hepatitis B Virus (HBV) persistence was found to correlate with a failure to develop an efficient virus-specific T cell response due to high HBV antigen load. We evaluated the capacity of stabilized, liver-targeted siRNAs to (i) suppress HBV gene expression, (ii) allow recovery of HBV-specific B- and T cell responses spontaneously or (iii) after therapeutic vaccination.

Method: High viremic HBV-transgenic or C57/Bl6 mice transduced with an Adeno-Associated Virus (AAV)-HBV vector were treated with nucleoside analogue Entecavir (ETV), shRNA-expressing AAV (AAV-shHBV) or *N*-Acetylgalactosamine (GalNAc)-conjugated siRNAs. B and T cell immunity were monitored following therapeutic vaccination with a HBV core (HBc) and surface (HBs) protein prime vaccination and a Modified Vaccinia Ankara virus (MVA)-boost immunization (TherVacB).

Results: RNAi by monthly s.c. injections of 3 mg/kg GalNAc-siRNA or 1×10^{11} geq AAV-shHBV i.v. suppressed serum HBsAg and HBV DNA by 2–3 $\log_{10}$ and HBeAg by >1 $\log_{10}$. ETV reduced viremia by 4 $\log_{10}$ but antigen levels remained unchanged. TherVacB induced HBV-specific B-cell immunity and CD4 T cell responses independent of antigen levels, but HBV-specific CD8 T cell responses were only seen in animals with reduced antigen levels after RNAi. Induction of CD8 T cell responses coincided with suppression of HBV replication in the liver to levels undetectable by Southern blot or PCR. To evaluate if the combinatorial RNAi/vaccination therapy could achieve long-term control of HBV replication and functional cure, C57/Bl6 mice were transduced with 2×10^{11} geq AAV-HBV to establish high-titer, persistent HBV replication. 3 monthly doses of GalNAc-siRNAs followed by therapeutic vaccination using TherVacB reduced HBsAg and HBeAg to levels below the detection limit by 5 and 4 $\log_{10}$, respectively, and triggered seroconversion to anti-HBs and anti-HBe. Control of HBV replication was maintained for >5 months after the last siRNA dose. Mild, but long-term ALT elevation was observed after start of vaccination lasting until the siRNA effect had ceased. This suggests that by reducing antigen expression, siRNA therapy could mitigate killing of hepatocytes by CD8 T cells and thereby could attenuate liver damage.

Conclusion: We developed a combinatorial RNAi/therapeutic vaccination therapy for hepatitis B that is achieving long-term functional HBV cure in a preclinical mouse model, suggesting potential for clinical translation.

PS-026

Novel and potent HBV capsid modulator reduces HBeAg and cccDNA in core site directed T109I mutant in HepNTCP cells

L. Bassit[1], B. Cox[1], S.K. Ono[2], K. Verma[1], J. Yoon[1], F. Amblard[1], R.F. Schinazi[1]. [1]*Center for AIDS Research, Emory University School of Medicine, Atlanta, GA, USA, Pediatrics: Laboratory of Biochemical and Pharmacology;* [2]*University of São Paulo School of Medicine, Gastroenterology, Sao Paulo, Brazil*
Email: rschina@emory.edu

Background and Aims: A major barrier towards eradication of HBV in chronically infected individuals is elimination of cccDNA, which is not addressed by existing antiviral agents. Safe, potent agents that

destabilize cccDNA even in the presence of potential emergence of resistant variants, in combination with existing antiviral agents could confer a functional cure or eradication of HBV. We evaluated the ability of our novel, potent HBV capsid effector GLP-26 to block cccDNA formation and HBeAg production in HepNTCP-DL cells transfected with HBV wild type or HBV core T109I mutant. T109I mutant is present in ~1.2% of genotype B sequences and has shown resistance to both NV-010-001 and BAY 41–4109 capsid effectors (*Klumpp et al., PNAS 2015*).

Method: HepNTCP-DL cells were transfected 18 hr prior addition of antiviral drugs for 3-days, and total nucleic acid was purified, and cccDNA was amplified by real-time-PCR. HBeAg antigen production was measured by EIA. Additionally, drug-drug combination of GLP26 with ETV was also performed in HepAD38 cells and the effect on HBV DNA replication and other viral associated parameters were determined.

Results: Both GLP-26 or GLS4 reduced secreted HBeAg in HepNTCP-DL cells transfected with HBV wild type, with EC_{50} values of 0.7 and 1.7 µM, respectively. The core T109I mutant was more susceptible to inhibition of HBeAg production by GLP26 *versus* GLS4 when compared to wild type, with fold changes in EC_{50} values of 0.7 and 2.4, respectively. In addition, T109 mutant was also more susceptible to inhibition of cccDNA formation/amplification by GLP-26 *versus* GLS4, with 1.5 log reduction by GLP-26 *versus* no effect by GLS4. There was no effect on pgRNA or sRNA by both capsid effectors, whereas GLS4 but not GLP-26 reduced HBs antigen production in both wild type and T109I transfected cells. Combination of GLP-26 with ETV reduced cccDNA amplification of T109I mutant *versus* no effect by GLS4. Dual combination of GLP-26 with ETV resulted in a strong synergistic antiviral effect, with weighted average combination index value (CI_{wt}) of 0.4 in the HepAD38 system.

Conclusion: These data demonstrate that (1) GLP-26 and GLS4 demonstrate similar block on HBeAg production against wild-type virus, (2) GLP26, but not GLP4 is a potent inhibitor of cccDNA formation and HBeAg production against the mutant core T109I, and (3) GLP-26, but not GLS4 demonstrated synergistic activity with ETV in the HepAD38 system, reducing HBV DNA replication. These data underscore the utility of GLP-26 against drug-resistant variants of HBV, and its application in combination with existing antiviral agents. Together, combinations with GLP-26 could represent a tandem mechanism to block cccDNA formation towards a functional or sterilizing cure for HBV.

PS-027

Preclinical antiviral drug combination studies utilizing novel orally bioavailable investigational agents for chronic hepatitis B infection: AB-506, a next generation HBV capsid inhibitor, and AB-452, a HBV RNA destabilizer

N. Mani[1], A.H.L. Li[2], A. Ardzinski[1], L. Bailey[1], J.R. Phelps[2], R. Burns[2], T. Chiu[2], A.G. Cole[1], A. Cuconati[1], B.D. Dorsey[1], E. Evangelista[2], D. Gotchev[1], T.O. Harasym[2], A. Jarosz[2], S. Kadhim[2], A. Kondratowicz[2], S.G. Kultgen[1], K. Kwak[2], A.C.H. Lee[2], S. Majeski[2], K. Mcclintock[2], J. Pan[2], C. Pasetka[2], R. Rijnbrand[1], A. Shapiro[2], H.M. Steuer[1], K. Stever[1], S. Tang[2], X. Teng[2], M. Wong[2], M.J. Sofia[1]. [1]*Arbutus Biopharma Inc., Warminster, PA, United States;* [2]*Arbutus Biopharma Inc., Burnaby, BC, Canada*
Email: nmani@arbutusbio.com

Background and Aims: Chronic hepatitis B infection affects ~240 million people worldwide who are at risk of developing cirrhosis, liver failure, and hepatocellular carcinoma and, unfortunately, currently approved therapies have poor cure rates. Increasing cure rates will require a combination regimen that blocks viral replication, reduces antigen load, attenuates cccDNA formation, and activates host immune responses to control residual virus. We evaluated the anti-HBV activities of two novel orally administered agents, a HBV capsid inhibitor AB-506 and a HBV RNA destabilizer AB-452, in combination with approved nucleos(t)ide analogs (NA), entecavir (ETV), tenofovir disproxil fumarate (TDF), tenofovir alafenamide (TAF), as well as the investigational RNA interference agent, ARB-1467.

Methods: *In vitro* combination studies were conducted using three-dimensional modeling for antiviral drug-drug interactions (Prichard and Shipman1990) by measuring the reduction of rcDNA and HBsAg levels in HBV cell culture systems. Results were analyzed using MacSynergy II software to determine if a combination was additive, synergistic, or antagonistic. Cell viability was assessed using the CellTiter-Glo® reagent. *In vivo* antiviral activities were studied in a hydrodynamic injection (HDI) HBV mouse model. HBV markers were measured using bDNA, qPCR and ELISA assays.

Results: The *in vitro* dual combinations of AB-506 or AB-452 with approved NAs or ARB-1467 ranged from additive to moderately synergistic at reducing HBV rcDNA and HBsAg levels with no significant effects on cell viability. After a once-daily 7-day oral treatment period in HDI HBV mice, dual combinations of AB-506 + AB-452, AB-506 + TDF, and AB-452 + TDF demonstrated a strong antiviral activity with mean 1.4, 1.9, and 2.2 log reductions in serum HBV DNA *vs* the vehicle control, respectively, whereas the triple combination effected larger serum HBV DNA reductions, 2.8 log *vs* the vehicle control. All AB-506 and AB-452 treated groups demonstrated reductions in liver HBV DNA, with negligible reduction observed with TDF alone. Serum HBsAg reduction was detected in AB-452 treated groups, and when combined with AB-506 and/or TDF there was no adverse effect on the ability of AB-452 to reduce HBsAg.

Conclusion: These preclinical investigations suggest that these agents when combined have distinct but mechanistically compatible *in vitro* and *in vivo* antiviral activities and may feasibly be used in future combination therapeutic regimens.

PS-028

Combination treatment of a TLR7 agonist RO7020531and a capsid assembly modulator RO7049389 achieved sustainable viral loadsuppression and HBsAg loss in an AAV-HBV mouse model

L. Dai[1], Y. Yu[1], L. Gu[1], J. Zhao[1], L. Zhu[1], H. Yun[1], Y. Ji[1], W. Zhu[1], J. Young[2], L. Gao[1]. [1]*Roche Innovation Center Shanghai, Shanghai, China;* [2]*Roche Innovation Center Basel*
Email: lu.gao@roche.com

Background and Aims: The ideal endpoint of therapy for CHB patients is sustained viral suppression as evidenced by the loss of HBsAg with or without anti-HBs seroconversion. With existing HBV therapies (Peg IFN, nucleos(t)ides), HBsAg loss only occurs in approximately 3% of patients after 1 year of treatment. Here we evaluated the oral combination of two novel clinical Phase I molecules, a TLR7 agonist RO7020531 and a capsid assembly modulator RO7049389, in the AAV-HBV mouse model.

Method: In vivo efficacy of compounds was studied in a mouse model with a recombinant adeno associated virus carrying hepatitis B virus genome (AAV-HBV) for 6 weeks followed by a 6-week off-treatment period. The levels of HBV DNA, HBsAg, and HBeAg in mouse serum were measured by quantitative polymerase chain reaction (qPCR), HBsAg chemiluminescent immunoassay (CLIA), HBeAg CLIA kits, and a mouse IgG ELISA development kit, respectively. Germinal center B cell population in the spleen was analyzed by FACS analysis.

Results: In an AAV-HBV model, oral administration of the TLR7 agonist RO7020531 significantly reduced both HBV DNA and HBsAg levels with gradual rebound in these markers during a follow-up off-treatment period. Combining this TLR7 agonist with the approved nucleoside analog entecavir did not lead to greater HBsAg reduction. In striking contrast, however, the combination of RO7020531 and the capsid assembly modulator RO7049389, led to a dramatic reduction of HBsAg and HBV DNA with the levels declining to at or below the lower limit of quantification. Most importantly, during the off-treatment period, the effect on HBsAg was sustained, whereas HBV DNA rebound was minimum. Emergence of high levels of anti-HBs antibodies was also observed in a number of mice during the

off-treatment period. The combination therapy of TLR7 agonist and capsid assembly modulator was also associated with upregulated germinal center B cells in the spleen and increased level of anti-HBs antibody in the serum. In addition, HBeAg level in the combination group was reduced by more than 1-log, and similar to that in the monotherapy group of capsid assembly modulator.
Conclusion: In the AAV-HBV mouse model, the combination of the TLR7 agonist RO7020531 and the capsid assembly modulator RO7049389 demonstrated robust suppression of both HBsAg and HBV DNA levels and with the additional emergence of anti-HBs antibodies in several animals. These data highlight the merits of exploring this combination in the clinic as a potential means to achieve a functional cure for CHB infection.

PS-029

Durable inhibition of hepatitis B virus replication and antigenemia using a subcutaneously administered siRNA agent in preclinical models

A.C.H. Lee[1], J. Heyes[1], X. Ye[1], R. Holland[1], E.P. Thi[1], M. Wood[1], A. Judge[1], N.M. Snead[1], A. Martin[1], M.J. Sofia[2]. [1]*Arbutus Biopharma, Burnaby, Canada;* [2]*Arbutus Biopharma, Warminster, United States*
Email: alee@arbutusbio.com

Background and Aims: Developing a cure for chronic hepatitis B (CHB) must address multiple factors involved in viral persistence and likely will require combination of drugs with different modes of action. Reducing HBV proteins, particularly HBsAg, may abrogate viral suppression of immune function and facilitate reinvigoration of host defense. We have recently reported up to 2.7 log HBsAg reduction from ARB-1467 treatment in CHB patients regardless of HBeAg status and with favorable safety profile (AASLD 2017). Here we describe ARB-270729, a next-generation small interfering RNA (siRNA) therapeutic targeted to hepatocytes using a novel covalently conjugated N-acetylgalactosamine (GalNAc) moiety. ARB-270729 is a promising new agent to potentiate HBV cure and acts on multiple hepatitis B viral transcripts, enabling inhibition of HBV replication and suppression of all viral antigens.
Method: *In vitro* anti-HBV activity was studied in primary and immortalized hepatocyte culture systems and *in vivo* anti-HBV activity was studied in a tolerized mouse model of CHB, C57BL/6 mice infected with an adenovirus-associated virus (AAV) carrying a 1.2-fold overlength genome of genotype D.
Results: In comparison to lipid nanoparticle (LNP)-mediated intravenous delivery, GalNAc-conjugated subcutaneous delivery of the same reference siRNA required a 10-fold larger dose to achieve similar mean maximum inhibition of serum surface antigen (HBsAg) in AAV-HBV mice. However, HBsAg suppression in the LNP treatment group had fully resolved by Week 4 whereas the GalNAc treatment group nadir persisted from Week 2 through to Week 6. One dose of ARB-270729 was sufficient to achieve mean maximum HBsAg reductions of 1.1, 2.4 and 3.5 $\log_{10}$ at 1, 3 and 9 mg/kg, respectively, in AAV-HBV mice with baseline serum HBsAg 3.6 $\log_{10}$IU/ml. *In vivo* ARB-270729 suppression of HBsAg was also highly durable, with 83%, 89% and 99%, respectively, of the mean maximal effect remaining at Week 10 after a single dose. The GalNAc moiety is required for ARB-270729 activity; reduction of HBV RNA and HBsAg was completely blocked by asialofetuin competitive inhibition *in vitro*.
Conclusion: ARB-270729 is a next-generation siRNA agent possessing a well-defined mechanism of action as well as a different route of administration and more durable *in vivo* preclinical activity than earlier-generation siRNA agents for the treatment of chronic hepatitis B infection.

PS-030

Development of subcutaneously administered RNAi therapeutic ARO-HBV for chronic hepatitis B virus infection

C. Wooddell, R. Zhu, H. Hamilton, Q. Chu, H. Sternard, J. Schumacher, T. Schluep, M. Seefeld, Z. Li, B. Given. *Arrowhead Pharmaceuticals, Arrowhead Madison, Madison, United States*
Email: cwooddell@arrowheadpharma.com

Background and Aims: Chronic HBV (CHB) infection is a global health problem with high unmet medical need. HBV proteins, in conjunction with pregenomic RNA (pgRNA), replenish the virus and contribute to chronicity by interacting with the host immune system. RNA interference (RNAi) cleaves viral mRNA, reducing viral proteins and replication products.
Methods: The novel RNAi therapeutic ARO-HBV combines RNAi triggers in the S and X open reading frames, both ligand-targeted to hepatocytes, designed to reduce all HBV transcripts (including from host-integrated HBV DNA), to have broad genotype coverage and to avoid development of resistance. ARO-HBV was subcutaneously administered to mice expressing HBV RNA from a hydrodynamically injected 1.3 genome length HBV plasmid, either wild type or with a mutated binding site for the X trigger (HBV_{mut}) to simulate S transcripts produced from integrated HBV lacking a target site for the X trigger. HBV mRNA in liver and viral products in serum were measured: S antigen (HBsAg), e antigen (HBeAg) and HBV DNA. A combination index study was performed with entecavir. A pilot rat toxicity study was conducted with up to 300 mg/kg given on days 1, 8 and 15.
Results: A single injection of ARO-HBV (4.0 mg/kg) reduced HBsAg by 2.0 log, HBeAg by 1.1 log and serum HBV DNA by 1.3 log. Repeated injections of ARO-HBV (4 mg/kg every 3rd week x 3) reduced HBsAg (≥3.4 log), HBeAg (≥2.1 log) and HBV DNA (3.1 log), with multiple samples below LLOQ for HBsAg and HBeAg. Total HBV transcripts were reduced by 94% and precore/pgRNA transcripts by 89% at nadir following a single injection (4 mg/kg). S trigger alone gave 1.3 log less HBeAg reduction after 3 injections than the S plus X combination. The S trigger maintained full activity on RNA from HBV_{mut} (−3 logs HBsAg after single 3 mg/kg dose) despite a 10-fold excess of X trigger, which was inactive as monotherapy. ARO-HBV is synergistic with entecavir.

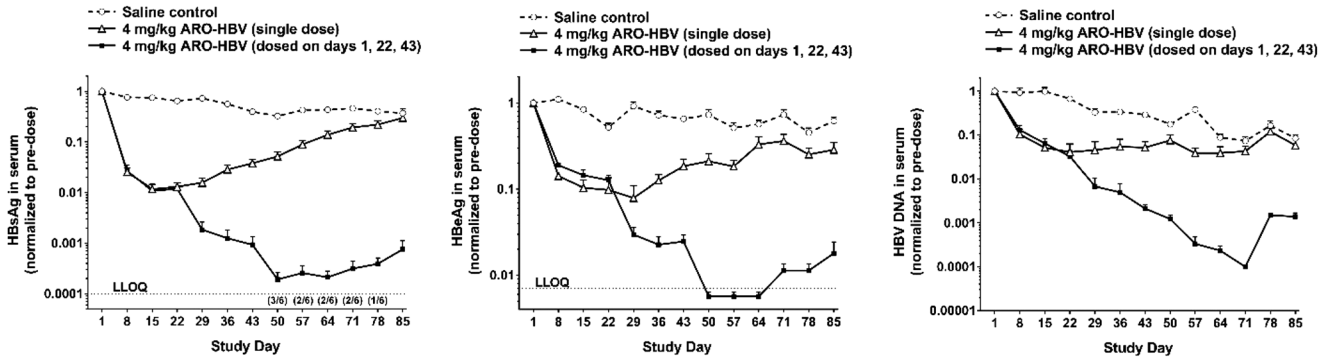

Figure: (abstract: PS-030): Single and multi-dose effects in pHBV-infected mice.

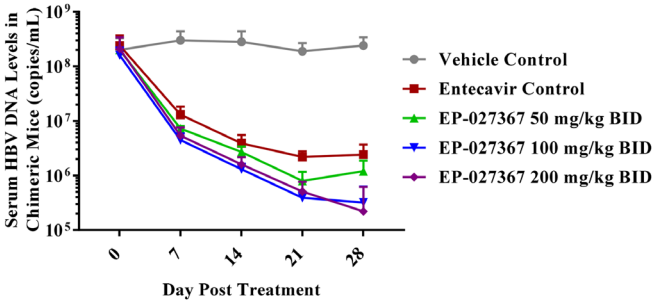
Based on clinical observations, clinical chemistries and histopathology evaluations, ARO-HBV was well tolerated, including when 900 mg/kg was given over 2 weeks.
Conclusion: ARO-HBV showed deep and prolonged reductions in viral antigens and HBV DNA, including in a model of integrated HBV DNA-derived HBsAg. It also appears to have low toxicity in rats. ARO-HBV is progressing to clinical trials in patients with CHB and is expected to synergize with other antiviral compounds.

PS-031
T cells grafted with HBV-specific T-cell receptors of high functional avidity achieve functional cure of HBV infection in humanized mice
K. Wisskirchen[1,2], J. Kah[2,3], A. Malo[1], L. Allweiss[2,3], K. Metzger[1], T. Volz[3], A. Krackhardt[4], M. Dandri-Petersen[2,3], U. Protzer[1,2]. *[1]Institute of Virology, Technical University of Munich/Helmholtz Zentrum München, Munich, Germany; [2]German Center for Infection Research (DZIF), Germany; [3]University Medical Center Hamburg-Eppendorf, 1st Department of Medicine; [4]3rd Medical Clinics, University Hospital rechts der Isar, Munich, Germany*
Email: protzer@tum.de
Background and Aims: Adoptive T-cell therapy of chronic hepatitis B or hepatitis B virus (HBV)-induced hepatocellular carcinoma intends to restore antiviral T-cell immunity to clear the infection or control tumor growth. We isolated HB-specific T-cell receptors (TCR) with high functional avidity to redirect T cells and aimed to test their potential to cure HBV infection *in vitro* and *in vivo*.
Method: We isolated a series of HLA-A*02 restricted TCRs specific for HBV S or core protein derived peptides from patients with acute and resolved HBV infection. Primary human T cells were genetically modified by retroviral transduction to express these HBV-specific TCRs. One S20- and C18-specific TCR each with high functional avidity were selected for further analysis. These HBV-specific TCRs recognized peptide of different HBV genotypes and presented on different HLA-A*02 subtypes common in areas with high HBV prevalence.
Results: Upon TCR grafting, $CD8^+$ as well as $CD4^+$ T cells became polyfunctional HBV-specific effector T cells recognizing even picomolar concentrations of cognate peptide. Upon antigen recognition, TCR-grafted T cells secreted IFN, TNF and interleukin-2, controlled HBV replication and effectively killed hepatoma cells with an integrated HBV genome. When co-cultured with HBV-infected cells, TCR-grafted T cells stopped viral replication, killed infected cells and eliminated viral antigens as well as cccDNA from the cell culture. TCRs mediated elimination of HBV when expressed on $CD8^+$ or $CD4^+$ T cells and also when grafted on T cells from patients with chronic hepatitis B. *In vivo*, TCR-redirected T cells targeted the liver when injected into HBV-infected humanized mice repopulated with HLA-A*02-matched primary human hepatocytes. After a single T cell injection, viremia and HBsAg dropped by more than 4–5 $\log_{10}$ to undetectable levels in 5/6 animals and HBeAg as well as cccDNA became negative. Alanine amino transferase levels peaked after 5 days and normalized thereafter. After three weeks, HBcAg staining in the liver had become negative. No HBV rebound was observed until the end of the experiment after 40 days.
Conclusion: Our experiments indicate that T cells stably transduced with TCRs of high functional avidity allow functional cure of HBV infection after a single injection causing limited liver injury. T-cell therapy of chronic hepatitis B and HBV-induced hepatocellular carcinoma thus is an interesting therapeutic approach that should be further evaluated.

PS-032
Discovery of a novel core inhibitor EP-027367 with potent antiviral activity both in vitro and in a humanized mouse model
M. Vaine[1], S. Clugston[1], J. Kass[1], X. Gao[1], H. Cao[1], W. Li[1], X. Peng[1], L. Jiang[1], K. Daniels[1], Y.-L. Qiu[1], Y.S. Or[1], K. Lin[2]. *[1]Enanta Pharmaceuticals; [2]Enanta Pharmaceuticals, Watertown, United States*
Email: mvaine@enanta.com
Background and Aims: Current therapies for hepatitis B virus (HBV) using nucleos(t)ides and IFN can effectively suppress viral replication but rarely lead to a functional cure, which necessitates the development of new antiviral drugs. Core inhibitors or capsid assembly modulators are a new class of HBV inhibitors which misdirect the assembly and function of the viral capsid. We have identified EP-027367 as a novel core inhibitor with a favorable antiviral, pharmacokinetic, and safety profile to treat HBV infection.
Method: The effect of EP-027367 on viral capsid assembly was determined *in vitro*. Its anti-HBV activities at different stages of the viral lifecycle were characterized in HepG2.2.15, HepAD38, HepDE19, HepaRG, and primary human hepatocytes. *In vivo* efficacy of EP-027367 was evaluated in a humanized mouse model consisting of uPA/SCID mice with livers repopulated by human hepatocytes and infected with a genotype C HBV.
Results: EP-027367 modulates HBV capsid assembly and blocks viral pgRNA encapsidation *in vitro*. It inhibits the production of HBV rcDNA with EC_{50}s of 20, 24 and 40 nM in HepG2.2.15, HepAD38, and HepDE19 cells, respectively. It is active across HBV genotypes A-H with potencies ranging from 7 to 50 nM and is not affected by known nucleos(t)ide resistant variants. Combinations of EP-027367 with other HBV inhibitors display additive to synergistic antiviral activity *in vitro*. Additionally, EP-027367 can prevent *de novo* infection of susceptible cell lines at sub-micromolar concentrations by inhibiting the formation of new cccDNA. In a human liver chimeric mouse model, EP-027367, given orally at 50, 100 and 200 mg/kg BID for 28 days, reduced HBV DNA level by 2.2, 2.7 and 3.0 logs from baseline, respectively.



Conclusion: EP-027367, a novel HBV core inhibitor with potent antiviral activities both *in vitro* and *in vivo*, represents a promising new therapeutic candidate for treating HBV infection.

Email: ev77@cumc.columbia.edu
Background and Aims: Direct-acting antiviral (DAA) HCV therapy is now being used in difficult to treat patient populations, including

decompensated cirrhosis. While high SVR rates have been reported in a limited number of clinical trials, we evaluated the real-world safety and effectiveness of DAAs in this population, and the impact on hepatic function.

Method: Patients with advanced cirrhosis enrolled in HCV-TARGET, who initiated HCV therapy with NS5A-containing DAAs, were included. Advanced cirrhosis was defined as cirrhosis and MELD score of ≥10, without prior liver transplantation (LT). Safety cohort (N = 473): Patients who started therapy prior to July 2017 and completed or discontinued therapy due to lack of efficacy, adverse event (AE), or death. Efficacy cohort (N = 386): Patients who started therapy by April 2017 with known virologic outcome who did not undergo LT during treatment or SVR12.

Results: In the safety cohort, mean age was 60 years, 67.2% male, 49.9% had failed prior antiviral therapy and 21.4% had failed prior all DAA regimens. The median MELD at treatment was 12 (range 10–39), with mean total bilirubin 1.6 (0.2–16.1), albumin 3.2 (1.0–4.7), platelets 82×10^3 (15–647), and creatinine 0.9 (0.4–12.7). 67% had a history of decompensating events. Genotype, MELD category, treatment regimen and SVR 12 rates are shown in the Table. At least one AE was reported in 74% of patients and 19.7% experienced SAEs. 13 patients in safety cohort died (5 on treatment and 8 in follow up) and 10 underwent liver transplant. At the time of SVR12, MELD had decreased by ≥2 points in 79 (39.9%), increased by ≥2 points in 33 (16.7%), and was unchanged in 86 (43.4%) patients.

Total Cohort	SOF/LDV +/− RBV (n = 309)	SOF/DCV +/− RBV (n = 75)	SOF/VEL +/− RBV (n = 69)	ELB/GRZ+/− RBV (n = 20)	ALL (n = 473)
GT 1 (n/%)	289 (94%)	11 (15%)	19 (28%)	20 (100%)	339 (72%)
GT 2	1 (0.3%)	15 (20%)	16 (23%)	0 (0%)	32 (7%)
G3	6 (2%)	48 (64%)	30 (44%)	0 (0%)	84 (18%)
G4/Other	13 (4%)	1 (1%)	4 (6%)	0 (0%)	18 (4%)
MELD					
10–15	258 (84%)	65 (87%)	57 (83%)	5 (25%)	385 (81%)
16–21	42 (14%)	7 (9%)	8 (12%)	1 (5%)	58 (12%)
>21	9 (3%)	3 (4%)	4 (6%)	14 (70%)	30 (6%)

History of HCC	34 (11%)	12 (16%)	10 (15.0%)	1 (5.0%)	45 (14.3%)
History of Decomp events	205 (66%)	53 (71%)	47 (68%)	10 (50%)	315 (67%)
Discontinued due to AE	9 (3%)	4 (5%)	1 (1%)	1 (5%)	15 (3%)
Died	6 (2%)	5 (7%)	1 (1%)	1 (5%)	13 (3%)
Response*	(n = 260)	(n = 59)	(n = 51)	(n = 16)	(n = 386)
SVR 12	233 (90%)	50 (85%)	49 (96%)	16 (100%)	348 (90%)
Relapse	26	6	2	0	34
Non-response	1	3	0	0	4

*Efficacy cohort only.

Conclusion: In a large real world experience, NS5A-containing DAA therapy was effective in patients with advanced cirrhosis; adverse events were as previously observed in clinical trials in this population. Importantly, markers of hepatic function improved or remained unchanged in most at the time of SVR12. Long term follow up is ongoing to determine the degree and predictors of hepatic function recovery.

PS-034

8 weeks sofosbuvir/velpatasvir in genotype 3 patients with significant fibrosis: Highly effective amongst an OST cohort

A. Boyle[1,2], F. Marra[2,3], E. Peters[4], M. Heydtmann[5], H. Cairns[6], S. Datta[7], S. Barclay[8]. *[1]NHS Greater Glasgow and Clyde, Pharmacy Department; [2]University of Liverpool, Department of Molecular and Clinical Pharmacology; [3]NHS Greater Glasgow and Clyde, Pharmacy Dept; [4]NHS Greater Glasgow and Clyde, Brownlee Centre for Infectious Diseases; [5]NHS Greater Glasgow and Clyde, Royal Alexandra Hospital; [6]NHS Greater Glasgow and Clyde, Gartnavel General Hospital; [7]NHS Greater Glasgow and Clyde, Queen Elizabeth University Hospital, Glasgow; [8]NHS Greater Glasgow and Clyde, Glasgow Royal Infirmary*
Email: alisonboyle2@nhs.net

Background and Aims: Twelve weeks of sofosbuvir/velpatasvir (SOF/VEL) is highly effective at treating genotype 3 (GT3) hepatitis C. A phase 2 trial reported high sustained viral response (SVR) rates in treatment-naïve non-cirrhotic patients, treated with 8 weeks of SOF/VEL (SVR 98.1% (52/53)). In order to maximise the number of patients potentially cured within a fixed treatment budget, we elected to treat non-cirrhotic GT3 patients eligible for treatment (F2/3) with 8 weeks of SOF/VEL. DAAs in our centres are dispensed from community pharmacies in line with patients' opiate substitution therapy (OST). Those still injecting or in early stages of recovery are prescribed methadone (and DAAs) as daily observed therapy (DOT), with more stable patients dispensed 2–3 x weekly or weekly. Patients not on OST are dispensed at 2 weekly intervals.

Method: By local treatment protocol, treatment-naive patients with F2 or F3 fibrosis (LSM > 6.9 kPa & <9.5 kPa and ≥9.5 kPa & <12.5 kPa respectively), were eligible for treatment with 8 weeks SOF/VEL. Such patients commencing treatment before October 1st 2017 were identified from the Scottish HCV database, and baseline data on age, gender, liver stiffness measurement (LSM), premature discontinuation and treatment response were obtained. Dispensing frequency was obtained from pharmacy records.

Results: Ninety-two patients (72 (78.3%) male), mean age 45.1 (IQR ± 6.1)) started 8 weeks SOF/VEL, prior to October 1st 2017. Median LSM was 8.5 kPa (IQR ± 2.3). 28 (30.4%) had F3 disease. Median baseline viral load was 5.63 log iu/ml (IQR ± 1.45), with 5 (5.4%) greater than 6 million iu/ml. 83 (90.2%) were on OST, including 39 (42.4%) on DOT. Six patients (6.5%) were treated in prison. To date, 84 (91%) patients have completed treatment, 3 (3.6%) prematurely. Intention to treat (ITT) SVR is 42/45 (93.3%). In non SVR patients, 1 was re-infected (with subsequent spontaneous clearance), 1 discontinued treatment at week 4, and one died following treatment completion. Modified intention to treat (mITT) SVR is 42/42 (100%). In DOT patients, ITT and mITT SVR to date are 13/14 (92.9%) and 14/14 (100%) respectively. Further SVR data will be presented.

Conclusion: Eight weeks of SOF/VEL is highly effective in GT3 infected patients with significant (F2/3) fibrosis. Patients on daily supervised OST have excellent SVR rates when given DAAs along with OST. Widespread adoption of 8 weeks treatment would reduce drug acquisition costs, and increase clinic treatment capacity, without sacrificing SVR. In settings with limited resources, such a strategy may help achieve the HCV elimination goals.

Email: brian.mcnabb@gilead.com

Background and Aims: The single tablet regimen of sofosbuvir/velpatasvir (SOF/VEL) is a highly effective and well-tolerated treatment for GT3 HCV-infected patients. In the Phase 3 ASTRAL-3 study, SOF/VEL for 12 weeks resulted in 95% of GT3 HCV-infected patients achieving SVR; patients with compensated cirrhosis had numerically lower SVR rates (91%) compared to those without cirrhosis (97%). This study evaluated the efficacy and safety of SOF/VEL ± RBV for 12 weeks in GT3 HCV-infected patients with cirrhosis.

Method: At 29 sites in Spain, patients with cirrhosis and chronic GT3 HCV infection who could be treatment – experienced but were NS5A-inhibitor naïve were randomized 1:1 to receive open-label SOF/VEL 400/100 mg daily for 12 weeks with or without weight-based RBV, stratified by prior treatment experience. Patients had cirrhosis defined by liver biopsy, Fibroscan >12.5 kPa, or combined Fibrotest >0.74 and APRI >2.0. HCV RNA was measured with the CAP/CTM HCV 2.0 assay with LLOQ = 15 IU/mL. The primary efficacy endpoint was SVR 12 weeks after treatment (SVR12). Evaluation for resistance associated substitutions (RASs) was performed by sequencing HCV NS5A and NS5B coding regions with a 15% cut-off. The primary safety endpoint was adverse events (AEs) leading to SOF/VEL discontinuation.

Results: A total of 204 GT3 HCV-infected patients with cirrhosis were randomized and treated. The mean (range) age was 51 (31–85); 79% were male, 88% were white, 27% were treatment-experienced, 57% had IL28B CC genotype, and 15% had HIV coinfection. The overall SVR12 rates (n/N; 95% CI) were 91% (92/101; 84–96%) for the SOF/VEL group and 96% (99/103; 90–99%) for the SOF/VEL + RBV group. Among SOF/VEL treated patients, there were 5 relapses, 1 on-treatment virologic failure, and 3 patients lost to follow-up (LTFU); for SOF/VEL + RBV treated patients, there were 2 relapses and 2 patients LTFU. SVR12 rates were 96% for both SOF/VEL and SOF/VEL + RBV treated patients with prior treatment experience. Baseline NS5A resistance associated substitutions (RASs) were present in 20% of patients (n = 40). Within this subgroup, SVR12 was 83% (15/18) among patients treated with SOF/VEL and 95% (21/22) among patients treated with SOF/VEL + RBV. One patient in each group discontinued SOF/VEL due to AEs (anxiety and dizziness in the SOF/VEL group and increased bilirubin in the SOF/VEL + RBV group). Common AEs (>10% of patients) were asthenia (12%) for SOF/VEL and asthenia (27%), headache (24%), and insomnia (12%) for SOF/VEL + RBV. No treatment-related serious AEs occurred in either group, and there were no deaths in this study.

Conclusion: GT3 HCV-infected patients with cirrhosis have high overall rates of SVR12 after treatment with SOF/VEL with or without RBV. Among those with baseline NS5A RASs and cirrhosis, the addition of RBV to 12 weeks of SOF/VEL led to numerically higher SVR rates.

PS-036

Scaling up HCV-DAA treatment in patients on opioid substitution therapy (OST) – does alcohol and cannabis diminish cure rates? Data from the German Hepatitis C-Registry (DHC-R)

Email: christensen@cim-ms.de

Background and Aims: People who inject drugs (PWID) are most affected by HCV infection. To reach the WHO goal of HCV eradication by 2030 DAA therapy has to be scaled up in these patients. We compared sustained virological response (SVR) rates and proportion of lost to follow up (LTFU) depending on alcohol and cannabis consumption in OST and non-OST patients starting DAA treatment between 2/2014 and 9/2015.

Method: The DHC-R is a national multicentre non-interventional real-world registry study. Non-OST patients were divided in patients with former/current drug use (non-OST/DU) and no drug use (non-OST/NDU). 7,747 chronic HCV patients started DAA therapy: 739 OST and 7,008 non-OST (1,500 non-OST/DU; 5,508 non-OST/NDU) patients. 528 OST and 5,582 non-OST patients had completed antiviral therapy and at least one follow-up documentation (Intention-to-treat (ITT) population).

Table 1: SVR rates and proportion of LTFU in non-OST/NDU, non-OST/DU and OST patients stratified by alcohol and cannabis consumption.

Baseline parameter	Lost to Follow Up (ITT), % (n/N)		
	Non-OST/NDU	Non-OST/DU	OST
alcohol consumption, yes	**3.0** (16/532)	8.8 (17/193)	12.4 (12/97)
>40g/d (m)/>30g/d (f)	7.4 (5/68)	9.5 (4/42)	14.8 (4/27)
≤40g/d (m)/≤30g/d (f)	**2.4** (11/464)	8.6 (13/151)	11.4 (8/70)
alcohol consumption, no	**3.2** (125/3,907)	8.5 (79/929)	9.2 (39/426)
cannabis consumption, yes	1.7 (1/57)	10.7 (11/103)	8.4 (7/83)
cannabis consumption, no	**3.2** (141/4,398)	8.3 (85/1,023)	10.6 (47/445)
Baseline parameter	**SVR rates (Intention-to-treat), % (n/N)**		
	Non-OST/NDU	**Non-OST/DU**	**OST**
alcohol consumption, yes	**91.2** (485/532)	83.4 (161/193)	83.5 (81/97)
>40g/d (m)/>30g/d (f)	85.3 (58/68)	78.6 (33/42)	85.2 (23/27)
≤40g/d (m)/≤30g/d (f)	**92.0** (427/464)	84.8 (128/151)	82.9 (58/70)
alcohol consumption, no	**92.4** (3,612/3,907)	86.5 /804/929)	86.2 (367/426)
cannabis consumption, yes	91.2 (52/57)	84.5 (87/103)	84.3 (70/83)
cannabis consumption, no	**92.3** (4,060/4,398)	86.2 (882/1023)	85.4 (380/445)
Baseline parameter	**SVR rates (Per-Protocol), % (n/N)**		
	Non-OST/NDU	**Non-OST/DU**	**OST**
alcohol consumption, yes	94.2 (484/514)	90.9 (159/175)	95.2 (79/83)
>40g/d (m)/>30g/d (f)	92.1 (58/63)	86.8 (33/38)	100 (23/23)
≤40g/d (m)/≤30g/d (f)	94.5 (426/451)	92.0 (126/137)	93.3 (56/60)
alcohol consumption, no	95.6 (3,598/3,763)	94.3 (796/844)	96.0 (362/377)
cannabis consumption, yes	92.9 (52/56)	94.4 (85/90)	93.3 (70/75)
cannabis consumption, no	95.5 (4,045/4,236)	93.7 (874/933)	96.4 (373/387)

Values highlighted in bold significantly differ from respective values of OST patients ($p<0.05$)
OST, opioid substitution therapy; DU, drug use; NDU, no drug use; SVR, sustained virological response

Results: Alcohol consumption was reported in 17.3% (128/739) of OST, in 17.1% (256/1,500) of non-OST/DU and in 11.3% (631/5,508) of non-OST/NDU patients. Among OST patients, 25% (32/128) consumed high amounts (>40 g alcohol/d (men)/>30 g/d (women)) of alcohol. In non-OST/DU, high amounts of alcohol were consumed in 22.2% (57/256). In non-OST/NDU, significantly less patients (13.9%, 88/631) consumed high amounts of alcohol when compared to OST patients ($p < 0.05$). Similarly, cannabis consumption was significantly higher in OST patients (18.8%, 139/739) than in non-OST/DU (9.4%, 141/1,500, $p < 0.05$) and non-OST/NDU patients (1.2%, 66/5,508, $p < 0.05$). In alcohol consuming patients, proportion of LTFU was significantly higher in OST (12/97) compared non-OST/NDU (16/532), but occurred mainly (8/97) after end of therapy (EOT). Therefore, the overall ITT SVR rate was significantly ($p < 0.05$) diminished in OST (85%) and non-OST/DU (86%) compared to non-OST/NDU patients (91%), but not in per protocol analysis (PP; OST 96%, non-OST/DU 94%,

NON-OST/NDU 95%). When stratified by alcohol consumption (yes/no) and moderate daily intake of alcohol (≤40 g/d (men)/≤30 g/d (women)), non-OST/NDU patients had significantly higher SVR rates than OST patients in ITT but not in PP analysis (Table 1). With respect to cannabis consumption, SVR rates did not differ between the three patient groups. Of note, relapse rates were lower in OST than in non-OST/DU and non-OST/NDU patients.

Conclusion: High SVR rates can be achieved in both OST and non-OST patients. Alcohol or cannabis consumption did not diminish cure rates in PP analysis. However, LTFU is more likely in patients with current or former drug use than in patients without drug history and in patients with high alcohol consumption, but occurred mainly after EOT, leaving a high chance for a cure in these patients.

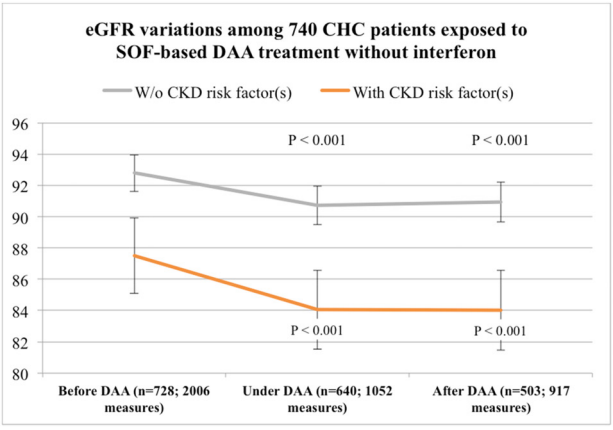
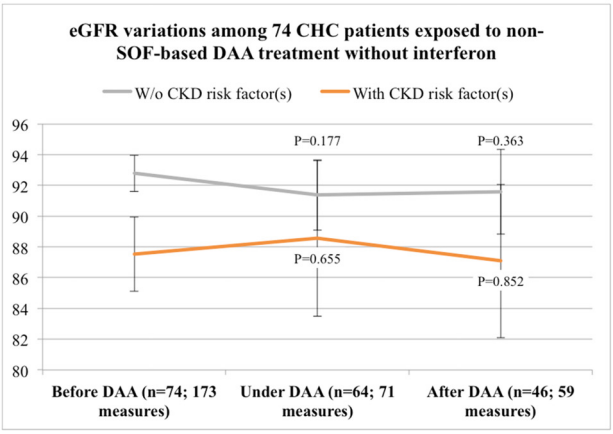
Background: Nucleoside analogue treatment has been associated with renal toxicity. We evaluated the evolution of eGFR during and after DAA treatment for chronic hepatitis C (CHC).

Patients and Methods: We conducted a retrospective cohort study among consecutive and non-selected patients (n = 1131) who underwent direct acting antivirals (DAA) treatment for chronic hepatitis C (CHC) between 2013 and 2016. All serum creatinine measures, including those before DAA treatment, were retrieved from the biological database of the institution and merged in the patients' characteristics dataset. We selected patients with at least one creatinine measure. We excluded patients with HIV or HBV coinfections, patients with primary liver cancer or decompensated cirrhosis, patients with haematological malignancy, transplant recipients and patients under immunosuppressive therapy. Patients with a less than 30 ml/min/1.73 m2 estimated glomerular filtration rate (eGFR) on the first available creatinine measure were also excluded. Overall, the analyses included 4278 longitudinal eGFR measures assessed over a maximum 37 and 81 months post-treatment and total follow-up time period. We compared first and last measures with the pairwise T-test. We isolated the effect of DAA exposure on eGFR with a linear mixed model adapted for repeated measures allowing for the use of time-independent, here chronic kidney disease (CKD) risk factors, and – dependent, here DAA exposure, covariates.

Results: We selected 814 CHC patients treated with a sofosbuvir (SOF, n = 740) and a non-SOF (n = 74)-based regimen without interferon. Median age was 58 years, 40% had cirrhosis, 25% had CKD risk factors, including diabetes mellitus (9.8%) and high blood pressure (22.9%), and 96.5% had a baseline eGFR ≥ 60 ml/min/1.73 m^2. Median number of eGFR measures was 4 per patient and 784 (96.3%) patients had at least 2 eGFR measures. Mean eGFR decrease between first and last measure was 2.6 (p < 0.001) and 1.7 (p = 0.115) ml/min/1.73 m^2 for SOF and non-SOF patients. When all measures were taken into account, mean eGFR variations were −2.1 (95% confidence interval [CI] −2.70, −1.44; p < 0.001) and −1.8 (95% CI −2.6, −1.1; p < 0.001) and −3.5 (95% CI −4.7, −2.2; p < 0.001) and −3.5 (−4.8, −2.2; p < 0.001) ml/min/1.73 m^2 under and after SOF-based DAA treatment among patients with and without CKD risk factors, respectively. Other DAA combinations without SOF were not associated with eGFR variations.





Conclusion: SOF-based DAA treatment is associated with eGFR decrease among CHC patients, especially among those with CKD risk factors. Renal function should be monitored under and after SOF-based DAA treatment. The clinical implication(s) of these findings should be explored.

Background and Aims: Relapse after a course of therapy with direct-acting antivirals (DAAs) is rare (~3.5%) and usually results in recurrence of chronic hepatitis requiring retreatment. We have observed patients with documented relapse who spontaneously cleared infection without retreatment. Our aim is to compare clinical and virologic characteristics of patients with spontaneous clearance after relapse to those who achieved sustained virologic response (SVR) or relapsed without clearance.

Method: Clearers: CHC who relapsed with detectable HCV RNA 12 weeks after DAA therapy and then spontaneously resolved the infection within 6 months were compared to 2 control groups: "SVR" who had undetectable HCV RNA 12w post-treatment and "Relapse" who had detectable HCV RNA 12w after treatment without clearance. For each case, 2 SVR and 2 Relapse controls were randomly selected from the Toronto Centre for Liver Disease database. Demographic and laboratory data were compared between groups.

Results: Of 70 patients with documented relapse at SVR12, 10 (14%) spontaneously cleared infection without retreatment (Clearers). Baseline characteristics were similar between Clearers and Controls (Table 1). DAA regimens, use of ribavirin and treatment duration did not differ by group. Baseline and on-treatment liver enzymes and HCV RNA levels were similar, however at SVR12, despite detectable HCV RNA, Clearers had ALT values similar to those in the SVR group and significantly lower than in the relapse group (Table 1). Of the 10 Clearers, 9 had ALT values in the normal range at the time of relapse. HCV RNA levels were lower in the Clearers than Relapsers (4 log vs 6 log, p < .05). ALT levels remained low after the SVR12 time-point in Clearers. No Clearers had risk factors for reinfection.

		Relapse with Clearance (n = 10)	Relapser (n = 20)	SVR (n = 20)	p-Value
Age		60 (4)	60 (8)	60 (14)	0.97
Male		6 (60)	15 (75)	16 (80)	0.64
Fibrosis	Fibroscan	14.7 (9.4)	18.6 (16.5)	16 (9.5)	0.93
	FIB4	3.9 (2.9)	6.1 (3.2)	4.4 (3.2)	0.13
	Cirrhosis	5 (50)	15 (75)	14 (70)	0.45
Genotype	1	8 (80)	10 (50)	15 (75)	0.13
	2	0	2 (10)	0	
	3	1 (10)	7 (35)	5 (25)	
	4	0	1 (5)	0	
	6	1 (10)	0	0	
HCV RNA (log IU/mL)	Baseline	3.E6 (4.E6)	4.E6 (8.E6)	3.E6 (2.E6)	0.65
	Week 4	7.5E0 (8.7E0)	1.1E1 (1.6E1)	7.7E0 (1.3E1)	0.85
	SVR12	1.5E4 (3.9E4)	3.1E6 (7.1E6)	0	0.07
	Post SVR12	0	1.1E6 (1.0E6)		0.004
ALT (U/L)	Baseline	102 (62)	102 (63)	85 (112)	0.08
	SVR12	31 (30)	103 (68)	17 (8)	<.001
	Post SVR12	22 (5)	76 (41)	19 (7)	<.001

Mean(SD) or n(%).

Conclusion: Spontaneous clearance after documented relapse has not been described but occurred in over 14% of patients who relapsed after completed DAA therapy. Normal or near-normal liver enzymes despite detectable HCV RNA may identify patients likely to spontaneous clear after relapse. While the mechanisms for clearance remain obscure, the frequency of this observation highlights the need for confirmation of viremia prior to retreatment.

PS-039

NS5A resistance patterns and treatment outcomes in DAA-naive genotype 1a chronic hepatitis C patients with and without baseline resistance-associated substitutions

Sarrazin[1,14]. *[1]Goethe University Hospital, Department of Internal Medicine I, Frankfurt am Main, Germany; [2]IFI-Institute for Interdisciplinary Medicine, Hamburg, Germany; [3]University Hospital Würzburg, Department of Internal Medicine II, Würzburg, Germany; [4]University Medical Center Hamburg-Eppendorf, Department of Internal Medicine I; [5]Practice of Gastroenterology, Kiel, Germany; [6]Justus Liebig University Gießen, Department of Medicine II, Gießen, Germany; [7]University Medical Center Göttigen, Department of Gastroenterology and Gastrointestinal Oncology, Göttingen, Germany; [8]Practice of Gastroenterology, Düsseldorf, Germany; [9]University Hospital Regensburg, Department of Internal Medicine I, Regensburg, Germany; [10]Katholisches Klinikum Oberhausen, St. Josef-Hospital, Oberhausen, Germany; [11]University Hospital Freiburg, Department of Medicine II, Freiburg, Germany; [12]University Hospital Freiburg, Department of Internal Medicine II, Freiburg, Germany; [13]University Hospital Tübingen, Department of Gastroenterology, Hepatology, and Infectiology, Tübingen, Germany; [14]St. Josefs-Hospital, Wiesbaden, Germany*
Email: julia.dietz@em.uni-frankfurt.de

Background and Aims: For patients with hepatitis C virus HCV genotype (GT) 1a infection who should be treated with grazoprevir (GZR) plus elbasvir (EBR), testing of NS5A resistance-associated variants (RASs) is recommended. In patients harboring RASs, SVR (sustained virologic response) rates were increased by the addition of ribavirin (RBV) and prolonging treatment to 16 weeks (wks.). Other regimens using sofosbuvir (SOF) plus ledipasvir (LDV) or velpatasvir (VEL) as well as paritaprevir, ombitasvir, dasabuvir (3D) and glecaprevir/pibrentasvir (G/P) are approved for GT1a as well. This study investigated the prevalence of EBR-specific RASs and the outcome of a DAA-based (direct acting antivirals) treatment in GT1a-infected patients according to the presence of RASs.
Method: In the European Resistance Database, we collected between October 2016 and May 2017, serum samples of 379 GT1a-infected and DAA-naïve patients, who were intended to receive GZR/EBR. Population sequencing was performed and NS5A RASs which conferred a >5-fold changed susceptibility to EBR were analysed and limited clinical and virological parameters were collected retrospectively.
Results: Overall, 82% of patients were treatment-naïve, 21% had a cirrhosis and EBR-specific RASs were detected in 6% of patients. A treatment based on a resistance analysis was started in 224/379 (59%) patients as yet and the median baseline viral load was 1.700.000 IU/mL. Patients without RASs (n = 210) were treated with GZR/EBR for 12 wks. (n = 122, 58%), GZR/EBR/RBV for 12/16 wks. (n = 17, 8%), LDV/SOF ± RBV (n = 46, 22%), G/P (n = 13, 6%), 3D/RBV (n = 10, 5%) and VEL/SOF (n = 2, 1%). Follow-up (FU) data was available for n = 83 patients and 99% achieved an SVR. In individuals with RASs (n = 14), Q30R/H (50%), Y93F/H (36%), L31M (21%) and M28T (14%) were detected. These patients received GZR/EBR/RBV for 16 wks. (n = 5, 37%), GZR/EBR for 16 wks. (n = 1, 7%), LDV/SOF (n = 3, 21%), VEL/SOF (n = 2, 14%), G/P (n = 1, 7%), 3D/RBV (n = 1, 7%) and SMV/SOF (n = 1, 7%). FU is completed in n = 5 individuals so far. All patients treated according to the guidelines achieved an SVR (n = 4/4, 100%) and one individual not treated appropriately did not receive RBV in addition to GZR/EBR and relapsed.
Conclusion: EBR-specific NS5A RASs were sparse in DAA-naïve patients with GT1a. A treatment based on a baseline resistance analysis according to the guidelines led to high SVR rates of ≥99% in patients with and without RASs.

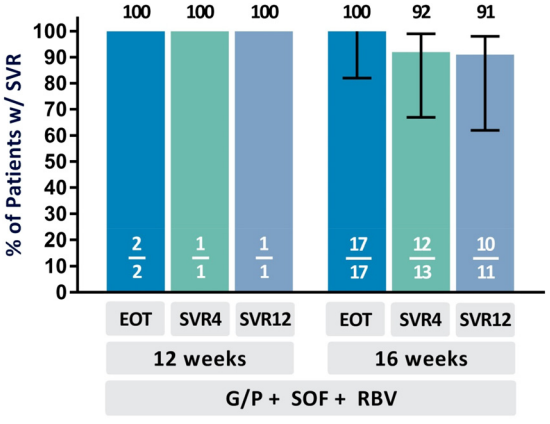
Email: david.wyles@dhha.org

Background and Aims: Glecaprevir/pibrentasvir (G/P; glecaprevir identified by AbbVie and Enanta) has demonstrated high rates of sustained virologic response at posttreatment week 12 (SVR12) across all six major hepatitis C virus (HCV) genotypes (GT). Roughly 1% of patients treated with G/P in Phase II or III clinical trials, across all genotypes, had virologic failure. These patients were offered enrollment into a retreatment study, MAGELLAN-3.
Method: MAGELLAN-3 is an ongoing open-label, phase 3b trial to determine the efficacy and safety of G/P (300/120 mg once daily) + sofosbuvir (SOF; 400 mg once daily) + ribavirin (RBV; 1,000–

1,200 mg daily, divided into two doses) in patients who had virologic failure on G/P treatment in an AbbVie-sponsored clinical trial. Patients who had non-GT 3 infection, without cirrhosis, and were naïve to NS3/4A protease and NS5A inhibitors prior to failure with G/P, received 12 weeks of treatment; all others received 16 weeks. Efficacy (percentage of patients with SVR12), safety, and baseline resistance were assessed. Patients with at least end-of-treatment (EOT) data are reported here.

Results: Of 23 patients enrolled, 19 reached EOT; 2 patients were treated for 12 weeks (both reached EOT) and 21 were treated for 16 weeks (17 reached EOT). Overall, 30% (7/23), 9% (2/23), and 61% (14/23) of patients had HCV GT 1, 2, and 3 infection, respectively, and 30% (7/23) of patients had compensated cirrhosis. Twenty six percent (6/23) of patients had NS3/4A protease and/or NS5A inhibitor experience prior to their original G/P treatment; 39% (9/23) of patients had prior experience to other HCV treatment regimens. Twenty two percent (5/23) of patients had baseline resistance-associated substitutions (RAS) in NS3; the most common were at position D/Q168 (n = 4). All 23 patients had baseline RAS in NS5A (14 had multiple NS5A RAS); the most common were at position Q30 (n = 6) in GT1, and Y93 (n = 11) and A30 (n = 9) in GT3. One patient had virologic failure; currently available SVR12 rates are shown in the Figure. The retreatment regimen was well tolerated. One patient had a serious adverse event of cholelithiasis at treatment week 10. Complete efficacy and safety data will be presented at the conference.



EOT: HCV RNA below lower limit of quantification at end-of-treatment
SVR4/12: HCV RNA below lower limit of quantification at posttreatment week 4/12

Conclusion: Preliminary data show that retreatment with G/P + SOF + RBV for 12 or 16 weeks was well tolerated and has demonstrated a high rate of SVR12, regardless of HCV genotype or baseline resistance-associated substitutions.

Liver transplantation: Clinical

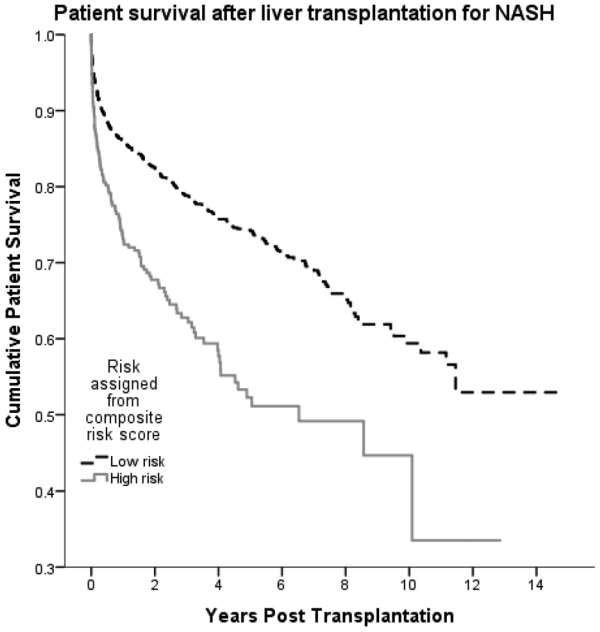
Email: debashishaldar1983@gmail.com

Background and Aims: Non-alcoholic steatohepatitis (NASH) is an evermore-prevalent cause of liver disease in the western world. However, outcomes after liver transplantation (LT) for NASH are seldom reported. We aim to describe the relative frequency and analyse the outcomes of LT for NASH from a pan-European prospective database.

Method: We performed a retrospective cohort study of all adult patients (age > 18) who underwent primary LT for end stage liver disease between 1st January 2002 and 31st December 2016 using the European Liver Transplant Registry database. We compared data from patients transplanted for NASH to data from patients transplanted for other indications.



Kaplan-Meier survival curve describing cumulative patient survival after liver transplantation for NASH. Patients have been assigned to a risk group based on a composite score assigned to significant predictors of outcome in this cohort. The 5-year survival in the high-risk and low-risk group are 52% and 74% respectively (p<0.001).

Results: 68950 patients underwent a primary LT in the study period; NASH was the primary indication in 2741 patients (4.0%). The proportion of LTs done for patients with NASH has increased from 1.2% in 2002 to 8.7% in 2016. Patients with NASH undergoing LT are significantly older (median age 60 vs 55, $p < 0.001$) and of a greater body mass index (BMI) (32.6 ± 4.6 kg/m^2 vs 25.8 ± 4.4 kg/m^2, $p < 0.001$). A greater proportion of patients transplanted for NASH have concomitant HCC (39.1% vs 28.9%, $p < 0.001$). Patients with NASH receive organs from donors who are more likely to be male (62.3% vs 57.6%, $p < 0.001$) and of a greater body mass index (26.9 ± 4.8 kg/m^2 vs 25.5 ± 4.3 kg/m^2, $p < 0.001$). They also receive more donor organs after circulatory death (6.6% vs 2.6%, $p < 0.001$). Survival at 1 year

(84.3% vs 86.4%) and 5 years (71.3% vs 73.3%) after LT for NASH is marginally worse than for other indications (p = 0.005). However, on multivariable logistic regression, recipient (age, sex, BMI, blood group, presence of HCC) and donor (age, BMI, blood group, type of donor) factors are found to significantly affect post-transplant (PT) survival. On adjusting for these factors, NASH is not found to be an independent predictor of outcome (HR 1.07, p = 0.18). Graft survival is similar in patients transplanted for NASH compared to other indications other than HCV for which graft survival is comparatively poor. A multivariable analysis of the NASH cohort identifies recipient age, BMI, MELD, donor blood group and organ type to predict PT survival. A composite risk score (using the regression coefficient in significant variables) identifies a sub-cohort with poor 5-year survival after transplant (ROC AUC 0.636) (see image).

Conclusion: NASH is a growing indication for liver transplantation in Europe. It is not an independent predictor of PT survival, but patients are older, have a greater BMI, and have more likely to be transplanted with concomitant HCC. Predictive recipient and donor factors can be used to stratify potential transplantation risk and inform listing decisions.

PS-042

Liver transplantation in patients with multiple organ failures is feasible with good outcomes

P.J. Thuluvath[1], A. Thuluvath[2], Y. Savva[3]. *[1]Mercy Medical Center & University of Maryland School of Medicine, Medicine, Baltimore, United States; [2]Johns Hopkins University, Medicine, Baltimore, United States; [3]Mercy Medical Center, Institute of Digestive Health & Liver Diseases, Baltimore, United States*
Email: thuluvath@gmail.com

Background and Aims: Patients who are transplanted within 30 days after listing for transplantation usually have very high MELD scores and many of these patients may have ACLF. There is a paucity of data on immediate and short-term outcomes of patients with multiple organ failures (OF) who undergo liver transplantation (LT).

Method: To examine the impact of OF on LT outcomes, we analyzed UNOS data from 2002 to 2016 of all adults who received LT within 30 days after listing for LT. We defined OF if patients were on dialysis, ventilator, life support or had stage 3 or 4 HE. Based on this, patients can have no OF or between 1 and 4 OF. Since organ failure is most likely to influence short and intermediate term outcomes, we analyzed only 30-day, 90-day and 1-year graft and patient survival. Kaplan-Meier estimator was used to construct survival curves and multivariate Cox proportional hazard regressions were used to study the association between the risk factors.

Results: During this period, 21,347 patients were transplanted within 30 days of listing. Of these 14,459 (68%) had no OF, 3,457 (16%) had one, 1,349 (6%) had two, 1,449 (7%) had three and 633 (3%) had four OF. The patient and graft survival outcomes of patients based on the number of OF are shown in Figures 1 & 2; 30-day and 90-day patient survival was highest without OF (97%, 95%) and lowest for those with 3 or 4 OF (89%, 86%). There was a progressive decline in survival with increasing number of OF. Multivariate Cox regression analysis for patient survival is shown in the table below. MELD score was not a predictor of mortality at 30 days and 90 days, when OF was included in the Cox regression, but the risk of death increased with increasing number of OF after adjustment for age, gender, race, BMI, etiology of liver disease, MELD, Karnofsky performance status scores (severe disability defined as 30% or less) and donor risk index (DRI). DRI and poor performance status were also strong independent predictors.

Conclusion: Our observations suggest that patients with multiple organ failures, when transplanted within 30 days of listing, have very good post-LT survival rates. Although the impact of OF is significant, survival outcomes are acceptable even with multiple OF.

	Predictor of Patient Mortality - Adjusted HR (from multivariate Cox regression)					
	30-day mortality	p-value	90-day mortality	p-value	1-year mortality	p-value
MELD score	1.01 (0.99–1.02)	0.3	1.00 (0.99–1.01)	0.27	1.01 (1.001–1.012)	0.03
KPS 30% or less	1.69 (1.35–2.11)	<0.01	1.49 (1.26–1.76)	<0.01	1.34 (1.19–1.51)	<0.01
Organ failure						
1	1.36 (1.07–1.72)	0.01	1.28 (1.07–1.53)	<0.01	1.19 (1.04–1.36)	0.01
2	1.68 (1.25–2.27)	<0.01	1.68 (1.33–2.12)	<0.01	1.50 (1.26–1.79)	<0.01
3	2.63 (2.02–3.41)	<0.01	2.35 (1.90–2.90)	<0.01	1.92 (1.62–2.28)	<0.01
4	2.20 (1.53–3.17)	<0.01	2.01 (1.49–2.72)	<0.01	1.87 (1.48–2.36)	<0.01
Donor Risk Index	1.26 (1.06–1.51)	0.01	1.40 (1.23–1.60)	<0.01	1.40 (1.27–1.54)	<0.01

Email: nicolasgolse@me.com

Background and Aims: Liver macrosteatosis is a major predictor of graft dysfunction after liver transplantation (LT) and the impact on LT outcomes depends directly on the percentage of macrosteatosis.

However, the quantification of steatosis by frozen-section histological evaluation is not a reliable technique, and is often unavailable at night for logistical issues. Non-invasive imaging techniques are poorly correlated with permanent sections, so that decision for graft acceptance finally rests with the surgeon, by gross appearance. The goal of our study was to prospectively validate a non-invasive (=contact-free) pocket spectrometer (PS) giving an extemporaneous estimation of macrosteatosis and to ensure that we could obtain a reliable estimation.

Method: We evaluated a commercial PS (SCIO) never assessed for medical use. The gold standard for steatosis evaluation was the permanent section analysis. The PS communicated with a smartphone (Bluetooth connection) connected to internet (online database). A first stage (S1) of calibration was performed on 35 livers (macrosteatosis from 0% to 60%) and an algorithm was created, allowing a correlation between the estimation and the known values of graft steatosis. Then a second stage (S2) was carried out on 60 grafts (new cohort) during the procurement or after revascularization in the recipient to test the accuracy of the algorithm. The PS was placed at a distance <1.5 cm from the perfused liver (37°C).

Results: The algorithm established after S1 reached a coefficient of determination R2 = 0.811. The validation of this algorithm (S2) showed a Lin's concordance correlation coefficient of 0.89. After the creation of clinically relevant ranges of steatosis (0–20%, 21–40%, 41–60%), the Kappa score evaluating the inter-tests variability (pathologists vs PS) was of 0.77 ($p < 0.0001$). The liver graft weight, the donor body mass index and the scannographic liver-to-spleen attenuation ratio did not predict the macrosteatosis ($r < 0.5$).

Conclusion: Our study demonstrates that a PS allows a reliable and reproducible assessment of liver graft macrosteatosis. Its low cost and the immediacy of results may provide great value-added decision support, particularly when procurements are performed by unknown surgeons, to get an objective evaluation. This tool may avoid the travel of the surgical team in case of steatotic grafts, and avoid the prolonged cold ischaemia required by pathological examination in case of (potentially) marginal graft.

PS-044

Effect of longitudinal exposure to tacrolimus on chronic kidney disease occurrence at one year post liver transplantation

P. Maurel[1], V. Loustaud-Ratti[1], P. Carrier[1], E. Marie[1], A. Rousseau[2], M. Debette-Gratien[1], C. Silvain[3], X. Causse[4], L. Barbier[5], A. Prémaud[6], E. Salamé[5]. *[1]CHU Dupuytren, Limoges, France; [2]INSERM UMR 850, Limoges, France; [3]CHU la Miletrie, Poitiers; [4]CHU La Source, La Source, France; [5]CHU Trousseau, Chambray-Lès-Tours, France; [6]INSERM UMR 850, Limoges*
Email: paul_23_88@hotmail.fr

Background and Aims: Renal failure during the first year post-liver transplantation (LT) is predictive of mortality and increases health care costs. The nephrotoxic effects of calcineurin inhibitors are a major concern. Our aim was to study the relationship between tacrolimus (TAC) exposure and the risk of chronic kidney disease (CKD) in the first year post-LT.

Method: Retrospective data of consecutive patients transplanted in a single French Center (Tours University hospital, France as part of university hospital federation or FHU SUPORT) between 2011 and 2016 were collected. A joint model for longitudinal and time-to-event data were developed, using mixed effects models, to simultaneously analyse longitudinal exposure to tacrolimus (described using repeated residual concentrations) and risk of CKD within the first year post-LT. CKD was defined as a calculated glomerular filtration rate (eGFR) below 60 mL/minute/1.73 m2 (MDRD-4 formula), during three consecutive months. The effect of longitudinal exposure to tacrolimus, pre- and post-LT factors were investigated as potential predictors of CKD before M12 post-LT.

Results: Among 355 LT patients, 180 patients were studied after exclusion of LT for Acute Liver Failure, pré-LT dialysis, double kidney-LT and patients not receiving tacrolimus. CKD-free survival at one year was 74.5% and was not associated with tacrolimus longitudinal exposure within the observed exposure ranges. Pre-LT acute kidney injury (AKI) and post-LT eGFR at one month (<60 vs. ≥60 ml/min/1,73 m²) were statistically significant predictors of the hazard of CKD. By identifying two status within AKI, hepatorenal syndrome (HSR)-AKI and non HRS-AKI, only HRS-AKI remained predictive of CKD. HSR-AKI and eGFR at M1 under 60 ml/min significantly increased the risk of CKD (HR = 2.8; 95% confidence interval (CI):1.3–5.8 and HR = 4.4; 95%CI: 2.3–8.8, respectively).

Conclusion: Within the observed ranges of residual concentrations, the tacrolimus exposure was not significantly associated with post-LT CKD. This result is not so surprising as the different target concentrations of tacrolimus according to the post-LT delay are now well-defined and were respected in our population. On the other hand, HRS, classically considered as reversible, appears to be a key predictive factor of post-LT CKD, and the definition of non-reversibility criteria will be a new challenge.

PS-045

Donor specific antibodies after liver transplantation-still an underestimated risk?

K. Willuweit[1], A. Frey[1], P. Lisa[1], A. Heinold[2], P.A. Horn[2], G. Gerken[1], K. Herzer[1]. *[1]Department of Gastroenterology and Hepatology, Essen, [2]Institute for Transfusion Medicine*
Email: kerstin.herzer@uk-essen.de

Background and Aims: There is an ongoing controversy about the importance of donor specific antibodies (DSA), their prevalence and consequences for graft and patient survival after liver transplant (LT). Relative importance of antibody specificity and their strength (mean fluorescence intensity, MFI) remains to be elucidated. This analysis addresses the association of DSA with complications after LT and the relevance of antibody (AB) subspecies as well as MFI level.

Methods: Clinical and demographic data of 430 LT recipients were collected who are registered for aftercare at the LT unit of the University Hospital Essen. Antibody detection was performed using Luminex single antigen beads and a MFI value of more than 500 was considered positive. Statistical significance was analyzed by chi-quadrat test with Pearson approximation. A p-value less than 0.05 was considered statistically significant.

Results: Among all patients, 18.8% (81/430) were positive for DSA. Of these 81.5% (66/81) were HLA class II AB and 14.8% (12/81) HLA class I AB. HLA class II AB show a higher MFI (mean 4900 (600–20,600)) compared to HLA class I AB (mean XX (500–20,200)). Patients who developed DSA experienced more complications after LT (75.3%, 61/81) compared to DSA negative patients (72.8%, 254/349, $p = 0.67$). Cirrhosis after LT occurred significant more often in DSA positive patients than in patients without detectable DSA (18.5 vs. 8.8%, $p \leq 0.027$). Of the DSA positive patients 10% (8/81) developed de novo autoimmune hepatitis (dnAIH) while in DSA negative patients dnAIH occurred in only 4.3% (15/349, $p = 0.055$). Acute rejections (AR) were experienced by 24.7% (20/81) of the DSA positive patients compared to 16.6% (58/349, $p = 0.076$) of the DSA negative patients. We observed no significant difference in the frequency of complications with regard to either HLA class. Of HLA class II AB 50.1% (35/69) with an MFI >5,000 (p = ns) developed complications.

Conclusion: Patients who develop DSA after LT have a higher risk to experience complications withcirrhosis, dnAIH and AR being the most relevant. In particular, high-level HLA class II AB can be a predictor for complications. Therefore, detection of DSA and regular monitoring is important to maintain graft quality and survival. Furthermore, to specify risk factors for DSA development can influence the management of immunosuppression in order to prevent graft damage.

PS-046

Severe histological injury of common bile ducts in donation after circulatory death liver transplantation

F. Tinti[1,2], I. Umbro[1,2], S.G. Hubscher[3], J. Isaac[4], P. Onori[2], A. Franchitto[2], E. Gaudio[2], P. Muiesan[5], A.P. Mitterhofer[1]. *[1]Sapienza University of Rome, Department of Clinical Medicine, Nephrology Unit, Rome, Italy; [2]Sapienza University of Rome, Department of Anatomical, Histological, Forensic Medicine and Orthopedics Sciences, Rome, Italy; [3]Queen Elizabeth Hospital, University Hospitals Birmingham NHS Foundation Trust, Department of Cellular Pathology, Birmingham; [4]Queen Elizabeth Hospital, University Hospitals Birmingham NHS Foundation Trust, Liver Unit, Birmingham, United Kingdom; [5]Queen Elizabeth Hospital, University Hospitals Birmingham NHS Foundation Trust, Liver Unit, Birmingham, United Kingdom*
Email: francesca.tinti@uniroma1.it

Background and Aims: Within the model of donation after circulatory death (DCD), a more severe degree of ischaemia-reperfusion injury (IRI) is occurring, that seems to play a role on the pathogenesis of biliary complications.
Aim of the study was to assess the bile duct injury occurring in two different models of ischaemia, DCD and donation after brain death (DBD), in liver transplanted grafts.
Method: Bile duct injury was evaluated on histological samples of common bile duct retrieved after liver graft reperfusion, before biliary anastomosis.
Severity of donor bile duct injury was assessed and scored on the basis of Biliary epithelial cell loss, Mural stroma necrosis, Inflammation, Peribiliary vascular plexus damage, Arteriolonecrosis, Thrombosis, Periluminal and deep peribiliary glands damage.
Cholangiocyte apoptosis in periluminal and peribiliary glands was evaluated by quantitative terminal deoxy-nucleotidyl transferase dUTP-mediated nick-end labeling (TUNEL) analysis and cholangiocyte proliferation was studied by PCNA immunohistochemical expression in bile duct sections.
Results: Sixty-two patients had the bile duct sample available for histological evaluation (2014–2015). A significantly higher number of DCD patients presented necrosis >50% of the bile duct wall [DCD 14/28 (50%), DBD 9/34 (26.5%) p = 0.056], peribiliary vascular plexus damage [DCD 8/28 (29%), DBD 3/34 (9%); p = 0.053] and periluminal peribiliary gland damage [DCD 20/28 (71%), DBD 14/34 (41%); p = 0.016], defining the occurrence of severe histological injury, that was significantly more frequent in DCD liver transplant patients [15/28 (53.6%)] compared to DBD [7/34 (20.6%)] (p = 0.007). A significant increased apoptosis and decreased proliferation was evidenced in both periluminal (Tunel p = 0.029; PCNA p = 0.029) and deep PBGs (Tunel p = 0.002; PCNA p = 0.006) from bile duct sample with severe *histological injury.*
Conclusion: This study shows the early picture of microscopic damage at the level of the bile duct soon after reperfusion of liver graft during transplantation. Bile duct samples from DCD grafts expressed more severe injury at the histological level, defining the new feature of *severe histological injury*. Bile ducts with *severe histological injury* showed increased apoptosis and reduced proliferation as evaluated by Tunel assay and PCNA expression, both on periluminal and deep PBG. This study raises the hypothesis of a correlation between the occurrence of microscopic damage and the development of ischaemic biliary complications.
This study was supported by the ESOT Grant 2017.

PS-047

Prevalence of subclinical histological lesions and tolerance biomarkers in long-term adult liver transplant recipients considered for immunosuppression withdrawal

A. Sanchez-Fueyo[1], A. Douiri[1], M. Elstad[1], E. Kodela[1], J. Wall[1], E.B. Riani[2], G. Alexander[3], A. Marshall[4], M. Navasa[5], J. Ferguson[6], K.J. Simpson[7], A. Pascher[8], E. Jaeckel[9], P. Tachtatzis[10], F. Nevens[11], S. Masson[12]. *[1]King's College London, Institute of Liver Studies, London, United Kingdom; [2]Cliniques universitaires Saint-Luc, Woluwe-Saint-Lambert, Belgium; [3]Addenbrooke's Hospital, United Kingdom; [4]Royal Free Hospital, United Kingdom; [5]Hospital Clínic, Barcelona, Spain; [6]Queen Elizabeth Hospital, United Kingdom; [7]Royal Infirmary, United Kingdom; [8]Charité – Universitätsmedizin Berlin, Berlin, Germany; [9]Medizinische Hochschule Hannover, Hannover, Germany; [10]Leeds Teaching Hospitals NHS Trust, United Kingdom; [11]Leuven; [12]Hepatology, Newcastle*
Email: sanchez_fueyo@kcl.ac.uk

Background and Aims: LIFT is a multi-national prospective randomized controlled trial of immunosuppression withdrawal in adult liver transplantation initiated in 2015 in which a liver tissue transcriptional biomarker of tolerance is employed to stratify patients prior to immunosuppression weaning. Eligibility criteria, derived from a previous multi-center trial in which immunosuppression was successfully withdrawn in 40% of participants (Benitez et al. Hepatology 2013), include: >3 years post-transplant, normal liver function, no autoimmune or replicative viral liver disease, and absence of significant inflammatory/fibrotic lesions in a screening liver biopsy. We report here on the applicability of the trial and the estimated prevalence of operational tolerance.
Method: Between November 2015 and October 2017, 463 patients were screened and 127 were consented to participate in the trial and undergo a screening liver biopsy. Two central pathologists reviewed all biopsies. RNA was extracted from a cryopreserved portion of the biopsy cylinder and employed to assess the transcript levels of a previously described 5-gene signature of spontaneous operational tolerance (*IFNG, MIF, TFRC, CDHR2, PEBP1*).
Results: 108 biopsies were available for review: 59 met histological eligibility and 49 did not. In non-eligible patients the most frequent histological abnormalities were portal inflammation (74%), portal vein endotheliitis (49%), interface hepatitis (43%), bile duct lesions (43%), and fibrosis (75%; Ishak ≥3 in 20%). These abnormalities resulted in non-eligible patients exhibiting higher liver stiffness than those who were eligible (FibroScan 7 kPa versus 4; p = 0.001), despite being no differences in liver function tests between them. At the time of inclusion eligible patients were older (mean 62 years versus 58; p = 0.04), had a shorter post-transplant follow-up (mean 9.5 versus 11.3 years; p = 0.04), had higher Tacrolimus trough levels (mean 4.2 ng/mL versus 3.4; p = 0.04), and were more likely to have been transplanted for alcoholic liver disease (32% versus 14%; p = 0.03), than non-eligible patients. Overall 36% of patients had a positive biomarker profile (39% of eligible and 33% of non-eligible). Among the non-eligible group there were no significant differences between biomarker-positive and –negative patients.
Conclusion: A large proportion of adult stable liver transplant recipients exhibit potentially significant subclinical histological abnormalities. As a result, only a small proportion of them are eligible to participate in an immunosuppression withdrawal trial. Among patients meeting eligibility criteria, the proportion displaying a positive biomarker profile closely matches the estimated prevalence of operational tolerance.

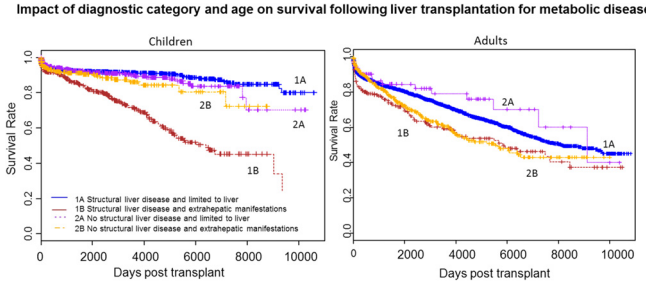
30 years of liver transplantation for metabolic disease in the United States

P. Mckiernan[1], J.E. Squires[1], R. Squires[2], G. Vockley[2], G.V. Mazariegos[3], Q. Sun[3], K. Soltys[3], A. Ganoza[3], R. Sindhi[3]. *[1]Children's Hospital of Pittsburgh, Division of Gastroenterology Hepatology and Nutrition, Pittsburgh, United States; [2]Children's Hospital of Pittsburgh, Division of medical genetics, Pittsburgh; [3]Children's Hospital of Pittsburgh, The Starzl Transplant Institute*
Email: patrick.mckiernan@chp.edu

Background and Aims: The indications for liver transplantation (LT) in metabolic disease (met) evolve as long-term outcomes are appreciated and new options develop. We reviewed the US experience with primary LT for metabolic disease in the Scientific Registry for Transplant Recipients (SRTR October 1987 to June 2017) to determine: (1) changes in indications with time, (2) long-term outcomes, and 3. factors predicting survival.
Method: Subjects were grouped by whether or not the primary defect caused structural liver disease (SLD) [categories 1 or 2 respectively] and whether or not the primary defect was confined to the liver [A or B respectively]. This resulted in 4 diagnostic categories. Indications and outcomes were compared over 3 consecutive 10 year eras, 1–3. Chi-square, t-test or Wilcoxon rank sum test were used as appropriate. Kaplan-Meier analysis or Cox proportional hazards were used to compare survivals.
Results: 6,048 underwent LT for met, 2406 [39.8%] being children. Compared to era 1, LT for met nearly doubled by era 3, from 603 to 1044 in children, and from 759 to 1617 among adults. Children experienced a six-fold increase in LT for non-SLD met in children, from 91/603 (15.1%) LT in era 1 to 578/1044 (55.4%) LT in era 3 ($p < 0.001$). Indications for LT remained relatively stable in adults. Living donor LT increased with eras from 5.6% to 7.6% in children, and 0–4.5% in adults. Fewer living donor LT were utilized in children with met compared with all other pediatric LT in the study period (179/1044, 7.6%, vs 1640/14125, 11.6%, $p < 0.001$). LT combined with transplantation of other organs was undertaken in 179/2406 children (8%) and 394/3642 (12%) adults ($p = 0.0001$) and was associated with reduced 10-year survival in children (87 vs 76%, $p < 0.001$) but not in adults (68% vs 62%, $p = 0.22$).
Outcomes improved with time. Latest 5-year patient survival were 94.4 and 81.5% in children and adults respectively, $p < 0.01$. Outcomes were worse in adults and in those with extrahepatic disease ($p < 0.01$, Figure] while SLD did not affect outcome. On multivariate analysis diagnostic category, inpatient status and transplant era significantly predicted outcome in all ages, with age at LT a predictor in adults and gender in childhood.



Conclusion: LT is increasingly utilized for phenotypic disease correction in children with excellent longterm survival.
Extrahepatic manifestations significantly impact longterm survival following LT for met at all ages.

NAFLD: Experimental and pathophysiology

PS-049

Acceleration of NASH in a mouse model provides novel insights on the mechanisms by which I148M PNPLA3 drives steatohepatitis

B. Banini[1], S. Cazanave[1,2], H.-K. Min[1], D. Kumar[1], P. Santhekadur[1], L. Wang[3,4], H.-P. Guan[3,5], M. Seneshaw[6], P. Bedossa[7], A. Oseini[6], F. Mirshahi[1], C. Alonso[8], S. Koduru[9], A. Sanyal[6]. *[1]Virginia Commonwealth University; [2]Glympse Bio, North Cambridge, United States; [3]MERCK Research Laboratories; [4]Morphic Therapeutic, Waltham, United States; [5]Quixgen Inc, New Brunswick, United States; [6]Virginia Commonwealth University, Richmond, United States; [7]Hôpitaux de Paris, Beaujon Hospital, Paris, France; [8]OWL Metabolomics, Parque Tecnológico de Bizkaia, Derio, Spain; [9]Pennsylvania State University, College of Medicine, Division of Plastic Surgery, Hershey, United States*
Email: arun.sanyal@vcuhealth.org

Background and Aims: The mechanisms by which $I^{148}M$ PNPLA3 mutation leads to NASH are unclear. The Diet-Induced Animal Model of NAFLD (DIAMOND) mouse develops steatosis and steatohepatitis with fibrosis after 4 and 16 weeks, respectively, on a Western diet (WD). The purpose of this study was to accelerate development of NASH in DIAMOND mice by liver-specific adenovirus-associated vector (AAV) delivery of human wild type (WT) or mutant (MT) PNPLA3 and to elucidate the underlying mechanisms.
Method: Three groups of mice, AAV-luciferase empty vector (AAV-LUC), AAV-WT and AAV-MT received chow diet (CD) or WD for 8 wks. Histology, gene (qPCR), protein (Western blot), lipidomic and transcriptomic (RNA seq) analyses were performed. ANOVA, chi-square for trend and Fisher Exact test were used for comparisons between groups.
Results: *Histology*: *All mice fed WD showed similar weight gain, insulin resistance and dyslipidemia regardless of AAV group. However, AAV-MT fed WD showed increased liver to body weight ratio when compared to all other groups, as well as increased ALT. On CD, all three groups had normal histology. On WD, AAV-LUC and AAV-WT both developed NAFL but AAV-WT had significantly less steatosis, triglyceride (TG) and diacylglycerol (DAG) than AAV-LUC ($p < 0.05$). NASH with fibrosis developed in 82% of AAV-MT mice compared to 35% of AAV-WT and 7% of AAV-LUC ($p < 0.01$ for all). *Lipidomics*: AAV-MT on WD (vs CD) had higher FFA, DAG, TG, ceramides, free cholesterol and multiple inflammatory eicosanoids (8-, 11-, 12-, 15-HETE) ($p < 0.05$); only DAG and eicosanoids were increased in AAV-MT vs AAV-LUC on WD. *Transcriptomics*: AAV-WT (vs AAV-LUC) on WD induced pathways related to inflammation. AAV-MT (vs AAV-WT) led to further activation of inflammatory pathways (multiple TLRs, CD14 and STAT3), as well as activation of LXR, FXR and mTOR. Metacore network analysis identified inflammation-innate immunity, iron transport and chemotaxis as the top pathways altered in AAV-MT compared to AAV-WT. *Cell-signaling*: Lipid metabolic targets increased in all groups on WD (ACC, FAS). ER stress markers (eif2α, ATF4, CHOP, GRP78, XBP-1) were significantly increased along with ASK1, p38MAPK and JNK in AAV-MT vs other groups on WD. Fibrogenic (procollagen 1, α-SMA) and oncogenic (pSTAT3/T705) signals were increased only in AAV-MT.
Conclusion: $I^{148}M$ PNPLA3 induces accumulation of multiple lipids and induces ER stress with inflammatory-fibrotic signaling to induce NASH with fibrosis.

Craig Venter Institute, Human Biology;* [5]*University of California, Medicine, Gastroenterology, San Diego;* [6]*University of California at San Diego, Division of Gastroenterology, Department of Medicine, San Diego, United States*
Email: ccaussy@ucsd.edu

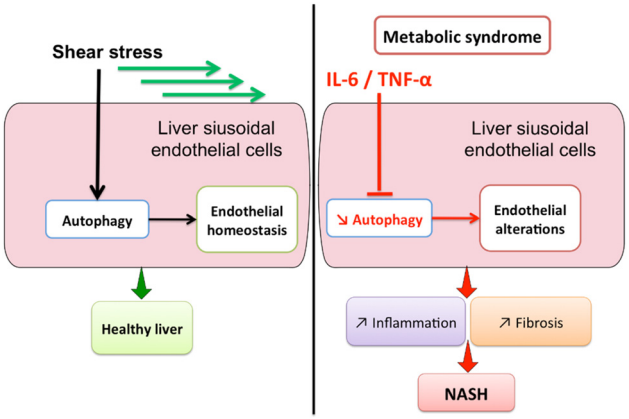
Background and Aims: Previous studies have shown that gut-microbiome is associated with NAFLD. We aimed to examine if serum metabolites especially those derived from the gut-microbiome have a shared gene-effect with hepatic steatosis and fibrosis.
Method: This is a cross-sectional analysis of a prospective discovery cohort including 156 well-characterized community-dwelling twins and families residing in Southern California with untargeted metabolome profiling assessment. Hepatic steatosis was assessed using magnetic-resonance-imaging proton-density-fat-fraction (MRI-PDFF) and fibrosis using MR-elastography (MRE). A twin AE model was used to estimate the shared gene-effect between metabolites and hepatic steatosis and fibrosis. The findings were validated in an independent prospective validation cohort of 156 participants with biopsy-proven NAFLD including shotgun metagenomics sequencing assessment in a subgroup of the cohort.
Results: The mean (±sd) age and BMI of the *discovery* cohort were 46.3 (±19.8) years and 26.6 (±6.0) kg/m2, respectively, and 36 subjects (23%) had NAFLD (MRI-PDFF ≥ 5%) and 28 subjects (18%) had hepatic fibrosis (MRE > 3 kPa). In the *discovery* cohort, 56 metabolites including 6 microbial metabolites had a significant shared gene-effect with both hepatic steatosis and fibrosis after adjustment for age, sex and ethnicity. In the *validation* cohort 6 metabolites were associated with advanced fibrosis. Among them, only one microbial metabolite, 3-(4-hydroxyphenyl)lactate, remained consistent and statistically significantly associated with liver fibrosis in the *discovery* and *validation* cohort (fold-change of higher-MRE versus lower-MRE:1.78,p < 0.001 and of advanced versus no advanced fibrosis:1.26, p = 0.037, respectively). The share genetic determination of 3-(4-hydroxyphenyl)lactate with hepatic steatosis was R_G:0.57,95%CI:0.27–0.80, p < 0.001 and with fibrosis was R_G:0.54,95%CI:0.036–1,p = 0.036. Pathway reconstruction linked 3-(4-hydroxyphenyl)lactate to several human gut-microbiome species. In the *validation* cohort, 3-(4-hydroxyphenyl)lactate was significantly correlated with the abundance of several gut-microbiome species including species previously reported as associated with advanced fibrosis.
Conclusion: Gut-microbiome-derived metabolite 3-(4-hydroxyphenyl)lactate shares gene-effect with hepatic steatosis and fibrosis and may be a biomarker of the severity of NAFLD.

PS-051

Defective autophagy in liver sinusoidal endothelial cells promotes non alcoholic steatohepatitis and fibrosis development

A. Hammoutene[1,2], J. Lasselin[1,2], A.-C. Vion[1,2], N. Colnot[3,4], V. Paradis[3,4,5], S. Lotersztajn[4,5], C. Boulanger[1,2], P.-E. Rautou[1,2,4,6]. [1]*INSERM U970, Paris Cardiovascular Research Center – PARCC, Paris, France;* [2]*Université Paris Descartes, Sorbonne Paris Cité, UMR-S970, Paris, France;* [3]*Service d'Anatomie Pathologique, Hôpital Beaujon, Assistance Publique-Hôpitaux de Paris, Clichy, France;* [4]*Université Denis Diderot-Paris 7, Sorbonne Paris Cité, Paris, France;* [5]*UMR 1149 INSERM, Inflammation Research Center, Paris, France;* [6]*Service d'Hépatologie, DHU Unity, Hôpital Beaujon, Assistance Publique-Hôpitaux de Paris, Clichy, France*
Email: amsadel@hotmail.com

Background and Aims: Autophagy is a cellular conserved process involved in the degradation of dysfunctional material. Nothing is known about the role of autophagy in liver sinusoidal endothelial cells (LSECs) in chronic liver diseases. Our aim was to analyze the potential implication of autophagy in LSECs in non-alcoholic steatohepatitis (NASH) and fibrosis.
Method: (a) Human samples: We quantified autophagic vacuoles in LSECs from patient without liver histological abnormalities, with simple steatosis or with NASH. **(b) Cultured LSECs:** We analyzed autophagic flux in transformed liver sinusoidal endothelial cells (TSECs) exposed to shear stress using chloroquine. We then tested the effect of IL-6, TNFα, MCP-1 and insulin (at concentrations present in the portal venous blood of patients with NASH) on autophagy in TSECs. **(c) Transgenic mice:** We analyzed the effect of a defect in endothelial autophagy on early stages of NASH, by using *Atg5$^{lox/lox}$-VECadherinCre^{+}* or *Atg7$^{lox/lox}$-VECadherinCre^{+}* mice, fed a high fat diet (HFD) for 16 weeks, and on advanced stages of liver fibrosis by treating *Atg5$^{lox/lox}$-VECadherinCre^{+}* mice with CCL4 (6 weeks).



Results: (a) Human samples: LSECs from patients with NASH contained twice less autophagic vacuoles than LSECs from patients without liver histological abnormalities or from patients with simple steatosis. **(b) Cultured LSECs:** TSECs exposed to shear stress exhibited an effective autophagic flux. IL-6 and TNFα decreased autophagy level (LC3II/GAPDH) in TSECs, but MCP-1 and insulin had no effect. **(c) Transgenic mice:** Compared to littermate controls, mice deficient in endothelial ATG5 fed a HFD had a more frequent nodular liver surface, a higher liver expression of inflammatory genes (*Mcp-1* and *Rantes*) and more liver fibrosis (increased liver gene expression of *Collagen1α2* and *Tgfβ1* and more Picrosirius staining). Similar results were obtained with mice deficient in ATG7 in endothelial cells. Mice deficient in ATG5 in endothelial cells treated with CCL4 had more liver fibrosis (more liver *Collagen1α2* and *Tgfβ1* mRNA, more Picrosirius staining).
Conclusion: Autophagy is defective in LSECs of patients with NASH. IL-6 and TNFα present in the portal blood of patients with NASH could be responsible for this defect. Autophagy defect in LSECs contributes to the development of liver inflammation and fibrosis at early and advanced stages of the disease. Stimulating endothelial autophagy could be an attractive strategy for NASH treatment.

PS-052

Modelling non-alcoholic fatty liver disease using human induced pluripotent stem cells

C.M. Morell[1], S. Tilson[1], M. Perrin[1], T. Gieseck[1], I. Geti[1], C. Rimland[1], F. Sampaziotis[1], L. Vallier[1,2]. [1]*Wellcome Trust – MRC Cambridge Stem Cell Institute, Surgery, United Kingdom;* [2]*Wellcome Trust Sanger Institute, United Kingdom*
Email: cmm94@cam.ac.uk

Background and Aims: The incidence of non-alcoholic fatty liver disease (NAFLD) in the western world has strongly increased in recent

years, while therapeutic interventions remain limited to liver transplant for end stage disease. Our understanding on NAFLD pathogenesis remains elusive due to the lack of a suitable tool to faithfully recapitulate the human pathology. Indeed, growing primary hepatic cells remains difficult while currently available culture systems do not capture tissue organization and cellular diversity. human Induced Pluripotent Stem Cells (hIPSC) provide an advantageous opportunity, since they retain the ability to self-renew and to differentiate into liver cells. Here, we aimed to take advantage of this unique system by developing a novel *in vitro* platform for NAFLD modeling that mimics the hepatic architecture by reproducing its multicellularity.

Method: We generated hepatocytes, cholangiocytes and macrophages from hIPSC, while the LX2 cell line was used to model stellate cells. The hepatic microenvironment was reproduced by co-culturing the cells in a 3D collagen matrix, taking advantage of fluorescent reporter cell lines to monitor cellular interactions. For each cell type, gene expression analyses, immunofluorescence and biochemical assays were performed to monitor key functions and markers. Free fatty acids were used to induce NAFLD phenotype.

Results: In the 3D environment, hepatocyte like cells (HLC) retained the expression of typical hepatocyte markers and functions, and their maturation improved with time in culture. Cholangiocytes preserved their biliary identity in the collagen matrix, while LX2 cells did not show an activated phenotype. Similarly, macrophage polarization was not influenced by the 3D environment. Interestingly, HLC spontaneously arranged around biliary structures without losing their functionality, while LX2 established contacts with HLC only after TGFβ treatment. Fatty acids treatment led to steatosis and lipotoxicity in HLC, and also interfered with CYP3A4 activity. The presence of non-parenchymal cells sustained fatty acid-induced hepatocyte damage.

Conclusion: Different hepatic cell types can be co-cultured in our novel 3D platform to model pathophysiological cellular interactions. We were able to mimic the mechanisms of hepatocytes steatosis and lipotoxicity, including the inflammatory and fibrotic response associated with NAFLD progression. Thus, our system represents an important step forward to model NAFLD *in vitro*.

PS-053

NLRP6 Inflammasome-mediated intestinal dysbiosis drives steatohepatitis and promotes HCC progression

K. Schneider[1], A. Mohs[1], L.S. Candels[1], C. Elfers[1], L. Lijun[1], V. Bieghs[1], E. Latz[2,3], I. Bergheim[4], T. Strowig[5], C. Trautwein[6]. [1]*University Hospital RWTH Aachen, Department of Medicine III, Aachen, Germany;* [2]*University Hospital Bonn, Institute of Innate Immunity, Bonn, Germany;* [3]*University of Massachusetts Medical School, Department of Infectious Diseases and Immunology, Worcester;* [4]*University Vienna, Department of Nutritional Sciences, Vienna, Austria;* [5]*Helmholtz Centre for Infection Research, Microbial Immune Regulation Research Group, Braunschweig, Germany;* [6]*University Hospital RWTH Aachen, Department of Medicine III, Aachen, Germany*
Email: kai.markus.schneider@gmail.com

Background and Aims: Today, the link between intestinal dysbiosis and chronic liver disease has been well established. However, the role of intestinal microbiota in HCC development remains incompletely understood. Here, we hypothesized that Nlrp6 mediated intestinal dysbiosis may impact hepatic inflammation and HCC development.

Method: Hepatocyte-specific NEMO/IKKγ knockout mice ($NEMO^{\Delta hepa}$) were used as a model of experimental steatohepatitis. Disease progression in $NEMO^{\Delta hepa}$ mice was monitored in different hygienic/microbiota environments of our animal facility. Additionally, $Nemo^{\Delta hepa}$ mice were crossed with Nlrp6 knockout ($Nlrp6^{-/-}$) animals. Here the impact of intestinal dysbiosis on innate and adaptive immune response during progression of steatohepatitis towards HCC was studied. Finally, microbiota modulation was performed using treatment with broad-spectrum antibiotics (AB).

Results: $NEMO^{\Delta hepa}$ mice displayed striking differences in disease activity depending on the microbiota environment as evidenced by significantly elevated liver functions tests (LFTs) and tumor burden in the less restrictive area of our animal facility. In line, intestinal dysbiosis in $NEMO^{\Delta hepa}/Nlrp6^{-/-}$ mice was associated with more pronounced steatohepatitis encompassing elevated LFTs, leukocyte infiltration and apoptotic cell death, ultimately leading to aberrant hepatocyte proliferation and increased tumor burden in 52 weeks old $NEMO^{\Delta hepa}/Nlrp6^{-/-}$ mice. Interestingly, $NEMO^{\Delta hepa}/Nlrp6^{-/-}$ mice displayed an impaired gut barrier function assessed by intestinal tight junction and mucus expression, which was followed by a more pronounced innate immune response and infiltration of monocyte derived macrophages (MoMFs) in 52 weeks old $NEMO^{\Delta hepa}/Nlrp6^{-/-}$ compared to $NEMO^{\Delta hepa}$ mice. Interestingly, CD8+ cytotoxic T-cells were already suppressed at an early 13 weeks timepoint in livers of $NEMO^{\Delta hepa}/Nlrp6^{-/-}$ compared to $NEMO^{\Delta hepa}$ mice, indicating that Nlrp6-mediated intestinal dysbiosis may negatively affect antitumor immunity. Strikingly, depletion of the intestinal microbiota by administration of broad-spectrum antibiotics suppressed inflammatory cell infiltration and ameliorated steatohepatitis by promoting a restorative $Ly6C^{low}$ phenotype of hepatic macrophages.

Conclusion: Nlrp6-mediated intestinal dysbiosis promotes steatohepatitis progression and HCC development by shaping the hepatic inflammatory microenvironment. Microbiota modulation holds therapeutic potential for preventing liver disease progression.

PS-054

Serum bile acids alteration is associated with the presence of NAFLD in twins, and dose-dependent changes with increase in fibrosis stage in patients with biopsy-proven NAFLD

C. Caussy[1,2], C. Hsu[1], S. Seema[1], B. Shirin[1], K. James[1], C. Faulkner[1], R. Bettencourt[1], M. Valasek[3], L. Richards[1], B. David[1,4], R. Loomba[1,4,5]. [1]*University of California, NAFLD Research Center, San Diego;* [2]*University Lyon 1, Hospices Civils de Lyon;* [3]*University of California, Pathology, San Diego;* [4]*University of California, Medicine, Gastroenterology, San Diego;* [5]*University of California, Division of Epidemiology, Department of Family and Preventive Medicine, San Diego*
Email: ccaussy@ucsd.edu

Background and Aims: Bile acids (BA) alteration has been reported in patients with NAFLD. Data characterizing alteration in BA in the entire spectrum of NAFLD are limited. We aimed to assess serum BA level in twins with and without NAFLD, and then examine its association with stage of fibrosis and presence of NASH in patients with biopsy-proven NAFLD.

Method: This is a cross-sectional analysis of 2 prospective cohorts: a Twin and Family cohort of 156 participants assessed using MRI-PDFF, and a biopsy-proven NAFLD cohort of 156 participants using NASH CRN Histologic Scoring System. The serum level of 22 BA using LC/MS was assessed by Metabolon Inc. Differences between BA were assessed using Welch t test and Kruskal-Wallis test.

Results: In the Twin and Family cohort (mean age 46.3 yrs, 73.1% women), 23% of the subjects had NAFLD (MRI-PDFF ≥ 5%). The mean levels of 3 primary BAs and 1 secondary BA was significantly higher in NAFLD versus non-NAFLD controls including glycocholate (GCA), taurocholate (TCA), taurochenodeoxycholate (TCDCA), and ursodeoxycholate (UDCA) with fold-changes of 2.36, p = 0.046; 5.25, p = 0.02; 4.08, p = 0.03; 1.34, p = 0.002 respectively. The mean level of 2 secondary BAs were significantly lower in NAFLD versus non-NAFLD controls including glycohyocholate (GHCA) and 3b-Hydroxy-5-cholenoic acid (3beta-OH-delta 5) with fold-changes of 0.62, p = 0.004 and 0.7, p = 0.002 respectively.

In the biopsy-proven NAFLD cohort (mean age 49.8 yrs, 58.3% women), the distribution of stage 0, 1, 2, 3 and 4 fibrosis was 42.3%, 32.7%, 10.3%, 8.3%, and 6.4%, respectively; 13.0% of individuals had NAFL, 11.7% had borderline NASH and 75.3% had definite NASH. No significant differences in BA profile were seen between NAFL versus NASH. The level of primary BAs GCA, TCA, TCDA,

glycochenodeoxycholate (GCDCA) and tauro-beta-muricholate (TβMCA) was higher in fibrosis stage ≥2, ≥3 and ≥4 Figure 1. In addition, TCA and TβMCA levels increased across all stages of fibrosis (p = 0.004, and 0.001, respectively). The level of secondary BAs was higher in fibrosis stage ≥2 for Glycolithocholate (GLCA), GLCA sulfate, and taurideoxycholate (TDCA); in fibrosis stage ≥3 and ≥4 for GHCA and glycoursodeoxycholate (GUDCA); and in fibrosis stage ≥4 for tauroursodeoxycholate (TUDCA) Figure.

		Fold-change in fibrosis stage			
		F1-4 vs 0	F2-4 vs 0-1	F3-4 vs 0-2	F4 vs 0-3
Primary	Cholate (CA)	0.91	1.03	0.91	0.23*
	Glycocholate (GCA)	1.58	2.99**	3.83***	5.1**
	Glycochenodeoxycholate (GCDCA)	1.62	2.86*	4.07***	6.1**
	Taurochenodeoxycholate (TCDCA)	4.3	8.62**	11.22**	20.07**
	Taurocholate (TCA)	2.74*	5.73***	7.27**	12.17**
	Tauro-beta-muricholate (TβMCA)	4.57*	9.15***	8.13**	3.67*
Secondary	Glycolithocholate (GLCA)	1.95	2.91*	4.00	5.82
	Glycolithocholate sulfate(GLCAS)	1.31	1.66*	1.95	1.73
	Taurodeoxycholate (TDCA)	1.94	3.66*	3.09	3.61
	Glycohyocholate (GHCA)	1.7	3.4	5.48*	9.62*
	Glycoursodeoxycholate (GUDCA)	0.91	1.53	1.65*	2.41*
	Tauroursodeoxycholate (TUDCA)	2.17	4.69	4.04	8.33*

Figure 1: Serum BAs differences across fibrosis stage in biopsy-proven NAFLD.

Conclusion: Serum bile acid profile alterations are seen across the entire spectrum of NAFLD. Serum bile acid profiles did not differ significantly between NAFL versus NASH but were significantly perturbed in higher stages of fibrosis and especially in cirrhosis.
Fold change of BAs level across the dichotomized stage of fibrosis, *p < 0.05, ** p < 0.01, ***p < 0.001.

PS-055
Down-regulation of hepatic MBOAT7 by hyperinsulinemia favors steatosis development

M. Meroni[1,2], P. Dongiovanni[3], M. Longo[1], R. Rametta[4], S. Badiali[5], S. Fargion[1,2], S. Romeo[6], S. Gatti[7], L. Valenti[1,2]. *[1]University of Milan, Department of Pathophysiology and Transplantation, Milan, Italy; [2]Fondazione IRCCS Cà Granda, Internal Medicine, Milan, Italy; [3]Fondazione IRCCS Cà Granda, Milano; University of Milan, Italy, Internal Medicine, Milano, Italy; [4]Fondazione IRCCS Cà Granda, University of Milan, Italy, Internal Medicine, Italy; [5]Fondazione IRCCS Cà Granda, Surgery, Milan, Italy; [6]University of Gothenburg, Department of Molecular and Clinical Medicine, Sweden; [7]Fondazione IRCCS Cà Granda, Center for Surgical Research, Milan, Italy*
Email: luca.valenti@unimi.it

Background and Aims: We have recently shown that the rs641738 C > T variant in Membrane bound O-acyltransferase domain-containing 7 gene (MBOAT7), involved in phosphatidylinositol acyl-chain remodeling, increases the risk of developing nonalcoholic fatty liver disease (NAFLD), inflammation and fibrosis due to lower protein expression. Aim of this study was to evaluate the regulation of hepatic MBOAT7 and the impact on hepatic fat accumulation.
Methods: We examined hepatic MBOAT7 in 119 obese patients and in experimental models. We silenced hepatic MBOAT7 by i.v. administration of antisense oligonucleotides modified by morpholinos (MPO) for 4 consecutive days in C57Bl/6 male mice (n = 5) and in HepG2 cell lines, using the Crispr/Cas9 technology.
Results: In obese patients, hepatic mRNA levels of MBOAT7 progressively decreased from normal liver to simple steatosis and NASH (p < 0.05). At multivariate analysis, type 2 diabetes (p < 0.05), necroinflammation (p < 0.01) and MBOAT7 genotype (p < 0.01) were independently associated with MBOAT7 downregulation (Table 1). The mRNA and protein levels of MBOAT7 were reduced in experimental models of NAFLD, such as the methionine-choline deficient diet, but more so in genetically obese *ob/ob* mice and in insulin resistant mice with Insulin receptor haploinsufficiency, characterized by development of hyperinsulinemia (p < 0.05). Furthermore, in wild-type male mice MBOAT7 was downregulated by refeeding or by i.p. injections of insulin concomitantly with the rise of insulin levels and activation of hepatic insulin signaling through PI3K and AKT. Insulin (300 nM) downregulated MBOAT7 in primary mouse hepatocytes in a InsR/PI3Kinase/FoxO1 dependent manner. Finally, MPO induced a 45% silencing of hepatic MBOAT7 comparable to that associated with the genetic risk variant, resulting in a 80% increase in hepatic triglyceride content (p < 0.05 *vs* scramble) and in the development of microvesicular steatosis, related to enhanced expression of fatty acids transporters. Consistently, MBOAT7 knock-out cell lines developed spontaneously steatosis (p < 0.05).

Table 1:

	Estimate SE	*P* value
Age, years	−0.00±0.01	0.98
Sex, F	−0.07±0.09	0.43
BMI, Kg/m^2	+0.00±0.01	0.87
T2DM, yes	−0.16±0.08	0.04*
Steatosis	−0.02±0.07	0.84
Necroinflammation	−0.31±0.11	0.005*
PNPLA3, I148M alleles	−0.04±0.09	0.66
MBOAT7, T alleles	−0.25±0.08	0.004*

Conclusion: These data suggest that hyperinsulinemia causes down-regulation of hepatic MBOAT7, which both genetic and experimental data indicate is causally implicated in steatosis development. Further studies are needed to investigate the mechanisms linking reduced phosphatidyl-inositol desaturation by MBOAT7 with the development of steatosis and hepatic inflammation.

PS-056
NLRP3 inflammasome activation in hepatocytes results in pyroptotic cell death, release of NLRP3 particles and liver fibrosis

S. Schuster[1], F.A. Guerra[2], C.D. Johnson[1], C.J. Calvente[1], D. Povero[1], A. Eguchi[3], M.D. Mcgeough[1], H.M. Hoffman[1], P. Pelegrin[4], A. Feldstein[1]. *[1]University of California San Diego, Department of Pediatrics, San Diego, United States; [2]University of Valencia, Department of Pharmacology, Valencia, Spain; [3]Mie University, Department of Gastroenterology and Hepatology, Mie, Japan; [4]Hospital Universitario Virgen de la Arrixaca, Departamento de Cirugía, Murcia, Spain*
Email: suschuster@ucsd.edu

Background and Aims: Pyroptosis is a form of programmed cell death initiated by inflammasomes and characterized by Caspase-1 activation and pore formation in the cell membrane. Global NLRP3 inflammasome activation is sufficient to induce liver inflammation and fibrosis. Here, we tested the hypothesis that hepatocytes undergo pyroptosis upon NLRP3 inflammasome activation with subsequent release of NLRP3 particles that amplify and perpetuate inflammasome-driven fibrogenesis.
Method: In order to test the direct effects of persistent NLRP3 activation, we generated a hepatocyte-specific *Nlrp3* mutant mice strain (L351P *Nlrp3*^{KI}CreA) with constitutively activated NLRP3. Pyroptosis was assessed *ex vivo* in primary hepatocytes isolated from *Nlrp3*^{KI}CreA mice using FAM-FLICA Caspase-1/Propidium iodide (PI) assay. Liver fibrosis development and hepatic stellate cell (HSC) activation was studied in *Nlrp3*^{KI}CreA mice using Sirius red and alpha-SMA staining and qPCR analysis. HepG2 cells were incubated with LPS + Nigericin (Nig) or Palmitic acid (PA). AC-YVAD-AOM was used as an irreversible inhibitor of Caspase-1. LX2 cells were stimulated with ASC-YFP specks released from transfected HepG2 cells treated with LPS + Nig/PA or NLRP3-YFP speck particles isolated from a stable NLRP3 (p.D303N)-YFP hyperactive mutant HEK cell line to study endocytosis capability. NLRP3 particle uptake was analysed by confocal microscopy and immunoblot analysis.

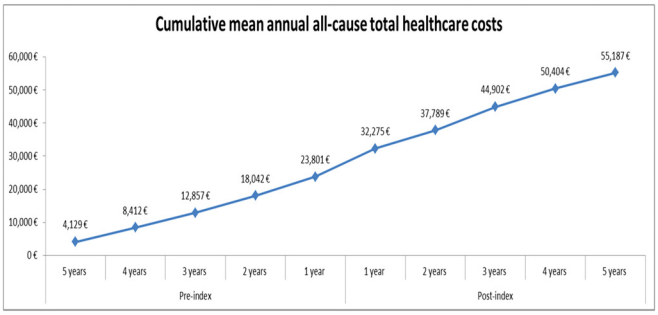
Results: Primary hepatocytes isolated from *Nlrp3*^{KI}CreA showed marked increase in pyroptotic cell death and Caspase-1 activation compared to WT control (5-fold, $p < 0.001$). Further, *Nlrp3*^{KI}CreA mice showed increased activation of HSCs (*Timp1:* 3.4-fold, *Fibronectin1:* 1.8-fold, $p < 0.05$) and liver fibrosis as assessed by morphometric quantitation of Sirius red and alpha-SMA staining (1.9-and 1.5-fold, $p < 0.05$). HepG2 cells incubated with LPS + Nig and LPS + PA showed increased Caspase-1 activation and pyroptosis as well as Caspase-1-dependent increased cell membrane permeability. Immunoblot analysis of HepG2 supernatant demonstrated the release of NLRP3 inflammasome components (NLRP3, ASC, pro-Caspase-1, pro-IL-1beta) including the activated form of Caspase-1 and mature form of IL-1beta. Further, our results revealed that LX2 cells are able to engulf ASC-YFP and NLRP3-YFP particles released from transfected HepG2 cells after pyroptosis induction or isolated from NLRP3 (p. D303N) mutant HEK cells, respectively.
Conclusion: Inflammasome activation in hepatocytes induces Caspase1-dependent pyroptosis and the release of NLRP3 inflammasome particles that are efficiently engulfed by HSC. Mice with hepatocyte-specific NLRP3 overactivation showed HSC activation and liver fibrosis demonstrating a novel crosstalk between hepatocytes and HSC. This represents a novel mechanism to propagate liver injury and liver fibrosis development.

Public health: General

PS-057
Substantial comorbidities and rising economic burden in real-world non-alcoholic fatty liver disease (NAFLD)/non-alcoholic steatohepatitis (NASH) patients with compensated cirrhosis (CC): A large German claims database study

A. Canbay[1], D. Meise[2], J.S. Haas[2]. [1]*Department of Gastroenterology, Hepatology and Infectiology, University of Magdeburg Medical School, Magdeburg, Germany;* [2]*Xcenda GmbH, Hannover, Germany*
Email: ali.canbay@med.ovgu.de

Background and Aims: NAFLD/NASH is a common cause of CC in Western countries and CC is associated with increased morbidity and mortality. However, Germany-specific data is lacking. This study examined the comorbidities, mortality and health care costs among German NALFD/NASH patients once they develop CC.
Method: Patients aged ≥18 years with a NAFLD/NASH diagnosis (ICD-10-GM) between 2011 and 2016 were identified retrospectively from the InGef research claims database with about 4 million insurees. They were followed from first NAFLD/NASH diagnosis and flagged as CC patients at the first occurrence of a CC diagnosis, which identified the index date. Patients were excluded if they had <1 year of continuous enrolment (CE) pre-index and post-index, and if they presented with hepatitis, Wilson's disease, Gaucher disease, LAL-D, alcoholism incl. alcoholic liver disease, HIV, primary biliary cholangitis, primary sclerosing cholangitis or hemochromatosis. Further, progression to decompensation, hepatocellular carcinoma and liver transplant in the post-index period was not allowed. All-cause mortality was investigated within 1 year of post-index period. Mean annual costs were also examined for patient subsets with 1–5 years of CE pre-index and post-index.
Results: The study population included 555 NAFLD/NASH patients with CC having 1 year of CE pre-index and post-index. Mean age was 66.1 years and 57.3% were males. In the post-index period, 7.6% of the patients deceased. The most common comorbidities were hypertension, diabetes, and dyslipidemia with annual pre-index prevalence rates of 76.6%, 53%, and 49.2%, respectively. 555 NAFLD/NASH patients with CC cumulated €4,702,927 in 1-year post-index time period. The annual all-cause healthcare costs averaged €5,759 in the pre-index period and €8,474 in the post-index period (+47%) ($p < 0.001$). The cost driver was the inpatient setting representing 41.3% in the pre-index and 57.1% in the post-index period. Cumulative mean annual all-cause healthcare costs increased 132% over a 5-year period, from €23,801 (1-year pre-index) to €55,187 (5-year post-index).



Conclusion: German NAFLD/NASH patients with CC have a high comorbidity burden. Healthcare costs are the highest in the first year following CC diagnosis with inpatient costs as the primary driver. Cumulative mean annual all-cause costs increased 132% over a 5-year period. Novel treatment options are needed to improve patient outcomes.

PS-058
Early versus delayed hepatitis C treatment provides increased health benefits at lower costs: A pan-genotypic cost effectiveness analysis set in Scotland

B. Pinsky[1], D. Mitchell[2], Y. Sanchez[1], S. Johnson[2], S. Sammy[3]. [1]*Abbvie Inc, HEOR, North Chicago, United States;* [2]*Medicus Economics LLC, Boston, United States;* [3]*UCLA, David Geffen School of Medicine, Los Angeles, United States*
Email: brett.pinsky@abbvie.com

Background and Aims: As hepatitis C virus-(HCV) infected patients who achieve sustained virologic response from advanced liver disease states continue to face an excess risk of liver-related and extrahepatic complications, treatment in early disease states is believed to increase health benefits and reduce downstream medical costs. This study considers both liver-related and extrahepatic complications to assess the cost-effectiveness of treating HCV patients across all genotypes at different fibrosis stages in Scotland.
Method: A health state transition model of the natural history of HCV was developed to forecast liver-related and economic outcomes over a lifetime horizon. The model population and mITT efficacy rates were based on clinical trials of glecaprevir (identified by AbbVie and Enanta) and pibrentasvir. Genotype and fibrosis distribution were identified from UK patient tracker data. Costs in UK pounds were based on systematic literature review. Comparative analyses were conducted for treatment in different fibrosis stages of liver disease: mild (F0–F1); moderate (F2–F3), and compensated cirrhosis (F4/CC). Health outcomes included lifetime risks of liver decompensation (DCC), hepatocellular carcinoma (HCC), liver transplantation (LT), and liver-related death (LrD). Other outcomes included lifetime costs post-treatment and quality-adjusted life years (QALYs), both discounted at a 3.5% rate.
Results: Lower rates of DCC, HCC, LT, and LrD were predicted in HCV patients when treatment was initiated in mild vs. CC disease (DCC: 4.0% vs. 11.6%; HCC: 1.8% vs. 35.2%; LT: 0.4% vs. 2.6%; LrD: 3.8% vs. 41.1%). While only considering the liver-related complications, early vs delayed treatment resulted in lower lifetime costs (mild: £30,719; moderate: £33,055; CC: £59,137) and greater lifetime QALYs (mild: 16.20; moderate: 13.86; CC: 10.05). When extrahepatic manifestations (EHMs) are considered, lifetime costs increased (mild: £33,297; moderate: £35,402; CC: £61,204).

Table: (abstract: PS-058)

	Decompensated cirrhosis	Liver cancer	Liver transplant	Liver-related mortality	Lifetime costs (including EHMs)	Lifetime QALYs
Genotypes 1-6						
Mild (F0-F1)	4.0%	1.8%	0.4%	3.8%	£33,297	16.20
Moderate (F2-F3)	8.9%	4.0%	1.0%	9.1%	£35,402	13.86
CC (F4)	11.6%	35.2%	2.6%	41.1%	£61,204	10.05

Conclusion: Delay of HCV treatment for higher fibrosis stages resulted in increased lifetime risks of liver-related morbidity and mortality, greater lifetime costs, and lower QALYs regardless of genotype. The magnitude of this impact increases when costs associated with EHMs of HCV are considered. Treatment at earlier fibrosis stages is a cost-effective and dominant strategy (more QALYs gained at a lower cost) compared to treatment at later stages.

PS-059

Outbreak of acute hepatitis A involving young men in Lombardy Region, Italy: risk factors, clinical and virological characteristics

Email: pietro.lampertico@unimi.it

Background and Aims: Hepatitis A virus (HAV) is transmitted mainly via the faecal-oral route and/or contaminated aliments. In last decades, several outbreaks of HAV in men who have sex with men (MSM) classified HAV as a sexually transmitted disease (STD). We aimed to analyse an ongoing HAV outbreak among a large group of young MSM adults from 7 hospitals in Lombardy region in Italy with respect to patients' characteristics and viral phylogenetic analysis.
Methods: We prospectively analysed 244 cases of acute HAV between January and May 2017 recording for all patients' demographics data, risk factors, presenting symptoms, sexual orientation, co-morbidities and further STD infections. The phylogenetic correlation of the current circulating viruses among them and other HAV strains was assessed by sequencing of the VP1/2A region.
Results: Most patients were male (230, 94%) with median age 33 years (range 18–76). One hundred and thirty-three (55%) were MSM, 17% had a chronic liver disease, 19% were HIV positive, 5% were active drug users, 63% referred a possible sexual contact in last 3 months and 18% with a HAV positive partner. One hundred and eighty-one (74%) required hospitalization (median stay 7 days, range 2–44). The median ALT and bilirubin peak levels were 2,368 (47–8,914)IU/ml and 6.6 (0.4–18)mg/dl, respectively. No liver transplant was needed. Molecular phylogenetic analyses revealed that 93% (197/211) patients were infected by HAV genotype IA and 7% (14/197) by genotype IB. Moreover, all genotype IA cases belong to one of the three separate cluster recently reported in a multi-country European outbreak: 59% (117/197) of cases were infected with UK-strain, 40% (79/197) with Netherlands-strain and 1% (1/197) with Germany-strain. Interestingly, the cases infected with Netherlands strain were prevalent at the beginning of the outbreak (January 100%), while the UK-strain increased in the last months (May 68%, June 70%).
Conclusions: Ongoing HAV in Lombardy primarily affects young MSM and is phylogenetically linked to current HAV outbreaks described in other European countries. Due to the high admission rate, these outbreaks may impact the admission pattern of referral Liver and Infectious Units. Control measures, i.e. vaccinations programs tailored to the MSM community, must be taken to control further spreading.

PS-060

Food insecurity increases the risk of advanced fibrosis in diabetics with nonalcoholic fatty liver disease

R. Rosenblatt[1], A. Buckholz[2], G. Ghosh[2], A. Jesudian[1], C. Lucero[1], R. Schwartz[1], B. Fortune[1], S. Kumar[1]. *[1]New York Presbyterian Hospital – Weill Cornell Medicine, Division of Gastroenterology and Hepatology, New York, United States; [2]New York Presbyterian Hospital – Weill Cornell Medicine, Department of Medicine, New York, United States*
Email: RussellRosenblatt@gmail.com

Background and Aims: Nonalcoholic fatty liver disease (NAFLD) is a leading cause of liver disease in developed nations. Outcomes in NAFLD are directly related to the stage of fibrosis, with an increased risk of overall and liver-related mortality with increasing stage. Diabetes, obesity, and age are well-established risk factors of advanced fibrosis in NAFLD, while there has been less investigation into the impact of economic factors. Patients with food insecurity have been found to have increased risk of both obesity and diabetes, related to lack of choice of food. This study aims to investigate the impact of food insecurity on advanced fibrosis in diabetics with NAFLD a nationally-representative survey.
Method: The National Health and Nutrition Examination Survey (NHANES), a nationally-representative survey, from 2005 to 2014 was

used. Using a validated algorithm, adult patients with diabetes were included. Patients were excluded if they had viral hepatitis, excessive alcohol consumption, were pregnant, or had transaminase elevation >500 IU/l. Advanced fibrosis was diagnosed based on the presence of an ALT > 40 and either an elevated NAFLD fibrosis score, FIB-4 score, or AST to platelet ratio index. The degree of food security was evaluated based on a validated survey included in the NHANES survey. Multivariate logistic regression was performed to evaluate for the presence of advanced fibrosis, and factors were included into the model if they independently increased the risk of advanced fibrosis.
Results: A total of 14,169,411 weighted participants were included in the sample. Most (77.0%) patients had full food security (FFS) while 6.2% had very low food security. Patients with very low food security (VLFS) were younger and more likely to be black and Hispanic. Those with VLFS also had a higher mean body mass index and mean hemoglobin A1c but had no significant differences in transaminase levels. When controlling for age, gender, race, insulin dependence, hemoglobin A1c, body mass index, and duration of diabetes, patients with VLFS had a significantly higher odds of advanced fibrosis (OR 3.34, 95% CI 1.29–8.62, p = 0.01).

Table: Risk of advanced fibrosis by food security level

Food security	OR (95% CI)	p-value
Fully food secure	REF	
Mild food insecurity	1.95 (0.91–4.20)	0.131
Low food security	1.22 (0.49–3.02)	0.75
Very low food security	3.34 (1.29–8.62)	0.01

*Controlling for age, gender, race, body mass index, diabetes duration, insulin dependence, and hemoglobin a1c.

Conclusion: In our study using a nationally-representative survey, VLFS more than tripled a diabetic patient's risk of having advanced fibrosis when controlling for other factors that can independently increase the risk of advanced fibrosis. This study highlights the importance of accounting for economic factors when evaluating patients with NAFLD.

PS-061

Cost-effectiveness analysis of hepatocellular carcinoma screening in hepatitis C cirrhosis after sustained viral response

H.F. Zangneh[1], W.W. Wong[2], B. Sander[3], C.C. Bell[4], K. Mumtaz[5], M. Kowgier[6], A. Van der Meer[6], S.P. Cleary[7], H. Janssen[8], K.K. Chan[9], J. Feld[1]. *[1]University of Toronto, Toronto General Hospital, Toronto Centre for Liver Disease, Toronto, Canada; [2]University of Toronto, School of Pharmacy, Toronto, Canada; [3]University of Toronto, Institute of Health Policy, Management and Evaluation, Canada; [4]University of Toronto, Department of Medicine, Toronto, Canada; [5]Ohio State University, Wexner Medical Center, United States; [6]Erasmus MC University Medical Center, Rotterdam, Netherlands; [7]University of Toronto, Department of Surgery, Toronto, Canada; [8]University Health Network, Toronto, Canada; [9]University of Toronto, Sunnybrook Odette Cancer Centre, Toronto, Canada*
Email: hooman.f.zangneh@mail.utoronto.ca

Background and Aims: Hepatitis C virus-related cirrhosis is strongly associated with hepatocellular carcinoma (HCC) development. After sustained virological response (SVR), the HCC risk in cirrhosis is reduced but not eliminated. Recent developments in direct antiviral agents (DAA) have increased SVR rates even in cirrhosis. HCC screening in cirrhotic patients is cost-effective before treatment; it is unknown whether it remains so after SVR.
Method: We made a Markov model to evaluate the cost-effectiveness of biannual or annual ultrasound (US) screening versus no screening in 50-year-old cirrhotic patients post-SVR. Parameter values were taken from the literature and expert opinion if unavailable. Primary outcomes are quality-adjusted life-year (QALY), cost and incremental cost-effectiveness ratio (ICER). Costs & QALYs were discounted at 5%/year.
Results: With 0.5% constant annual HCC incidence in F3 or F4 patients, biannual & annual screening provide extra 0.164 QALYs (ICER $84242/QALY) and 0.148 QALYs (ICER $53756/QALY), respectively. More recent data show the annual HCC incidence in patients with HCV-related cirrhosis post DAA-induced SVR to be as high as 1.82% which makes biannual HCC screening likely to be cost-effective (ICER $40803/QALY). Incidence has also been reported based on pre-treatment AST to platelet ratio index (APRI). With APRI < 2, the annual HCC incidence is 0.093% meaning that biannual US screening is dominated (ICER -$1024982/QALY). With APRI > 2, even without documented cirrhosis, the annual HCC incidence is 0.892% leading to an ICER of $55916/QALY for biannual screening. Some data suggest that HCC incidence increases, even after SVR, as patients age. With age-stratified HCC incidence, biannual & annual screening offered 0.466 QALYs (ICER $44170/QALY) and 0.396 QALYs (ICER $31549/QALY), respectively. Sensitivity analyses identified HCC incidence and transition rate to symptomatic disease in unscreened population as main drivers of the model.
Conclusion: For biannual US screening to be cost-effective in the post-SVR population, the constant annual HCC incidence must be above 1.1%, lower than the previous 1.5% threshold. With F3 fibrosis or pre-treatment APRI < 2, screening is very unlikely to be cost-effective, challenging current clinical practice guidelines. For cirrhotic patients, biannual or annual US screening is likely cost-effective post-SVR, mainly if HCC risk increases with age. Further data will hopefully allow for improved risk stratification to guide optimal screening strategies.

PS-062

Prevalence and explanatory factors for liver function testing and abnormality in a population-based study of children and young people

W. Li[1], K. Homer[2], K. Boomla[2], J. Robson[2], S. Hull[2], W. Alazawi[1]. *[1]The Blizard Institute, Queen Mary University of London, London, United Kingdom; [2]Centre of Primary Care and Public Health, Queen Mary University of London, London, United Kingdom*
Email: wenhao.li@doctors.org.uk

Background and Aims: Abnormal liver biochemistry is associated with increased liver- and all-cause mortality. Most studies have focussed on older adults and not children and young people (CYP) in whom obesity rates (among other liver risk factors) are rising. We determined the prevalence and explanatory factors of liver biochemistry testing and abnormal results in primary care records for CYP in an ethnically and socially diverse population.
Method: This was a retrospective study using routinely collected primary care electronic healthcare records in 150 contiguous practices in four boroughs in East London, UK. We extracted social and demographic data for all CYP aged 10–25 years who had had liver biochemistry requested between 2015–2017. Alanine transferase (ALT) was used to represent liver biochemistry requests and results. Abnormal ALT was defined as >40 U/l for both sexes. Body mass index (BMI) category thresholds were adjusted for ethnicity.
Results: In 257,746 CYP in East London, 14.1% had ALT measured within the study period. 7% of all ALT tests were abnormal. Valid BMI was captured in 84,574 individuals and the proportion of CYP classed as overweight or obese was 36%.
On multivariate analysis, factors independently associated with ALT testing included South Asian ethnicity (adjusted OR 1.76, p = 0.001, in 18–25 age group) and overweight/obese BMI categories (adjusted OR 1.15, p = 0.0001, in 18–25 age group). ALT testing was strongly associated with patients with known liver disease or those taking medication associated with liver abnormalities, albeit these were small numbers.
The same risk factors were independently associated with an abnormal high ALT result; in particular, South Asian ethnicity (adjusted OR 1.59, p = 0.001) and overweight/obese BMI (adjusted

OR 2.94, p = 0.0001). Individuals who had had an alcohol assessment completed, irrespective of the result, were protected against abnormal ALT (adjusted OR 0.77, p = 0.001).
Conclusion: In the largest population-based study of liver function testing in CYP to date, we show that a significant proportion of CYP have ALT requested and have elevated results. We have not studied abnormalities in AST or GGT, nor applied the Prati thresholds to ALT. Our data may indicate that brief alcohol-related interventions are protective. Apart from patients with prior knowledge or suspicion of liver disease, raised BMI category and ethnicity are significant factors in CYP for abnormal liver test results.

PS-063
Cases of transfusion-transmitted hepatitis E Virus infections at a tertiary referral center

D. Westhölter[1], H. Jens[2], J. Hartl[1], D. Ulrike[2], P. Sven[2], A. Francis[3], R. Meike[4], A.W. Lohse[1], M. Lutgehetmann[5], S. Pischke[1]. *[1]I. Medical Clinic, University Medical Center Hamburg-Eppendorf, University Medical Center Hamburg-Eppendorf; [4]University Heart Center, University Medical Center Hamburg-Eppendorf, University Medical Center Hamburg-Eppendorf; [5]Institute of Medical Microbiology, University Medical Center Hamburg-Eppendorf, University Medical Center Hamburg-Eppendorf*
Email: d.westhoelter@uke.de

Background and Aims: Hepatitis E is a major threat for immunosuppressed patients, as chronic HEV infection with possibly life-threatening complications might occur. The relevance of blood borne hepatitis E virus (HEV) infections for these patients has been discussed controversially within the last months and still requires further investigations.
Methods: All immunosuppressed patients at our center with an HEV infection between 2011 and 2017 were retrospectively studied (n = 37). All blood products given to chronically HEV infected patients were retrospectively analyzed for the presence of HEV RNA by in-house realtime PCR (LLoD 12 IU/ml).
Results: 11 immunosuppressed patients (11/37, 30%) developed chronic HEV infection. In 4/11 (36%) we were able to identify an HEV positive blood donation as source of HEV transmission. Interestingly two of the chronic HEV infected patients, who were infected by blood-borne transmission, were heart transplant recipients. Both had been treated with a combination of plasmapheresis and rituximab for humoral rejection. As these cases attracted our attention to this proceeding, we tested the remaining 3 heart transplant recipients who were treated according to the same protocol at our center within the last 5 years but none of them had acquired persistent HEV infection.
Conclusions: Blood products are a relevant source of HEV-infection for immunosuppressed individuals and in our series they are responsible for 36% of chronic HEV infections. Thus, we recommend screening of all blood products given to transplant or immunosuppressed recipients for HEV-RNA.

PS-064
Analysis of the influence of alcohol abstinence on the risk of developing hepatocellular carcinoma (HCC) in patients with alcoholic liver cirrhosis (ALC)

A. Castano-Garcia, C. Álvarez-Navascués, A. Gomez, M. Varela, M. Fraile, V. Cadahía-Rodrigo, M. Torner, M.L.G. Dieguez, M. Rodríguez. *Hospital Universitario Central de Asturias, Liver Unit. Gastroenterology and Hepatology Department, Oviedo, Spain*
Email: castaogarcia@gmail.com

Background and Aims: Cure of HCV infection and inhibition of HBV replication reduce the risk of developing HCC in patients with HCV and HBV liver cirrhosis. Abstinence is the only treatment of ALC but its effect on the risk of HCC is unknown. To investigate if abstinence reduces HCC risk in a series of patients with ALC.
Method: 602 patients with ALC, Child A/B, included in a HCC surveillance program and prospectively followed every six months were analyzed. 83% were male, mean age 55 ± 8 years, 83% have had previous cirrhosis complications and 79% had varices Abstinence was defined as null alcohol consumption from inclusion. HCC and ALC diagnosis was based on universally accepted criteria. Abstinence during follow up and 13 clinical-biological variables at inclusion were recorded. Usual statistical methods were used.
Results: During a mean follow-up of 77 ± 59 months, 298 patients (49%) remained abstinent and 93 (15,4%) developed HCC, with a mean annual incidence (MAI) of 2.4% and cumulative probability of 23% and 45% at 10 and 20 years. There were no differences in the probability of developing HCC between abstinent (MAI: 2.42%) and non-abstinent patients (MAI: 2.39%) (p = 0.88). In the univariate analysis, variables associated with HCC development were: male sex (p = 0.007), age > 55 years (p = 0.001), platelet count (PTC) <145 × 10^3/mm^3 (p = 0.003), BMI 25–30 (p = 0.002) and AST > 45 UI/l (p = 0.019). Variables associated with risk of HCC in the multivariate analysis were male sex (OR: 2.52; IC95%:1.26–5.05; p = 0.009), age > 55 years (OR: 2.15; IC95%:1.39–3.35; p = 0.001) and PTC < 145 × 103/mm3 (OR:1.94; IC95%:1.11–3.40; p = 0.019). After adjustment with these variables, abstinence was not related with the risk of developing HCC (OR: 0.96; IC95%:0.61–1.49; p = 0.86). In the subgroup of abstinent patients, development of HCC was independently associated with age > 55 (p = 0.038), PTC < 145 × 103/mm3 (p = 0.022) and previous cirrhosis complications (p = 0.048). In non-abstinent patients HCC risk was independently associated with male sex (p = 0.032), age > 55 (p = 0.005) and PTC < 145 × 103/mm3 (p = 0.025).
Conclusion: Alcohol abstinence in patients with Child A/B ALC is not associated with a reduction in the risk of developing HCC. Factors associated with HCC in ALC are sex, age and higher degree of liver dysfunction, and are similar in abstinent and non-abstinent patients. These results show the need of early diagnosis of the illness and of development of effective drugs for HCC prevention.

First real-world data on safety and effectiveness of glecaprevir/pibrentasvir for the treatment of patients with chronic hepatitis C virus infection: Data from the German Hepatitis C-Registry

T. Berg[1], U. Naumann[4], A. Stoehr[5], C. Sick[6], G. Teuber[7], W. Schiffelholz[8], S. Mauss[9], J. Hettinger[3], H. Kleine[3], A. Pangerl[3], C. Niederau[2]. *[1]Clinic of Gastroenterology and Rheumatology, University Hospital Leipzig, Leipzig, Germany; [2]Katholisches Klinikum Oberhausen, St. Josef-Hospital, Klinik für Innere Medizin, Akademisches Lehrkrankenhaus der Universität Duisburg-Essen, Oberhausen, Germany; [3]AbbVie Inc., North Chicago, Illinois, U.S.A; [4]Praxiszentrum Kaiserdamm, Berlin, Germany; [5]IFI Studien und Projekte GmbH, Hamburg, Germany; [6]Praxisonkologie Bremen, Bremen, Germany; [7]Practice PD Dr. med. G. Teuber, Frankfurt am Main, Germany; [8]Gastroenterologische Schwerpunktpraxis, Augsburg, Germany; [9]Center for HIV and Hepatogastroenterology, Düsseldorf, Germany*
Email: thomas.berg@medizin.uni-leipzig.de

Background and Aims: The direct-acting antivirals glecaprevir (an NS3/4A inhibitor discovered by AbbVie and Enanta) coformulated with pibrentasvir (an NS5 inhibitor) are approved to treat chronic hepatitis C virus (HCV) genotype 1–6 infection. Clinical trials demonstrated an overall cure rate of 98% with glecaprevir/pibrentasvir (G/P), but real-world data on this regimen are limited. Here we report real-world effectiveness and safety of G/P within the German Hepatitis C-Registry (DHC-R).

Method: The DHC-R is an ongoing, non-interventional, multicenter, prospective registry study. Data were collected between July 28, 2017 and February 9, 2018 from 104 sites in Germany. Adult patients with HCV genotype 1–6 infection were eligible. The analysis included patients treated with G/P according to the local label for 8, 12 or 16 weeks, with or without compensated cirrhosis, who were either HCV treatment-naïve or treatment-experienced. The primary endpoint is SVR12, assessed in patients who received at least one dose of study drug. Safety and tolerability were assessed.

Results: To date, 866 patients have enrolled; 638 patients who received the regimen according to the label are included in the analysis. The majority of patients were treatment-naïve and without cirrhosis, and thus treated for 8 weeks; Table 1 shows patient baseline demographics. Of the patients with viral load data at the end of treatment, 97% (263/271) had viral suppression. In the modified intention-to-treat population which excludes non-virologic failures, 100% (49/49) achieved SVR12. Four patients discontinued treatment; two of these discontinuations were due to an adverse event (AE) or serious AE. Four serious AEs have occurred; there have been no grade 3 or higher ALT elevations.

Conclusion: In this first real-world data analysis with the G/P regimen, G/P treatment yielded favorable effectiveness and safety results consistent with clinical trial data. Updated data including SVR4 and SVR12 results will be presented.

Acknowledgements: Medical writing support was provided by Zoë Hunter, PhD, of AbbVie and funded by AbbVie.

GS-008

Sustained efficacy of adjuvant immunotherapy with cytokine-induced killer cells for hepatocellular carcinoma: an extended 5-year follow-up

J.-H. Lee[1], J.H. Lee[2], Y.-S. Lim[3], J.E. Yeon[4], T.-J. Song[5], S. Yu[1], K.M. Kim[3], Y.J. Kim[1], J.W. Lee[6], J.-H. Yoon[1]. *[1]Seoul National University College of Medicine, Department of Internal Medicine and Liver Research Institute; [2]Sungkyunkwan University School of Medicine, Department of Medicine, Samsung Medical Center; [3]University of Ulsan College of Medicine, Department of Gastroenterology, Asan Medical Center; [4]Korea University Guro Hospital, The liver cancer; [5]Korea University Ansan Hospital, Department of Surgery; [6]Korea University, Department of Statistics*
Email: yoonjh@snu.ac.kr

Background and Aims: A previous randomized controlled trial demonstrated that adjuvant immunotherapy with cytokine-induced killer (CIK) cells prolonged both recurrence-free and overall survivals of patients with hepatocellular carcinoma (HCC) receiving curative treatment. We aimed to investigated whether the efficacy of CIK cell immunotherapy might be sustained after cessation of repeated transfer of CIK cells.

Method: We performed a follow-up study of our multicenter, randomized trial reported in 2015. We included 226 patients: 114 patients in the immunotherapy group (injection of 6.4×10^9 CIK cells, 16 times during 60 weeks) and 112 patients in the control group (no treatment) after potentially curative treatments for HCC. Among them, 162 patients (89 of the immunotherapy group and 73 of controls) underwent extended follow-up until 60 months after randomization of the last patient. The primary endpoint was recurrence-free survival (RFS); secondary endpoints included overall survival.

Results: The median follow-up duration was 68.5 (interquartile range, 45.0–82.2) months. During follow-up, the immunotherapy group maintained a significantly lower risk of recurrence or death (hazard ratio [HR] with immunotherapy was 0.67; 95% confidence interval [CI], 0.48–0.94; p = 0.009 by one-sided log-rank test). The 5-year RFS rate was 44.8% in the immunotherapy group and 33.1% in the control group. HRs were also lower in the immunotherapy

ELSEVIER

than control group for all-cause death (0.33; 95% CI, 0.15–0.76; p = 0.006).
Conclusion: In patients who underwent curative treatment for HCC, significant gain in recurrence-free and overall survival by adjuvant CIK cell immunotherapy was maintained for over 5 years. ClinicalTrials.gov number: NCT01890291.

GS-009
MGL-3196, a selective thyroid hormone receptor-beta agonist significantly decreases hepatic fat in NASH patients at 12 weeks, the primary endpoint in a 36 week serial liver biopsy study
S. Harrison[1], S. Moussa[2], M. Bashir[3], N. Alkhouri[4], J. Frias[5], S. Baum[6], B. Tetri[7], M. Bansal[8], R. Taub[9]. *[1]Oxford University; [2]University of Arizona for Medical Sciences; [3]Duke University Medical Center; [4]University Texas, San Antonio; [5]University of California San Diego, Endocrinology, San Diego, United States; [6]Florida Atlantic University; [7]St Louis University School of Medicine; [8]Icahn School of Medicine at Mount Sinai; [9]Madrigal Pharmaceuticals*
Email: rebeccataub@yahoo.com

Background and Aims: MGL-3196 is a liver-directed, orally active, highly selective THR-β agonist currently in Phase 2 for treatment of non-alcoholic steatohepatitis (NASH). In Phase 1 studies, 3196 demonstrated rapid reductions in lipids, LDL cholesterol (30%), triglycerides (40–60%), and lipoprotein(a) (Lp(a))(40%). This ongoing Phase 2 study evaluated the primary endpoint, relative reduction in (magnetic resonance imaging – proton density fat fraction) MRI-PDFF, biomarkers and safety in 116 NASH patients at 12 weeks.
Method: MGL-3196-05 (NCT02912260) is a 36 week multicenter, randomized, double-blind, placebo-controlled study in adults with biopsy-confirmed NASH (NAS ≥ 4, F1-F3) and hepatic fat fraction ≥10%, assessed by (MRI-PDFF). Randomized 2:1, MGL-3196 to placebo, patients receive MGL-3196 80mg, or placebo oral, once daily, for 36 weeks. Blinded increase or decrease in dose based on exposure was possible. The primary endpoint, relative reduction in MRI-PDFF, was assessed at 12 weeks, patients continued on treatment blinded, and, at 36 weeks, secondary endpoints were assessed by second liver biopsy and third MRI-PDFF, with ongoing safety and biomarker assessments at 12 and 36 weeks.
Results: Baseline characteristics (mean or %): age, 50.3 years; women, 50.4%; type 2 diabetes, 38.4%; BMI, 35 kg/m^2; Hispanic, 47.2%; mean hepatic fat fraction (FF), 20.2%; NAS 4.9 (44% F2-3). Baseline characteristics were similar among groups. The primary endpoint was met (p < 0.0001, LS mean), with 78 MGL-3196 treated patients demonstrating −36.3% relative and −7.6% absolute change from baseline (CFB) MRI-PDFF: −9.6%, −1.6%, respectively, in 38 placebo patients (median). Forty-seven/78 (60.3%) MGL-3196 treated (6/47 ≥ 5% weight loss) compared with 7/38 (18.4%) placebo treated (5/7 with ≥5% weight loss) demonstrated ≥30% reduction in MRI-PDFF (p < 0.0001). In MGL-3196 treated patients, lipids decreased, LDL-C −12.9, triglycerides −30.1 and Lp(a)−37.5 (% CFB relative to placebo) p < 0.0001; ALT, AST decreased 16.1%,16.2% relative to mean baseline (51.0, 35.7U/l) p < 0.01. Study drug was well-tolerated, AEs were generally mild (85%) or moderate (15%); 3 SAEs occurred and were considered unrelated (study remains blinded). Additional dose/exposure, biomarkers (safety, lipid, inflammatory, fibrosis, multiparametric MRI (subset)) still under analyses will be presented.
Conclusion: MGL-3196 QD for 12 weeks, compared with placebo, significantly decreased hepatic fat in patients with NASH relative to placebo. These combined results suggest that MGL-3196 has beneficial effects in NASH. Histopathologic assessment at 36 weeks will allow for comparison to baseline histology as well as multiple biomarkers (serologic and imaging).

GS-011
Results of a randomised controlled trial of budesonide add-on therapy in patients with primary biliary cholangitis and an incomplete response to ursodeoxycholic acid
G. Hirschfield[1], L. Kupcinskas[2], P. Ott[3], U. Beuers[4], A.M. Bergquist[5], M. Färkkilä[6], M.P. Manns[7], A. Pares[8], U. Spengler[9], R. Greinwald[10], M. Proels[10], R. Poupon[11]. *[1]NIHR Biomedical Research Centre, Centre for Liver Research, University of Birmingham; [2]Lithuanian University of Health Sciences; [3]Aarhus University, Department of Clinical Medicine; [4]Academic Medical Center, University of Amsterdam; [5]Hepatology, Karolinska University Hospital; [6]Clinic of Gastroenterology, Helsinki University Hospital; [7]Dept. of Gastroenterology, Hepatology and Endocrinology, Hannover Medical School, Hannover, Germany; [8]Liver Unit, University of Barcelona; [9]Department of Internal Medicine I, University of Bonn; [10]Research and Development, Falk Pharma; [11]Centre de Recherche Saint-Antoine*
Email: g.hirschfield@bham.ac.uk

Background and Aims: To evaluate the impact of adding budesonide (9 mg/day Budenofalk®) to patients with PBC and inadequate response to UDCA.
Method: Patients were randomised (2:1) to a placebo-controlled, double-blind, multi-centre, clinical trial of 36-months treatment of budesonide, with UDCA (12–16 mg/kg bw/d) maintained. We enrolled patients with histologically confirmed PBC and inflammatory activity according to the Ishak-score, failure to achieve sAP levels < 1.5x upper limit of normal after at least 6 months of UDCA therapy, and high risk of disease progression. The primary efficacy endpoint was the rate of patients with improvement of liver histology with respect to inflammation (an improvement by at least 3 points in the Ishak sum score or no inflammatory activity) and no progression of fibrosis (Ludwig staging), compared to baseline at the individual last patient visit within the study. The study was terminated early due to insufficient recruitment resulting in lack of power.
Results: 90 patients were screened. 62 patients were randomised and 43 patients had paired biopsies available. Baseline data were comparable between treatment groups (mean age 54 years, 97% females, BMI 26.1, mean ALP 341 U/L, mean ALT 72 U/L, mean disease duration of 7.8 years). Mean treatment duration was 25.3 months and 29 patients completed 3 years of treatment. The primary histologic end-point, in an ITT analysis comparing patients with paired biopsies only, was not met (Table 1). The surrogate "serum levels of sAP ≤1.67 ULN and ≥15% decrease and normal total bilirubin" was met by 17/40 (42.5%) and 5/22 (22.7%) patients in BUD and PBO, respectively (P = 0.099). Mean ALP was reduced from 327 U/L to 233 U/L, and mean ALT from 70 U/L to 58 U/L in the BUD group. This compared with no treatment effect in the PBO group: mean ALP changed from 367 to 358 U/L, mean ALT from 76 to 76 U/L. 35% of BUD and 9.1% of PBO treated patients had normalisation of sAP (P = 0.023). Pruritus reported as adverse events occurred in 6/40 (15%) in BUD and 7/22 (31.8%) in PBO. Serious adverse events occurred in 17 patients (10 in the BUD- and 7 in the PBO group). Adverse events were reported in a similar number of patients across groups. Adverse drug reactions were reported for 24 patients (60%) in the BUD- and 8 patients (36%) in the PBO-group.

Table 1: Number/proportion of patients with response (%) (Last observation carried forward)

	BUD (N = 40)	PBO (N = 22)	P values (one-sided)
Improvement of liver histology, paired biopsies only, n/N (%)	11/26 (42.5)	5/17 (29.4)	0.225*
Normalisation of sAP, N (%)	14 (35.0)	2 (9.1)	0.023**

*Cochran–Mantel–Haenszel test.
**Fisher's Exact Test.

Conclusion: Up to 36 months of budesonide add-on therapy to UDCA did not associate with significant improvements in histology in high-

risk patients with PBC. However, clinically meaningful improvements in biochemical markers of disease activity were apparent.

GS-012

Efficacy and Safety of Glecaprevir/Pibrentasvir in Patients with HCV Genotype 5 or 6 Infection: The ENDURANCE-5,6 Study

T. Asselah[1], T. Tran[2], K. Alves[3], T. Nguyen[4], F. Wong[5], A. Mahomed[6], S.G. Lim[7], S. Lee[8], A. Abergel[9], J. Sasadeusz[10], P. Krishnan[3], Z. Zhang[3], A. Pocalla[11], R. Trinh[11], E. Gane[12]. *[1]University Paris Diderot, Hepatology Department, Beaujon Hospital, Clichy, France; [2]Cedars Sinai Medical Center, Los Angeles, United States; [3]AbbVie, Inc., North Chicago, United States; [4]Research and Education, Inc., San Diego, United States; [5]Toronto General Hospital, University of Toronto, Toronto, Canada; [6]University of Witwatersrand, Charlotte Maxeke Johannesburg Academic Hospital, Department of Gastroenterology and Hepatology, Johannesburg, South Africa; [7]National University Health System, Division of Gastroenterology and Hepatology, Singapore; [8]University of Calgary, Canada; [9]CHU Estaing, France; [10]Royal Melbourne Hospital, Melbourne, Australia; [11]AbbVie, Inc., North Chicago; [12]Auckland Clinical Studies, Auckland, New Zealand*
Email: tarik.asselah@aphp.fr

Background and Aims: The pangenotypic direct-acting antivirals (DAAs) glecaprevir (developed by AbbVie and Enanta) coformulated with pibrentasvir (G/P) are approved to treat chronic HCV genotype (GT)1–6 infection. In Phase 2 and 3 studies, G/P achieved high SVR12 rates with no virologic failures in 80 patients with GT5 or 6 infection, leading to an 8-week and 12-week label indication in HCV GT1–6 patients without or with compensated cirrhosis, respectively. To increase the body of data for these genotypes, ENDURANCE-5,6 evaluates patients from countries where GT5 and GT6 are endemic, such as South Africa (GT5), Myanmar and Vietnam (GT6). This study evaluates the efficacy and safety of G/P in patients with chronic HCV GT5 or GT6 infection, with an expanded analysis of GT6 subtype diversity, for which there has been limited clinical trial data for all-oral, DAA-based therapies.

Method: ENDURANCE-5,6 is an ongoing phase 3b, non-randomized, open-label, multicenter study conducted in adults with chronic HCV GT 5 or 6 infection with or without compensated cirrhosis who are HCV treatment-naïve or experienced with interferon (IFN) or pegIFN with or without ribavirin (RBV) or sofosbuvir and RBV with or without pegIFN. G/P (300 mg/120 mg) was orally dosed once-daily for 8 or 12 weeks in patients without or with compensated cirrhosis, respectively. The primary efficacy endpoint was SVR12. Secondary endpoints were on-treatment virologic failure or relapse. Adverse events and clinical laboratory abnormalities were monitored in all patients.

Results: Seventy patients have enrolled to date, 61 and 9 in the 8- and 12-week treatment arms, respectively; 66 have completed treatment. Baseline demographics are shown in Table 1. The SVR4 among patients with available data is 61/62 (98%). One HCV GT6c-l-infected patient with compensated cirrhosis experienced virologic breakthrough at treatment week 12, and one HCV GT5a-infected patient without compensated cirrhosis who achieved SVR4 relapsed at post-treatment week 12. To date, three patients (4%) have experienced treatment-emergent serious adverse events, none of which were related to G/P or led to discontinuation; no Grade 3 alanine aminotransferase elevations have occurred.

Table 1. Baseline Demographics and Disease Characteristics

Characteristic	8-week G/P No Cirrhosis N=61	12-week G/P Cirrhosis N=9
Female, n (%)	36 (59)	4 (44)
Asian, n (%)	38 (62)	5 (56)
Age, median years (range)	57 (24–79)	65 (32–75)
Genotype 5, n (%)	20 (33)	3 (33)
Genotype 6, n (%)	41 (67)	6 (67)
GT6a/6b	19 (31)	1 (11)
GT6c-l	22 (36)	5 (56)
HCV treatment-naive, n (%)	55 (90)	8 (89)
Baseline HCV RNA, median log_{10} IU/mL (range)	6.85 (4.6–7.5)	6.29 (4.9–7.2)

Conclusion: In this ongoing dedicated study, HCV genotype 5- and 6-infected patients without and with compensated cirrhosis treated with G/P for 8 and 12 weeks, respectively, achieved high rates of SVR4. Complete SVR4 data and available SVR12 data will be presented.

Alcoholic liver disease

Alcohol relapse after liver transplantation: impact of a novel risk assessment scoring system

N. Zakeri, D. Chatzidis, L. De Luca, N. Lazaridis, J. Ryan, R. Westbrook, D. Patch, E. Tsochatzis, L. Shepherd. *Sheila Sherlock Liver Unit, UCL Institute for Liver and Digestive Health, Royal Free Hospital, London*
Email: nekisa.zakeri@nhs.net

Background and Aims: Relapse to harmful alcohol intake following liver transplantation (LT) for alcohol-related chronic liver disease (ALD) is reported in 10–33% of patients, however no consistent predictive factors have been shown. We evaluated the predictive ability of demographic, psychosocial and addiction-related variables to determine relapse risk, both in isolation and in conjunction as a novel risk assessment scoring system; we assessed the impact of relapse on post-LT survival.

Method: Consecutive patients (n = 187) with a history of alcohol excess who underwent LT in a tertiary centre (2004–2013) were included. Demographic variables, alcohol history, substance misuse, psychiatric comorbidities and family alcohol dependence were recorded. The Relative Risk Factors for Relapse (RRFR) score consists of abstinence history, dependence diagnosis, acceptance of diagnosis, willingness to engage in treatment, social network, drug misuse, and replacement activities, and has a numerical scale of 0–27, higher values indicating greater relapse risk. Relapse outcomes, 1-year, 3-year and 5-year survival after LT were evaluated.

Results: Patients were predominantly male (87%), mean age 54 ± 7 years, mean MELD score 15.7 ± 5.8. Mean follow-up was 6.7 ± 3.2 years. 21% remained abstinent, with a high rate of slips (66%) and few lapses (4%). Relapse to harmful alcohol intake occurred in 8% of patients (15/187). In univariate analysis, age at LT ($p = 0.002$), units of alcohol per week ($p = 0.007$), past alcohol treatment ($p = 0.05$) and total RRFR score ($p = 0.03$), were associated with relapse. Multivariate logistic regression revealed younger age at LT as the only independent predictor of relapse (48 ± 7 vs. 54 ± 7 years, $p = 0.015$). 1-year, 3-year and 5-year survival after LT was 92%, 90% and 84% respectively, compared to European Liver Transplant Registry survival rates of 84%, 78% and 73%. Relapse did not have a significant effect on survival.

Conclusion: The low rate of relapse to harmful alcohol intake and high survival rate in our cohort compares favourably to published literature. Younger recipient age was the only independent predictor for relapse identified. Comprehensive pre-assessment incorporating addiction and psychosocial assessment within the RRFR score might have contributed to better patient selection and improved outcomes. Further study is required to validate criteria for relapse risk stratification to assist LT selection in patients with previous alcohol excess.

PS-066

Alcohol disrupts a meta-organismal endocrine axis in murine models and patients with AH

J. Mark Brown[1], R.N. Helsley[1], S. Marshall[1], A. Kim[2], L. Nagy[2]. *[1]Cleveland Clinic, Cellular and Molecular Medicine; [2]Cleveland Clinic, Pathobiology*
Email: len2@po.cwru.edu

Background and Aims: Alcoholic liver disease (ALD) comprises a spectrum of disorders and pathologic changes. Alcoholic hepatitis

(AH) is the most severe form of ALD and can develop at any time in the progression of disease. There is mounting evidence that intestinal microbes represent a key transmissible factor promoting inflammatory diseases such as AH. However, the mechanisms by which gut microbiota synergize with excessive alcohol intake to promote AH are largely unknown. The role of specific microbial metabolites to progression of AH is an important, but understudied, area of investigation. One such microbial metabolite, trimethylamine (TMA), is generated by gut microbes and subsequently metabolized by flavin-containing monooxygenase 3 (FMO3) in the liver to produce trimethylamine-N-oxide (TMAO). TMA activates pro-inflammatory signalling via its G protein coupled receptor Taar5. Here we have investigated whether this meta-organismal endocrine axis promotes ethanol-induced liver injury in mice and is associated with severity of AH in patients.

Method: Female C57BL/6 mice exposed to the chronic Lieber-DeCarli (25 day) liquid diet feeding paradigm or pair-fed control diets or challenged with TMA or saline. Serum and clinical data from a sub-set of 119 patients enrolled in the Defeat Alcoholic Hepatitis (DASH) consortium were analysed. AH patient and control liver samples were obtained from the Clinical Resources in Alcoholic Hepatitis at Johns Hopkins.

Results: Chronic ethanol feeding to mice increased TMA concentration in serum to ~2.5 μM. Serum concentrations of TMA in patients with AH ranged from 1.5–2 μM. Illumina microarray analysis revealed that TMA challenge to mice reorganized expression of both pro-inflammatory and cell death pathways, including changes in expression of a multiple pattern recognition receptor pathways and pro-inflammatory cytokine pathways. Expression of FMO3 protein was decreased in liver of AH patients compared to controls. When AH patients were divided by tertile based on TMAO, there was a significant negative association with MELD. Importantly, survival probability was also associated with TMAO tertile, with the lowest tertile for TMAO predicting a poorer survival probability (40.9%) compared to the high tertile for TMAO (64.8%). Challenge of PBMCs with TMA exacerbated LPS-stimulated cytokine expression in patients with AH, but not controls.

Conclusion: Collectively, data from both murine models of ethanol-induced liver injury and patients with AH suggest that the TMA-FMO3-TMAO axis is dysregulated in AH. Lower hepatic expression of FMO3 in AH was associated with a shift in the TMA/TMAO ratios, likely favoring enhanced inflammatory signaling via TMA. These studies suggest that modulation of microbial synthesis of TMA and/or interruption the pro-inflammatory signalling of TMA on immune cells may be novel therapeutic interventions in AH.

PS-067
Ductular reaction cells display an inflammatory profile and recruit neutrophils in alcoholic hepatitis.

Email: aguilar@clinic.cat

Background and Aims: Alcoholic hepatitis (AH) is characterized by the expansion of ductular reaction (DR), which consists of a heterogeneous population of cells comprising reactive biliary cells and more immature facultative liver progenitor cells (LPCs). The aim of this study was to identify the transcriptomic profile of DR cells and to generate an *in vitro* model to study DR.

Methods: KRT7$^+$, KRT7$^-$ and total liver fractions were laser microdissected from liver biopsies (n = 6) of patients with AH, and the whole transcriptome was sequenced. The gene expression profile was evaluated in AH patients: in liver tissue (n = 40) by qPCR and in serum samples (n = 15) by ELISA. Human LPC organoids were generated from cirrhotic patients (n = 4) and analyzed by microarray, immunofluorescence and qPCR. Organoid-neutrophil crosstalk was assessed by incubating neutrophils with organoids conditioned medium.

Results: Transcriptomic analysis showed that DR presents a pro-inflammatory profile with expression of CXC and CCL chemokines. Gene expression of KRT7 positively correlated with the expression of CXCL1, CXCL3, CXCL5, CXCL6 and CXCL8 cytokines in AH liver tissue. Moreover, serum levels of LPC marker TROP2 correlated with circulating CXCL5 levels. Histologically, DR was associated with neutrophil infiltration at the periportal area, as demonstrated in KRT7-MPO immunofluorescence. To recreate an in vitro model of DR we generated liver organoids from cirrhotic patients, which expressed KRT7 and EpCAM as assessed by immunofluorescence. Transcriptomic analysis of organoids showed high enrichment in genes of the DR transcriptome. Organoid expression of LPC markers and inflammatory cytokines was confirmed by qPCR. Liver organoids produced CXCL5 (11.5 ± 5.6 ng/ml) in culture and stimulation with TNFα, further induced the expression of CXCL1, CXCL2, CXCL5, CXCL6, CCL20 and CCL28 as assessed by qPCR. Moreover, organoid conditioned medium enhanced neutrophils inflammatory profile.

Conclusion: DR in AH patients has a pro-inflammatory profile and is associated with neutrophils infiltration, suggesting the contribution of DR cells in neutrophil recruitment and liver inflammatory response. Human LPC organoids derived from cirrhotic patients mimicked the DR gene expression profile and enhanced neutrophils inflammatory profile, indicating their utility as a model to study DR. These results suggest that targeting LPCs may represent a novel strategy to modulate hepatic inflammatory response.

PS-068
Bile acids and intestinal dysbiosis in alcoholic hepatitis

D. Ciocan[1], C.S. Voican[2,3], L. Wrzosek[3], C. Hugot[3], D. Rainteau[4], L. Humbert[4], A.-M.C. Doulcier[3], G. Perlemuter[2,3]. *[1]INSERM, U 996, Clamart, France; [2]APHP, Hepatogastroenterology and Nutrition, Hôpital Antoine-Béclère, Clamart, France; [3]INSERM, U 996, Clamart, France; [4]INSERM, U1057, Paris, France*
Email: ciocanelro@yahoo.com

Background and Aims: Intestinal microbiota (IM) plays an important role in bile acids (BA) homeostasis, impacts the gut barrier and promotes inflammation. We aimed to study the structure of the IM and its functions in BA homeostasis in alcoholic patients according to the severity of ALD.

Method: In this prospective study, we included 4 groups of active alcoholic patients (N = 109): two non-cirrhotic: without (noAC_noAH, n = 61) or with alcoholic hepatitis (noAC_AH, n = 14) and two cirrhotic: without (AC_noAH, n = 17) or with severe alcoholic hepatitis (AC_sAH, n = 17). Plasma and fecal BA profiles, as well as IM composition were assessed.

Results: Patients with AC_sAH had an increase in total BA, primary BA, conjugated BA and total ursodeoxycholic acid in plasma. In feces,

there was a decrease in total BA and secondary BA. AC_sAH patients had a specific IM: at the phyla level, there was an increase in Actinobacteria and a decrease in Bacteroidetes; while at genus level there was 7 taxa increased and 4 decreased. Moreover, in AC_sAHc patients, as compared to AC_noAH patients, there was an increase in 4 and a decrease in 11 metabolic pathways involving upregulation of glutathion and nucleotid metabolism and downregulation of biotin metabolism.
Conclusion: Patients with AC_sAH have a specific BA pool with a shift towards more hydrophobic and toxic species that could be responsible for the specific IM associated with AC_sAH. Conversely, the IM will also change the BA pool by transforming primary BAs to secondary BAs leading to a vicious cycle between IM and BA modifications. These changes in IM structure and functions could play a role in AC_sAH initiation and progression, through BA effects on liver metabolism.

PS-069
Chronic plus binge alcohol consumption leads to Il-6 mediated inflammatory response in a new mouse model of acute-on-chronic liver injury
E. Karatayli[1], R. Hall[1], S.N. Weber[1], S. Dooley[2], F. Lammert[1]. [1]*Saarland University Medical Center, Department of Medicine II, Homburg, Germany;* [2]*Medical Faculty Mannheim, Heidelberg University, Section Molecular Hepatology, Department of Medicine II, Mannheim, Germany*
Email: Ersin.Karatayli@uks.eu

Background and Aims: Altered host response to injury in the setting of a chronically damaged liver plays a critical role in the development of acute-on-chronic liver injury, usually in the presence of an underlying precipitant. Here, we aim to combine a mouse model with pre-existing chronic liver injury (*Abcb4*$^{-/-}$) with the recently standardized ethanol feeding model (NIAAA model, *Nat Protoc* 2013) to dissect alcohol-related inflammatory responses in this novel preclinical model.
Method: Ten and 15 week-old wild type (WT) C57BL/6J and *Abcb4*$^{-/-}$ knock-out (KO) mice were either fed control (WT/Cont and KO/Cont groups) or liquid ethanol diet (5% v/v), followed by an acute ethanol binge (5 mg/kg; WT/EtOH and KO/EtOH groups). Liver-specific steady-state mRNA levels (relative to GAPDH) of IL-6, HGF, CRP and COL3A1 were evaluated using the $2^{-\Delta\Delta Ct}$ method. ELISA was performed for IL-6 and HGF in plasma. Hepatic collagen contents (hydroxyproline), plasma EtOH concentrations as well as ALT, AST and AP activities were measured. Data were analysed by ANOVA with Bonferroni post-hoc tests.
Results: Hepatic hydoxyproline and *Col3a1* expression were significantly higher in *Abcb4*$^{-/-}$ mice compared with controls and further increased by ethanol challenge. The older mice in the KO/EtOH group displayed 2-, 3- and 4-fold higher IL-6 expression vs. 15 week-old KO/Cont (all $p < 0.01$), 15 week-old WT/EtOH ($p < 0.001$) and WT/Cont groups ($p < 0.001$), respectively. This elevation was more prominent for IL-6 plasma concentrations, which reached a 10-fold increase ($p < 0.0001$) compared to age-matched controls, whereas HGF did not differ. Hepatic CRP levels were significantly ($p = 0.001$) elevated in 15 week-old *Abcb4*$^{-/-}$ mice challenged with ethanol. Male mice in this group exhibited 1.7 ($p = 0.01$) and 2.1 ($p < 0.001$)-fold higher IL-6 and CRP levels than females, respectively. Lipid droplets (LD) in liver were observed in 80% of mice challenged with ethanol, regardless of genotype. In these mice, hepatic *Pnpla3* mRNA levels were significantly ($p < 0.001$) repressed, and of note, the mean LD size was inversely correlated ($p < 0.01$) with hepatic *Pnpla3* levels.
Conclusion: We propose a novel promising set-up to model alcohol-related acute-on-chronic liver injury. We speculate that the acute inflammatory IL6-driven response might promote the transition from the stable chronic state to progressive liver damage in *Abcb4*$^{-/-}$ mice, further increasing the known and gender-specific HCC risk in this model. Repression of *Pnpla3* expression resulted in a notable expansion in LD size, indicating lipid remodelling in this model.

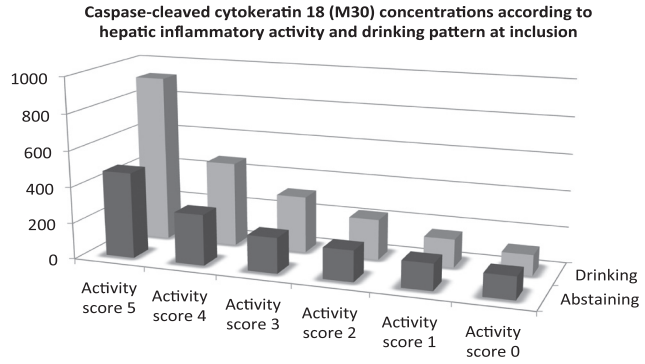
PS-070
Collagen proportionate area is an independent predictor of short and long-term survival in patients with alcoholic hepatitis
M.G. Misas[1], A. Koutsoumarakis[1], A. Hall[2], C. Covelli[1], E. Buzzetti[1], L.I. Prat[1], D. Roccarina[1], T.V. Luong[1], M. Pinzani[1], E. Tsochatzis[1]. [1]*UCL Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom;* [2]*Sheila Sherlock Liver Centre, Royal Free London NHS Foundation Trust and UCL Institute for Liver and Digestive Health, University College of London, London, United Kingdom*
Email: martaguemi@gmail.com

Background and Aims: Quantitative fibrosis assessment with the measurement of collagen proportionate area (CPA) predicts clinical outcomes in patients with chronic hepatitis C and non-alcoholic fatty liver disease and, in addition, is able to sub-classify cirrhosis. We tested the ability of CPA to quantify fibrosis and predict clinical outcome in patients with alcoholic hepatitis (AH).
Method: We retrospectively included a cohort of 141 patients, with biopsy-proven AH, irrespective of fibrosis stage. All patients with concomitant primary causes of liver disease were excluded. Clinical details and laboratory data were collected at biopsy time. Follow-up data were collected at the time of the last clinical follow-up or death. Liver related mortality was considered as primary outcome. For CPA analysis, we captured images of liver biopsy sections stained with picro-Sirius red and used digital image analysis to measure areas of collagen deposition. CPA was calculated as a proportion of the area of the whole parenchyma and expressed as a percentage.
Results: 83 patients (58.9%) were male with a mean age of 46 years. Mean alcohol intake prior to the episode of AH was 173.94 g/day; 47 (33.3%) patients were abstinent after the biopsy with a median abstinence period of 19 (276) months. 106 (75.2%) patients were cirrhotic at the time of the biopsy whereas 99 (70.8%) of the patients had a Maddrey score ≥32. 67 (67.7%) patients were treated with corticosteroids and 11 (11.1%) with pentoxyfilline. 63.6% of the patients treated with corticosteroids were responders based on a Lille score of <0.45. CPA significantly correlated with fibrosis stage across the whole spectrum of fibrosis. 67 patients (47.5%) died during a median follow-up of 65.48 (IQR 311.7) months. 30-days and 1-year mortality were 5% and 23.4% respectively. CPA was an independent predictor of 30-days mortality (OR 0.496, $p = 0.05$) along with the Lille score (OR 15.467, $p = 0.013$). Independent predictors of mortality at last follow up were CPA (OR 1.22, $p = 0.015$), abstinence (OR 0.315, $p < 0.001$) and ABIC Score (OR 1.323, $p = 0.002$).
Conclusion: CPA is a short and long term independent predictor of death in patients with AH and should be further explored as a prognostic index in such patients.

PS-071
Caspase-cleaved cytokeratin-18 (M30) and ActiTest predict hepatic inflammation in asymptomatic patients with alcoholic liver disease
K.H. Thorhauge[1], M. Thiele[1], B.S. Madsen[1], J.F. Hansen[2], S. Detlefsen[3], S. Antonsen[4], L.M. Rasmussen[5], A. Krag[1]. [1]*Odense University Hospital, Department of Gastroenterology and Hepatology, Odense;* [2]*Odense University Hospital, Department of Infectious Diseases;* [3]*Odense University Hospital, Department of Pathology;* [4]*Odense University Hospital Svendborg, Department of Clinical Biochemistry;* [5]*Odense University Hospital, Department of Clinical Biochemistry and Pharmacology*
Email: katrine.thorhauge@gmail.com

Background and Aims: Alcoholic cirrhosis is the cause of 500.000 deaths annually. The end-stage disease is preceded by years of subclinical progressive fibrogenesis driven by hepatic inflammation. Consequently, we need biomarkers to detect and monitor alcoholic hepatic inflammatory activity. M30 is a cytokeratin-18 based novel biomarker of hepatocyte apoptosis with high accuracy for diagnosing severe alcoholic hepatitis. It is not known whether M30 can detect subclinical liver inflammation or how it performs in comparison with

AST:ALT ratio and ActiTest; another patented inflammation marker. We therefore aimed to investigate the correlation of M30, ActiTest and AST:ALT ratio with histological inflammatory activity in asymptomatic alcoholic liver disease patients.
Method: Biopsy-controlled, single-center, prospective study in outpatients with an ongoing or prior excessive alcohol intake. Same-day liver biopsy and analysis of M30 Apoptosense® (VLV bio, Sweden), ActiTest (Biopredictive, France) and routine liver blood tests. Scoring of biopsies using the NAFLD Activity Score by a single liver pathologist. We graded hepatic inflammation using the sum of ballooning (0–2) and lobular inflammation (0–3).
Results: We included 267 patients from 2013–2016. Mean age 54 ± 11, 73% males, 52% not drinking at inclusion (average 10 weeks abstinence), 23% with severe fibrosis or cirrhosis, 48% with steatosis. The distribution of inflammatory activity (0–5) was 67/62/61/37/25/15. M30, ActiTest and whether patients where actively drinking at inclusion independently and significantly predicted increasing grade of hepatic inflammation, while AST:ALT ratio did not (Figure). M30 diagnosed presence of severe hepatic inflammation (score 4–5) with excellent accuracy (M30 AUROC 0.90, 0.85–0.94), significantly better than ActiTest and AST:ALT ratio (AUROC 0.77 and 0.74; $P < 0.001$). M30 was 122 ± 73 U/L in patients without inflammatory activity, and increased exponentially for every point increase in inflammation for a concentration of 773 ± 910 U/L in patients with ballooning = 2 and lobular inflammation = 3. ActiTest was 11.5 ± 11% in patients without inflammation, versus 36 ± 17% in patients with the highest activity score.



Conclusion: M30 and ActiTest are promising biomarkers for grading subclinical, alcoholic hepatic inflammation. M30 detect severe hepatic inflammation with excellent accuracy and increase exponentially for every grade of hepatic inflammatory activity.

PS-072
Impact of baclofen treatment in 212 alcohol-dependant patients of the french "OBADE-ANGH" series

Hagege[13], C. Jung[12]. *[1]CH Intercommunal de Créteil, gastroenterology and hepatology unit, CRETEIL, France; [2]CH Creil, gastroenterology and hematology unit, CREIL, France; [3]CH de Meaux, gastroenterology and hepatology unit, Meaux, France; [4]CHU Besançon, hepatology unit, Besançon; [5]CH Delafontaine, gastroenterology and hepatology unit, Saint Denis, France; [6]CHR Orléans, gastroenterology and hepatology unit; [7]CHU Jean Verdier, hepatology unit; [8]CH de Béziers, gastroenterology and hepatology unit; [9]CH de Saint Brieuc, gastroenterology and hepatology unit; [10]CH Creil, gastroenterology and hepatology unit; [11]CHU Henri Mondor, hepatology unit; [12]CH Intercommunal de Créteil, clinical research centre; [13]CH Intercommunal de Créteil, gastroenterology and hepatology unit*
Email: camille.barrault@chicreteil.fr

Background and Aims: Alcohol misuse is responsible for 50,000 deaths per year in France and the first cause of advanced liver disease in Europe. Baclofen has a temporary recommendation for use in the indications of (1) reduction of consumption and (2) maintenance of abstinence. Its renal elimination makes its use possible even in case of decompensated cirrhosis but few data are available. The aim of OBADE series was to evaluate: (1) the way of prescribing baclofen for alcohol misuse in gastroenterology units of ANGH (non-academic hospital) and: (2) evolution at 12 months of the reported alcohol consumption (DCA) and tolerability of treatment, especially in cases of cirrhosis. Clinical trial number is: NCT02835365.
Method: Consecutive out or inpatients of 10 gastroenterology units treated with baclofen for alcohol dependence after March 2012 (authorization for use on a case-by-case basis) were included and the data were collected prospectively or retrospectively. Psycho-social care was usually offered. We present 9 months results.
Results: Between February 2015 and December 2016, 212 patients (male 79,7%) aged 50.7 ± 10 years were included. Of these, 56 (31%) had alcoholic liver disease and 72 (38%) had cirrhosis. In the cirrhosis group, 13.5% of patients had severe acute alcoholic hepatitis (sAAHs) and 24% had ascites. We observed a history of sAAH in 22% of cases, gastrointestinal bleeding by portal hypertension in 13%, ascites in 37%, and hepatic encephalopathy in 13.5%. A metabolic syndrome was associated in 41% of cases. Three patients were transplanted from the liver. Active smoking was associated in 63% of cases and 3% of patients received opioïd substitution therapy. Baclofen was prescribed either by the addictologist (58%) or by the hepatologist (35%): in 43% of cases the patients had not received any other addictolytic drug. At M9, the median dose of baclofen was 75 mg/d (max = 260 mg/d) and DAC was significantly lower than at baseline: 30 (± 20) g/d versus 111 (± 95) g/d ($p < 0.0001$), 70% of patients had a DAC ≤ 30 g/d while 44% were completely abstinent. The evolution of DAC was the same in cirrhotic patients. In contrast, adverse effects (overall 17%) were less frequent in cirrhotic patients (5.5% vs 25.5%, $p = 0.02$) while the dose of baclofen was not different (65.5 mg vs 88 mg/day, $p = 0.09$). No discontinuation of treatment (n = 5) was related to an adverse event and no death was reported during follow-up.
Conclusion: Preliminary results from this multicentre national study suggest that baclofen treatment, integrated with medico-psycho-social care, is associated with a significant decrease in alcohol intake at 9 months, even in patient with severe ALD. The tolerance of baclofen was very good even in patients with decompensated cirrhosis. Updated results with longer follow up (M12) will be presented in April 2018.

Cirrhosis: ACLF and critical illness

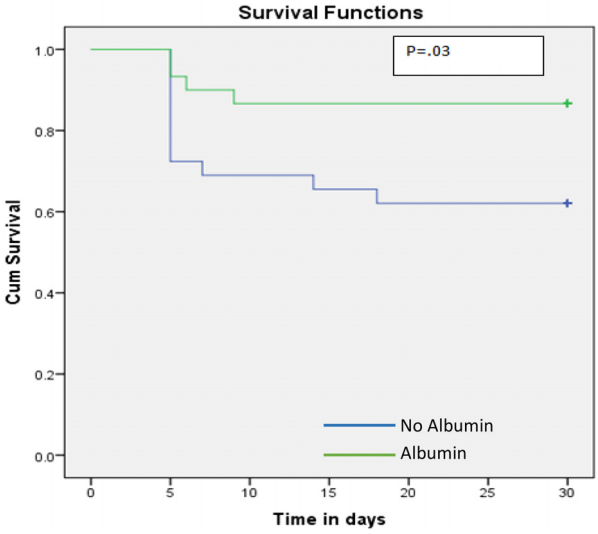
PS-073
Albumin decreases the incidence of paracentesis induced circulatory dysfunction with less than 5 litres of ascitic tap in acute on chronic liver failure (ACLF) patients: Randomized controlled trial (NCT02467348)
V. Arora[1], R. Maiwall[1], S.S. Thomas[2], V. Rajan[1], R. Ali[1], G. Kumar[3], P. Jain[3], S.K. Sarin[4]. *[1]Institute of Liver and Biliary Sciences, Hepatology, Delhi, India; [2]Institute of Liver and Biliary Sciences, Clinical Biochemistry, Delhi, India; [3]Institute of Liver and Biliary Sciences, Clinical Research and bio statistics, Delhi, India; [4]Institute of Liver and Biliary Sciences, Department of Hepatology, Vasant kunj, India*
Email: vinod_ucms@yahoo.com

Background and Aims: PICD is diagnosed by increase in plasma renin activity (PRA) (>50% from baseline or >4 ng/ml/hour) on day 6 post large volume paracentesis (>5 L). It is associated with hepatic encephalopathy (HE), hyponatremia and high mortality. Patients with ACLF have high portal pressure, cardiac output and lower systemic vascular resistance (SVR) compared to decompensated

cirrhosis. There is lack of data on the incidence, diagnosis and management of PICD in ACLF. We hypothesized an increased predisposition to circulatory dysfunction even with modest volume paracentesis (<5 L) in ACLF patients and aimed to determine the need for albumin infusion.

Method: 59 ACLF patients, undergoing paracentesis of <5 L were randomized to receive albumin (8 g/L of ascitic fluid, Gr A, n = 30) or no albumin (Gr. B, n = 29). Heart rate (HR), systolic BP (SBP), diastolic BP (DBP) were monitored for 6 days. PRA and NTpro-BNP were analysed at baseline, day 3 and 6. Hyponatremia was defined as Na < 130 Meq/l or > 5 Meq ↓, AKI as ICA-AKI criteria & HE ≥ grade 2.

Results: Baseline characteristics were comparable in two groups, including mean volume of tap (4.21 ± .15 vs 4.26 ± .24 L, p = .35), baseline PRA(19.59 ± 7.4 vs 22.52 ± 9.1 ng/ml, p = .18), HVPG (19.1 ± 4.6 vs 19.3 ± 5.7 mmHg, p = .18) & SVR 1357 ± 511 vs 1375 ± 419 dyn-sec/cm^5/m^2, p = .83). PICD was more frequent in Gr B than A (62% vs. 26%; p = 0.002). ↑ incidence of HE (24% vs 6.7%, p = .06), hyponatremia (62% vs 30%, p = .05), AKI (36% vs 11%, p = .001) and ↓ in DBP (4.37 ± 6.3% vs 9.61 ± 8.4%, p = .009) was more in Gr B than A. ↑ in PRA at day 3 correlated (p < .001, r2 = 0.8) with day 7, indicating reliability of PRA ↑ at day 3. Increase in NTproBNP was noted from baseline to day6 in Gr B (p = .009). Predictors of PICD on day6 on univariate analysis were: baseline HVPG (OR1.19,95% CI1.02–1.39, p = .02), PRA at day3 (OR1.08,95% CI = 1.02–1.15, p = .007) and non-albumin infusion (OR6.11,95%CI = 1.97–18.89, p = .002). On multivariate analysis, only non-albumin infusion (OR11.66, 95% CI 2.43–55.83, p = .002) was significant. Patients who developed PICD had higher mortality (80% vs 20%, p = .001). Gr B had a higher mortality than Gr. A patients (73% vs 26%, p = 0.03).



Conclusion: Even <5 L of ascitic tap without albumin resulted in PICD in 62% ACLF patients with increased incidence of complications &mortality. Albumin reduces the incidence of PICD and mortality to 1/3rd and is recommended as a plasma expander for even modest volume tap in ACLF patients.

PS-074

Secondary prophylaxis of hepatic encephalopathy in cirrhosis: A double blind randomized controlled trial of L-ornithine L-aspartate versus placebo

S. Varakanahalli, B. Sharma, S. Sachdeva, A. Dahale, S. Srivastava. *G B Pant Institute of Postgraduate Medical Education and Research, Gastroenterology, NEW DELHI, India*
Email: shivakumarvarakanahalli@gmail.com

Background and Aims: Hepatic encephalopathy (HE) is associated with a poor prognosis. L-ornithine L-aspartate (LOLA) has been useful in treatment of acute hepatic encephalopathy. There is no study on the prevention of recurrence of HE with LOLA.

Method: We conducted a double blind randomized controlled trial at a tertiary centre outpatient clinic. Consecutive cirrhotic patients who had recovered from HE within past 12 months were randomized to receive LOLA (6 grams thrice daily) or similar amount of placebo for 6 months. Randomization was done by computer generated random numbers to different codes by an independent observer who was unaware of patient characteristics. Patient received boxes of drugs according to their codes by the independent observer. Patients were assessed by number connection tests or figure connection tests, digit symbol test, serial dotting test, line tracing test, critical flicker frequency test, arterial ammonia and sickness impact profile scores at inclusion and at 3 months and 6 months follow up. Primary end-point was development of overt HE.

Results: Of 306 patients, 150 patients were enrolled. On intention to treat analysis, HE recurred in 11/75 (14.6%) and in 23/75 (30.6%) patients receiving LOLA and placebo respectively (p = 0.02) and hazard ratio (0.389) [95% CI = 0.174–0.870]. By Kaplan-Meier analysis, the time for first breakthrough episode of HE from the time of randomization to 6 months was (170.88) days (CI = 165.0–176.73) in LOLA group and (157.78) days (CI = 148.5–167.0) in placebo group with hazard ratio (0.43) and (p = 0.018). Mortality was similar in both groups (6.8% *vs.* 13.8%) (p = 0.18). At 6 months follow up, there was significant change in the psychometric hepatic encephalopathy scores (2.53 ± 2.18 *vs.* –0.01 ± 1.92, p < 0.001), arterial ammonia levels (–23.58 ± 14.8 *vs.* 1.41 ± 13.34 µmol/L, p < 0.001), critical flicker frequency (5.85 ± 4.82 vs 0.58 ± 4.53, p < 0.001) and sickness impact profile scores (–7.89 ± 5.52 *vs.* –0.95 ± 4.25, p < 0.001) in patients treated with LOLA compared to placebo. On multivariate analysis, only Model for end stage liver disease (MELD) score predicted the recurrence of overt HE with odds ratio (2.21) [CI 1.526–3.204] (p < 0.001).

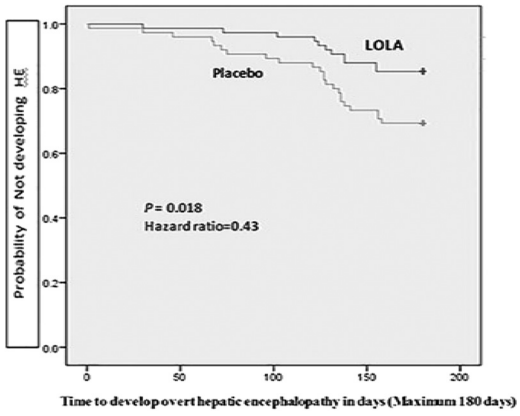


Figure: Kaplan –Meier analysis for recurrence of hepatic encephalopathy between LOLA group and placebo group.

Conclusion: LOLA is effective in the secondary prophylaxis of hepatic encephalopathy and is associated with significant improvement in psychometric hepatic encephalopathy scores, ammonia levels, critical flicker frequency scores and health related quality of life.

PS-075

Mucosal invariant T (MAIT) cells are depleted from blood in advanced cirrhosis and accumulate in the peritoneal cavity during bacterial peritonitis

O. Akinhanmi[1], S. Stengel[1], N. Köse[1], A. Stallmach[1], M. Bauer[2], T. Bruns[1]. [1]*Jena University Hospital, Dpt. of Internal Medicine IV, Jena, Germany;* [2]*Jena University Hospital, Dpt. of Anesthesiology and Intensive Care, Jena, Germany*
Email: oluwatomi.akinhanmi@med.uni-jena.de

Background and Aims: Mucosal invariant T (MAIT) cells are a subset of fast-acting unconventional T cells, which play essential roles in

mucosal immunity against pathogens. Patients hospitalized for advanced cirrhosis have a poor short-term prognosis especially when they encounter bacterial infections, such a spontaneous bacterial peritonitis (SBP) as a result of impaired immune responses. Aim of this study was to investigate the phenotype, function, and clinical relevance of MAIT cells in the peritoneal cavity during complications of cirrhosis.

Method: Peripheral blood and ascitic fluid from patients with decompensated cirrhosis and healthy controls were analyzed using flow cytometry. Vα7.2+ CD161+ CD3+ MAIT cells were quantified and markers of activation (CD69), tissue homing (Integrin αE, CCR7), immune exhaustion (PD-1), chemokine receptors, transcription factors, and intracellular cytokines were assessed.

Results: In contrast to other unconventional T cells, circulating MAIT cells were significantly lower in patients with decompensated cirrhosis (median 0.7% of T cells) compared to controls (median 4.3%; $p < 0.0001$) without significant correlation with classical liver disease scores. In the absence of SBP, the proportion of MAIT cells among T cells was higher in the peritoneal cavity than in blood (1.0% vs. 0.6%; $p = 0.02$), and peritoneal MAIT cells had a tissue homing phenotype (CD103+ CCR7-). Peripheral blood and peritoneal MAIT cells were predominantly CD8-positive and expressed more often CD69 than conventional T cells (13.9% vs. 0.4%; $p = 0.001$, 12.5% vs. 1.7%; $p = 0.01$ respectively) but did not differ in their expression of PD-1. During SBP, peritoneal MAIT cell frequency (1.2% vs. 2.7%; $p = 0.02$) and MAIT cell ascites-blood-ratio (1.4 vs. 5.2; $p = 0.007$) was increased at the day of diagnosis but normalized after 2 days of antibiotic treatment (5.2 vs. 2.0; $p = 0.06$). As compared to conventional T cells, ascitic fluid MAIT cells showed high expression of CCR6 and CXCR3 and were potent producers of IL-17 and TNF after PMA/ionomycin stimulation.

Conclusion: Recruitment and local activation of IL-17 producing CCR6+ CXCR3+ MAIT are observed in the early phases of SBP thus regulating the antimicrobial inflammatory response.

PS-076

Long-term administration of human albumin reduces hospitalization and improves survival in patients with cirrhosis and refractory ascites

M. DI Pascoli[1], S. Fasolato[1], S. Piano[2], M. Bolognesi[1], P. Angeli[3].
[1]University and General Hospital of Padova, Unit of Internal Medicine and Hepatology, Padova, Italy; [2]University of Padova, University and General Hospital of Padova, Padova, Italy; [3]of Internal Medicine and Hepatology, University and General Hospital of Padova, Padova, Italy
Email: m.dipascoli@tin.it

Background and Aims: In liver cirrhosis, ascites becomes refractory when it is not possible to resolve it through standard medical of care (SOC) with low sodium diet and diuretic medications. The clinical benefit of human albumin long-term administration for the treatment of ascites is debated, and for refractory ascites no data are available. In this study, in patients with cirrhosis and refractory ascites, we assessed the effect of long-term albumin administration on hospitalization and mortality.

Method: Seventy patients with cirrhosis and refractory ascites were prospectively and consecutively followed at the Unit of Internal Medicine and Hepatology, University and General Hospital of Padova, Italy, from January 2012 to June 2016. Forty-five patients were non-randomly assigned to receive long-term administration of human albumin at the doses of 20 grams twice per week, in association with hydro-saline restriction and the maximal daily tolerated doses of diuretics, and compared to 25 patients followed according to the SOC. When large-volume paracentesis was performed, all patients received also albumin at the dose of 6–8 grams per liter of ascites removed. Patients were followed up to the end of the study, liver transplantation, or death.

Results: There were no differences in clinical and lab data between the two groups at the time of inclusion in the study. The period free of hospitalization was significantly longer in patients treated with long-term administration of albumin: 0% of patients in the SOC group and 33% of patients treated with albumin were still free of inpatient admissions 24 months after inclusion ($p = 0.008$). Analysing separately the causes of inpatient admission, patients treated with albumin showed a reduction in the incidence of overt hepatic encephalopathy, ascites, spontaneous bacterial peritonitis (SBP) and non-SBP infections. In addition, a non-significant trend toward a reduced probability of hepatorenal syndrome was observed. The cumulative incidence of 24-months mortality was significantly lower in patients treated with albumin than in the group of patients treated with SOC (41,6% versus 65,5%; $p = 0.032$). Long-term administration of albumin was a predictor of survival both on univariate and on multivariate analysis (including age and MELD as other parameters).

Conclusion: In patients with cirrhosis and refractory ascites, long-term treatment with albumin reduces the probability of inpatient hospitalizations and improves survival.

PS-077

Continuous infusion of beta-lactam antibiotics in cirrhotic patients with bloodstream infection: results from a prospective multicentre observational study

Email: michele.bartoletti4@unibo.it

Background and Aims: Infection is a major cause of morbidity and mortality among patients with liver cirrhosis. Beta-lactams are time-dependent antibiotics frequently used to treat cirrhotic patients with infection. Previous studies on non-cirrhotic patients with infection suggest that continuous infusion (CI) of beta-lactams are associated with improved outcome. The aim of this study was to compare the 30-day mortality rate of patients receiving continuous versus intermittent administration (IA) of piperacillin-tazobactam (TZP) or carbapenems (CARs) in cirrhotic patients with BSI.

Method: This is a sub-study of the "bloodstream infection in cirrhotic patients (BICHROME) study", an observational, prospective multicentre study conducted from September 2014 to December 2015 in 17 European centres, enrolling patients with liver cirrhosis and BSI. Of the 312 patients enrolled in the core study we selected those receiving: (i) adequate empirical treatment and (ii) TZP or CAR as empiric or definitive treatment. Survival after 30 days of patients receiving CI or IA of antibiotics were compared by Kaplan-Meier curves. Efficacy of CI of TZP and CARs was assessed in a Cox regression model of 30-day mortality.

Results: During the study period 190 patients received both adequate empiric and definitive treatment. Of these, 123 received TZP or CARs as empiric or definitive treatment and were therefore analyzed. Mean age was 61 (±12) years and 83 (67%) of patients were male. The main

causes of liver cirrhosis were viral in 43 (36%), alcoholic in 32 (26%) and cryptogenic in 20 (16%) cases. Comparing patients receiving CI [38 patients (31%)] with patients treated with IA [85 patients (69%)] of TZP or CARs no differences were found in demographics and cirrhosis characteristics. Patients treated with CI of TZP or CARs were more likely to have hospital acquired infections (68% *vs.* 43%, p = 0.01), intra-abdominal infections (34% *vs.* 16%, p = 0.03) and infection caused by a multidrug-resistant Gram-negative pathogen (32% *vs.* 16%, p = 0.05). At the end of follow-up 31 patients died (25%). Mortality was significantly lower among patients receiving CI of antibiotics (Figure). In a Cox regression model including severity and source of infection, receipt of empiric CI of TZP or CARs was independently associated with a significative lower mortality [HR 0.34 (95% CI 0.11–0.93), p = 0.036]

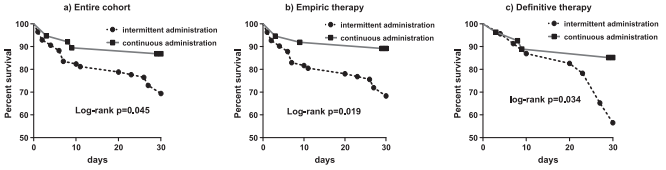

Figure: Kaplan-Meier curves indicate that patients receiving continuous versus intermittent administration of piperacillin-tazobactam or carbapenems, had a significative lower mortality rate (a). Comparable results were obtained performing separate analysis for patients receiving empiric treatment (b) or definitive treatment (c) with piperacillin-tazobactam or carbapenems.

Conclusion: In cirrhotic patients with BSI, administration of CI of beta-lactam antibiotics such as TZP or CARs is associated with improved outcome

PS-078

Therapeutic plasma-exchange improves systemic inflammation and survival in patients with acute on chronic liver failure

R. Maiwall[1], A. Choudhury[1], Z. Duan[2], Y. Chen[2], J. Hu[3], H.L. Ghazinyan[4], Q. Ning[5], K. Ma[5], G.H. Lee[6], S.G. Lim[6], S. Shah[7], C. Kalal[7], A.K. Dokmeci[8], G. Kumar[1], P. Jain[1], I. Paulson[1], S.K. Sarin[1], A. Choudhury[9]. *[1]ILBS, Hepatology, Delhi, India; [2]Beijing You'an Hospital, Hepatology, Beijing, China; [3]302 Millitary Hospital, Beijing, China; [4]Nork Clinical Hospital of Infectious Disease, Yerevan, Armenia; [5]Tongji Hospital, Tongji Medical College; [6]Yong Loo Lin School of Medicine, National University of Singapore, Singapore; [7]Global Hospital, Mumbai, India; [8]Ankara University School of Medicine; [9]ACLF APASL Research consortium, AARC Working party*
Email: rakhi_2011@yahoo.co.in

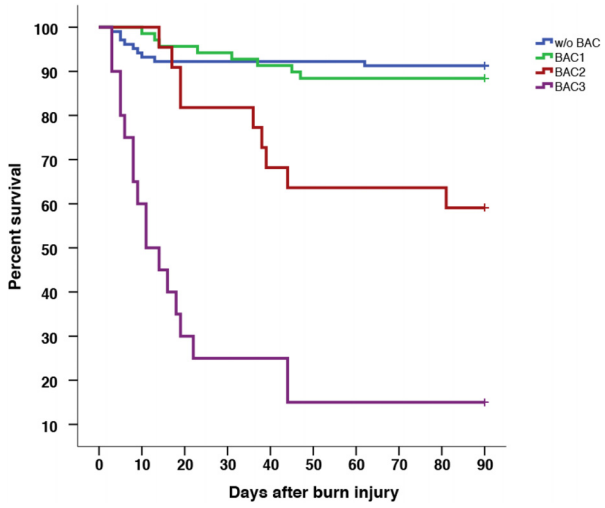
Background and Aims: Systemic Inflammation (SIRS) and infection form the pathogenetic hallmark of organ dyfunction in patients with Acute on Chronic Liver Failure (ACLF). Plasma-exchange (PE) has been shown to improve survival in patients with acute liver failure by combating SIRS, but there is paucity of data in patients with ACLF. We evaluated the role of artificial liver support systems (ALS), plasma-exchange (PE) and liver dialysis (FPSA) as compared to standard medical treatment(SMT) in improving SIRS, development of multi-organ failure(MOF) and survival (SMT) in a large multicentric-multinational cohort of ACLF patients. We also compared the efficacy of PE as compared to FPSA.
Method: Prospectively collected data from AARC data base was analysed. Matching by propensity risk score (PRS) was done to avoid selection bias. Competing risk Cox regression analysis was done to identify event specific death.
Results: ACLF patients (n = 1866,aged 44.3 ± 12.3 yrs, 93% males, 65% alcoholics) received either ALS (n = 162);[PE (n = 131), FPSA (n = 31)] or continued with SMT(n = 1704). Patients treated with ALS had a significantly lower MELD (p = 0.03) and CTP scores (p = 0.04) which was no more evident in the PRS-matched cohort (p > 0.05) (n = 208, [ALS-119;PE-94,LD-25)], SMT-89). Bacterial infections were noted in 363(19%), SIRS in 728(39%), which resolved in 511 (27%). ALS was associated with significantly(p < 0.05) higher resolution of SIRS [OR (1.56,1.03–2.34) (1.5,1.03–2.34)], lower persistence [OR(4.6,1.2–18.4) (1.09, 1.01–1.2)], development of new-onset SIRS [OR(4.38,1.1–17.5) (1.2,1.04–1.29)] and MOF [(HR(6.5,4.8–8.7)(7.1,4.5–11.1)] in pre-match and PRS-matched cohorts respectively. At 1-month, 656 (35%) died of which 233(35.5%) died of MOF, remaining due to sepsis and other causes. On multivariate Competing risk Cox-regression analysis, in both the pre-match and PRS-matched cohorts, treatment with ALS [(HR 0.11, 0.04–0.27), (HR-0.02, 0.002–0.15) and MELD score [(HR 1.1, 1.08–1.2), (HR 1.09,1.04–1.15) respectively were significant predictors of liver failure related death. Further, on subgroup analysis PE was associated with a significant survival benefit as compared to FPSA in pre-match (HR 3.4, 1.4–8.1) and PRS-matched (HR 3.9, 1.3–12.3) cohorts.
Conclusion: ALS in patients with ACLF improves systemic inflammation, lowers development of MOF and results in improved survival. Plasma-exchange has a significant survival benefit over FPSA and should be the therapy of choice in these patients.

PS-079

The relationship between burn-associated cholangiopathy and outcome of critically ill burn adults

C. de Tymowski[1], F. Depret[1], S. Soussi[1], M. Chaussard[2], N. Moreno[2], P. Sogni[3], M. Legrand[1], V. Mallet[3]. *[1]GH St-Louis-Lariboisière, Department of Anesthesiology and Critical Care and Burn Unit, Paris, France; [2]GH St-Louis-Lariboisière, Biochemistry laboratory, Paris, France; [3]Hopital Cochin, Hepatology, Paris, France*
Email: vincent.mallet@aphp.fr

Background and Aims: Burn-associated cholangiopathy (BAC) is reported among burn patients. There is a gap of knowledge on BAC-associated factors and outcomes.
Method: We conducted a retrospective, single-center, cohort study among consecutive and non-selected adult patients (n = 735) admitted in our Burn Unit (BU) between June 2012 and December 2015. Biological measures were retrieved from the biological database of our institution and merged in the patient's characteristics dataset. We selected patients with at least one of the following criteria: total body surface area burn (TBSA) ≥ 20%; full thickness BSA ≥ 10%; smoke inhalation; organ dysfunction, including the need for vasopressors and the need for mechanical ventilation, during the first 48. Patients with a length of stay BU ≤ 48 hours or with abnormal liver function tests prior to BU admission were excluded.
BAC was defined by cholestasis (ALP ≥ 1.5 times the upper limit of normal (ULN) and GGT ≥ 3 times the ULN) or by hyperbilirubinemia (total bilirubin ≥ 34.2 µmol/l) and was categorized in 3 groups: BAC1, cholestasis without any episode of hyperbilirubinemia during BU stay; BAC2: cholestasis and at least one episode of hyperbilirubinemia during BU stay; BAC3: hyperbilirubinemia without any episode cholestasis during BU stay. Acute kidney injury (AKI) was defined with the Kidney Disease Improving Global Outcomes (KDIGO) criteria. All episodes of infections were prospectively collected. The primary endpoint was 90-day mortality.
Results: Among 214 selected patients (median [IQR] age 48 [32–61], 68% male, TBSA 27 [18–45]), 111 (52%) had BAC during BU stay, including 69 (62%) patients with BAC1, 22 (20%) with BAC2 and 20 (18%) with BAC3. BAC was associated with severity at admission and complications during BU stay, including increased risk of bacteremia [adjusted OR = 3.27 95%IC (1.38–7.71); p = 0.007]. BAC2 and BAC3 patients had higher AST/ALT ratio, more nosocomial infections and septic shocks, more AKI, and higher 90-day mortality rate. A one-class increase in BAC injury was associated with 90-day mortality (adjusted hazard ratio [95% CI] 1.66 (1.07–2.58); p = 0.024; see Figure). BAC2 and BAC3 patients had the worst outcome (higher mortality): 85% of BAC3 patients died with a median survival of 11 [6–22] days, while 12% and 41% of BAC1 and BAC2 patients died, respectively.



Conclusion: BAC is independently associated with sepsis and outcome of severely burned patients.

PS-080

Adherence to EASL antibiotic treatment recommendations improves the outcomes of patients with cirrhosis and bacterial infections. Results from the ICA Global Study

Email: pangeli@unipd.it

Background and Aims: Bacterial infections are a common cause of decompensation in patients with cirrhosis. On 2014 EASL recommendations for antibiotic treatment in patients with cirrhosis and bacterial infections were published. The effects of the adherence to these recommendations have never been investigated so far. The aim of this study was to assess the clinical impact of the adherence to EASL recommendations in patients with cirrhosis and bacterial infections.
Method: In the International Club of Ascites (ICA) "Global Study", 1,302 patients with cirrhosis and bacterial infection were included. Demographic, clinical, microbiological and treatment data were collected at the diagnosis of infection and during the hospitalization. Patients were followed up until death, liver transplantation or discharge. The empirical antibiotic treatment was considered adherent to EASL recommendations if at least one of the antibiotic/combination recommended was administered.
Results: The antibiotic treatment was adherent to EASL recommendations in 61% of patients, while was broader in 14% and weaker in 25%. Northern American centers prescribed more frequently broader antibiotics (31% vs 13%; $p < 0.001$) while Northern European and Asian centers administered more frequently weaker ones (30 vs 21%; $p < 0.001$). Adherence to recommendations was poorer in pneumonia (27 vs 71%; $p < 0.001$) and nosocomial infections (54 vs 64% $p = 0.002$). In patients with positive cultures (57%), the administration of antibiotics weaker than those suggested by EASL recommendations resulted in lower antimicrobial susceptibility (50 vs 75%; $p < 0.001$). Importantly, bacteria isolated in Asian centers had a lower antimicrobial susceptibility to antibiotics suggested by EASL recommendations (58 vs 80%; $p < 0.001$), mainly due to a high prevalence of multi drug resistant bacteria (51 vs 28%; $p < 0.001$). The administration of antibiotics weaker than EASL recommendations was associated with a higher need to escalate treatment (50 vs 32%; $p < 0.001$). In addition, after adjusting for confounders (age, ACLF, quick SOFA and MELD-Na score), the administration of a weaker antibiotic regimen was associated with a higher risk to develop new organ failures (OR = 1.50; $p = 0.010$), septic shock (OR = 1.51; $p = 0.044$) and a higher in-hospital mortality (OR = 1.47; $p = 0.034$).
Conclusion: The adherence to EASL recommendations was associated with better outcomes in patients with cirrhosis and bacterial infections and should be promoted. However, different empirical antibiotic strategies should be developed in certain countries due to the high prevalence of MDR bacteria.

Experimental hepatology

PS-081

Hepatocyte-specific deletion of RuvBL1 leads to chronic liver damage and regeneration, enhancing HCC development

M. Materozzi[1,2], F. Zanieri[3], E. Ceni[3], S. Polvani[3], M. Tarocchi[3], O. Bereshchenko[4], A. Galli[3], T. Mello[3]. *[1]University of Siena, Dept. of Medicine, Surgery and Neuroscience; [2]University of Siena, Doctorate Course in Genetics, Oncology and Clinical Medicine; [3]University of Florence, Dept. of Experimental and Clinical Biomedical Sciences "Mario Serio", Firenze, Italy; [4]University of Perugia, Dept. of Medicine, Perugia, Italy*
Email: tommaso.mello@unifi.it

Background and Aims: The AAA+ ATPase RuvBL1 is overexpressed in several human cancers, including hepatocellular carcinoma (HCC), in

which high RuvBL1 expression correlates with a poor prognosis. A growing body of data from *in vitro* models supports the concept that increased RuvBL1 expression occurs in cancer to promote its growth and progression, making it an attractive target for anti-cancer therapies. However, whether RuvBL1 participates in the oncogenic transformation *in vivo* remains open to speculation. To address this question, we realized a hepatocyte-conditional RuvBL1 knock-out mouse model and evaluated the HCC onset and progression after DEN injection.

Method: Hepatocyte-conditional RuvBL1 knock-out mice were generated by crossing RuvBL1-floxed with Albumin-Cre mice. HCC was induced in male mice by single i.p DEN injection (5 mg/kg) at 14 days of age. Mice were sacrificed at 3, 6, 9 and12 months to monitor HCC onset and progression. By crossing RuvBL1 cKO mice with $B6^{mT/mG}$ mice we obtained a progeny in which mature (Alb^{+}, $RuvBL1^{-/-}$, $EGFP^{+}$) and non-mature (Alb^{-}, $RuvBL1^{wt/wt}$, $mTRed^{+}$) hepatocytes could be traced *in vivo* at single-cell resolution.

Results: Contrary to our expectation, DEN-induced cancerogenesis was strikingly increased in $RuvBL1^{hep-/-}$ *vs* Floxed mice. We found that RuvBL1 deletion in cKO mice resulted in hepatocellular damage, apoptosis and compensatory proliferation, suggesting a possible tumor-promoting mechanism. The liver damage induced by RuvBL1 deletion peaked around 2 weeks of age, corresponding to minimal RuvBL1 expression. Starting at 3 weeks of age, massive proliferation of non-mature hepatocytes and partial recovery of RuvBL1 protein levels were observed. Further characterization revealed that non-mature hepatocytes origin from $CK19^{+}CD133^{+}HNF4^{+}$ cells. We could establish that cycles of RuvBL1 deletion, hepatocytes loss and compensatory proliferation keep on occurring during the lifetime of cKO mice (followed up to 1 year).

Conclusion: This is the first report highlighting the essential role of RuvBL1 for hepatocyte survival and the impact of its loss on liver carcinogenesis. The increased HCC incidence does not reflect a tumor-suppressor role of RuvBL1, rather, it is the outcome of a chronic regenerative process from staminal precursors. This model may prove useful to investigate the mechanism underlying liver regeneration in the context of chronic hepatic damage.

PS-082

Beta-catenin-dependent erythropoiesis in adult mice deficient in hepatic ARID1A chromatin remodeler

R. Riou[1], M. Ladli[2], A. Gougelet[2], G. Cécile[2], Z. Wang[3], F. Verdier[2], S. Colnot[2]. [1]*Institut Cochin, Paris;* [2]*Institut Cochin;* [3]*University of Michigan, Department of Cardiac Surgery Cardiovascular Research Center*
Email: cecile.godard@inserm.fr

Background and Aims: One third of Hepatocellular Carcinomas (HCC) depend on activating mutations in *CTNNB1* gene encoding β-catenin. ARID1A, a SWI/SNF component, is the chromatin modifier the most frequently mutated in more than 13% of HCCs, initially found preferentially in *CTNNB1*-mutated ones. *ARI1DA* would rather be tumor suppressive, as its mutations are mainly inactivating. We hypothesized that HCC emergence and/or progression could be linked to the loss of ARID1A in a β-catenin-dependent context.
Our aim was to determine whether the loss of ARID1A increase the tumorigenic potential of β-catenin aberrant signaling in the liver.

Method: We took advantage of a transgenic murine model in which APC, the major brake of β-catenin signaling, is lost, leading within 9 months to HCC emergence. We thus engineered new transgenic models using Cre-loxP strategy, allowing hepato-specific and tamoxifen-inducible inactivation of *Apc* (leading to hepatic gain-of-function of β-catenin) and/or *Arid1a* (Apc/$Arid1a^{ko-hep}$ mice) in single hepatocytes.

Results: Seven months after tamoxifen injection, we unexpectedly observed in Apc/$Arid1a^{ko-hep}$ mice intrahepatic macroscopic amounts of red blood cells, associated with *de novo* transcription of hepatic erythropoietin (EPO). This leads to EPO secretion in the blood, to a dramatically increased hematocrit and to mouse letality. We found that this *de novo* transcription of *Epo* is cell-autonomous, occurring in mouse as well as in human primary cultures of hepatocytes only after both activation of Wnt/β-catenin pathway (obtained through *Apc* loss or through Wnt/Spondin co-stimulation) and loss of ARID1A. As a consequence of EPO systemic increase, Apc/$Arid1a^{ko-hep}$ mice became splenomegalic, with a dramatic increase of erythroid progenitor cells showing the establishment of a stress erythropoiesis.
At the molecular level, we showed by ChIP experiment an important change of histone marks at the hepatic erythropoietin enhancer in Apc/$Arid1a^{ko}$ hepatocytes compared to control ones. These marks consist in an increase of H3K27Ac and decrease of H3K27Me3, both being classically associated with increased enhancer activities. These activating histone changes are correlated with an increased binding of TCF4, a β-catenin cofactor, on *Epo* enhancer. These data altogether show that chromatin remodeling induced by ARID1A loss unmask new targets of β-catenin, such as *Epo*.

Conclusion: In liver physiology, chromatin remodeling through ARID1A is a powerful epigenetic brake, which could contribute to the shift from an embryonic liver that produces EPO to an adult liver status with no Epo transcription. Moreover, ARID1A inhibition and β-catenin signalling are new actors of the Epo transcriptional machinery, and could be used for genetic engineering of Epo for therapeutic purposes.

PS-083

Protection from Gao-Binge induced liver injury in Mif–/– Mice is associated with decreased ER stress

K. Poulsen[1,2], M. Mcmullen[1,2], M. Sheehan[3], L. Leng[4], R. Bucala[4], L. Nagy[1,2]. [1]*Cleveland Clinic, Department of Pathobiology, Cleveland, United States;* [2]*Northeast Ohio Alcohol Center, Cleveland, United States;* [3]*Cleveland Clinic, Lerner College of Medicine, Cleveland, United States;* [4]*Yale University School of Medicine, Department of Internal Medicine, New Haven, United States*
Email: poulsenk79@gmail.com

Background and Aims: Alcoholic liver disease (ALD) is a major cause of preventable morbidity and mortality worldwide. Alcoholic Hepatitis (AH) is a severe, episodic form of ALD with a high patient mortality rate. Recently, our work has provided strong evidence that the pluripotent chemokine/cytokine macrophage migration inhibitory factor (MIF) is implicated in murine models of ethanol-induced liver injury, as well as in AH patients. Utilizing the Gao-Binge model of murine steatohepatitis (mAH), here we tested the hypothesis that MIF would contribute to ethanol-induced liver injury through enhanced liver inflammation and neutrophil accumulation.

Method: Eight to ten week-old female wild-type and *Mif*–/– C57BL/6J mice were fed a 5% v/v (27% total kcal) ethanol-containing diet or pair-fed control diet for 10 days. On Day 11, mice were gavaged with 5 g/kg ethanol. MIF098 (40 mg/kg) was administered via i.p. injection at −18 h and −1 h to ethanol binge.

Results: A timecourse revealed the peak of liver injury and inflammation occurred 6 hours after ethanol binge as assessed by increased plasma ALT/AST activity. Plasma MIF levels, chemokines KC and MIP2 mRNA expression, as well as neutrophil marker Ly6G mRNA were increased at this time in wild-type mice. As expected, marked accumulation of neutrophils was detected in the livers of ethanol-fed wild-type mice. *Mif*–/– mice and wild-type mice treated with a small pharmacological inhibitor of MIF (MIF098) were protected from increased ALT/AST. Surprisingly, chemokine mRNA expression was unaffected by MIF deletion or inhibition. Despite the protection from liver injury in *Mif*–/– or MIF098-treated mice, neutrophils still accumulated in the liver, consistent with the sustained increases in chemokine expression. Bone marrow-derived neutrophils from WT and *Mif*–/– mice responded similarly to LPS challenge, as assessed by MPO release, suggesting MIF deletion or inhibition did not alter neutrophil oxidative burst. Therefore, we next asked if MIF directly injured hepatocytes in this model. Endoplasmic reticulum (ER) stress was detected in livers of mice 6 hours after binge as indicated by

increased eIF2α phosphorylation, CHOP and Grp78 mRNA expression, and CHOP protein expression. eIF2α activation and increased CHOP protein expression was prevented in *Mif*–/– mice and in wild-type mice treated with MIF098. Furthermore, liver tissue obtained from AH patient liver explants and healthy controls revealed that MIF expression and ER stress were robustly induced in AH patients.
Conclusion: Our results are consistent with MIF contributing to murine AH via induction of hepatocyte ER stress and the pathophysiological role of MIF is independent of hepatic neutrophil accumulation. Pharmacological intervention of MIF could therefore be a therapeutically-relevant target to improve outcomes in AH patients.

PS-084
Sigma 1 receptor: a potential actor in Hepato-Cellular Adenomas
L. Villemain[1], S. Prigent[1], S. Thietry[1], L. Pelletier[2], J. Zucman-Rossi[2], C. Laurent[1]. [1]*INSERM/Université Paris Sud;* [2]*INSERM/ Université Paris Descartes*
Email: laure.villemain@u-psud.fr

Background and Aims: SigR1 is an ubiquitous small protein of 223 amino acid, located in the ER, more precisely in the MAMs (Mitochondria Associated Membranes). This protein is highly expressed in the central nervous system (CNS) and the liver. SigR1 is also overexpressed in several types of cancer, especially in hormone dependent tumors such as breast and prostate cancer. In the CNS it has been shown that SigR1 is involved in neurodegenerative diseases such as Parkinson's disease, Huntington's disease and ALS (Amiotrophic Lateral Sclerosis). Although it is highly expressed in the liver, its function in this organ is totally unknown. We have been thus looking for a role of this protein in the liver.
Results: To identify a possible role of Sig1R in the liver, we looked for variations in the level of expression of this protein in different physiopathological situations, particularly in liver tumors. We found that SigR1 is overexpressed in only one type of liver tumors: HepatoCellular Adenomas (HCAs) mutated for HNF1A (H-HCA). H-HCAs are benign liver tumors that display a marked steatosis, they are mostly found in women taking oral contraceptives containing estrogens. We then investigated the effect of estrogen on the expression of the SigR1 in vivo and in three different cell lines (Huh7, HepG2 and IHH). Western blots measurements of Sig1R show that injection of 17βestradiol (10 mg/kg) induce a significant increase of the expression of Sig1R in mice liver ($n = 14$, $p < 0.05$). Similarly, incubation of Huh7, HepG2 and IHH in the presence of 17βestradiol (10 nM) induced an increase of the level of Sig1R. *In silico* analysis showed a putative ER binding site on the promoter region of Sig1R. Luciferase expression under the SigR1 promoter was highly decreased when this site was mutated. Finally, CHIP experiment showed a direct interaction between ERα and the promoter of SigR1. Otherwise, HepG2 cells overexpressing Sig1R showed a significant increase of the proliferation rate and an accumulation of lipid droplets. Moreover, the more SigR1 was overexpressed, the faster the cells grew. These findings resume the HCAs phenotype.
Conclusions: Taken together, our results suggest that Sig1R could be involved in the development of HCAs. SigR1 could be a therapeutic target, as many ligands of this protein are already used for brain diseases.

PS-085
CCAAT- Enhancer-binding protein homologous protein promotes liver ischemia and reperfusion injury by inhibiting beclin-1-mediated autophagy in hepatocytes
H. Zhou[1], Z. Rao[2], Y. Xia[1], J. Rao[1], X. Wang[1], L. Lu[1]. [1]*The First Affiliated Hospital of Nanjing Medical University, Liver Transplantation Center, Nanjing, China;* [2]*The First Affiliated Hospital of Nanjing Medical University, Dept. of Anesthesiology, Nanjing, China*
Email: doc2012zhm@163.com

Background and Aims: Critical role of endoplasmic reticulum (ER) stress has been found in ischemia and reperfusion (IR) injury models. However, the role of CCAAT-Enhancer-Binding Protein Homologous Protein (CHOP) signaling in liver IR injury still remains unclear. The aim of this study is to determine the role and its underlying mechanism of CHOP signaling in liver IR injury.
Method: Wild-type (WT) and CHOP KO mice were subjected to a murine liver partial warm ischemia model. Liver injury and hepatocellular apoptosis was compared between groups. Autophagy and its regulatory signaling pathways were analyzed both in the liver tissues and the primary hepatocytes. CHOP and autophagy signaling pathways were also studied in human liver tissues post ischemia.
Results: CHOP KO significantly decreased liver IR injury, as evidenced by lower sALT levels and better preserved liver architectures. Liver IR induced marked hepatocellular cell apoptosis, as indicated by HE/TUNEL staining and western blot analysis of cleaved-Caspase-3, BCL-2 and BCL-XL. CHOP KO mice demonstrated much less hepatocellular apoptosis but enhanced autophagy. Primary hepatocytes were isolated and subjected to an in vitro hypoxia/reoxygenation (H/R) model. CHOP KO in hepatocytes resulted in reduced cell death, as measured by LDH and CCK8 assay. Autophagy was enhanced in CHOP KO hepatocytes as evaluated by LC3B staining and the electron microscope examination. Beclin-1 activation was significantly increased in CHOP KO hepatocytes post H/R. Functionally, Beclin-1 siRNA or autophagy specific inhibitor (3-MA) effectively blocked autophagy in hepatocytes and abrogated the protective role of CHOP KO both in liver IR and hepatocyte H/R models. Finally, human liver tissues were collected in patients undergoing liver partial resection with hepatic portal blockade. CHOP and Beclin-1 activation was analyzed by Western blot. Indeed, CHOP activation was increased by liver ischemia. On the contrary, Beclin-1 activation was decreased post ischemia.
Conclusion: Our results indicated that CHOP activation promoted liver IR injury by inhibiting Beclin-1-mediated autophagy in hepatocytes. Strategies targeting CHOP or autophagy signaling may provide therapeutic effects against liver IR injury in patients.

PS-086
Faecalibacterium improves pathogenesis of nonalcoholic steatohepatitis via controlling Treg induced gut-permeability
T. Kessoku, K. Imajo, Y. Honda, Y. Ogawa, W. Tomeno, M. Yoneda, T. Kato, T. Higurashi, S. Saito, A. Nakajima. *Yokohama City University Graduate School of Medicine*
Email: nakajima-tky@umin.ac.jp

Background and Aims: Up to 25% of non-alcoholic fatty liver disease (NAFLD) patients develop a progressive inflammatory liver disease termed non-alcoholic steatohepatitis (NASH) that may progress towards cirrhosis, hepatocellular carcinoma, and the need for liver transplantation. In recent years, several lines of evidence suggest that the gut microbiome plays important roles for the pathogenesis of NASH. We demonstrated *faecalibacterium* (*FB*) was significantly decreased with exacerbated liver fibrosis in human study. The aim of our study was to assess if *FB* improves NASH pathogenesis in mice and mechanism between *FB* and improving NASH-pathogenesis.
Method: Eight-week-old male C57BL/6J mice were randomly distributed into 3 groups of 10 animals each: a basal diet group (B), a high-fat high-fructose high-cholesterol diet (HFCD) group (H), HFCD plus administrated FB group (F). *FB* was daily administrated per os in F group. After 20 weeks of dietary treatment, the mice were euthanized and relevant tissues were prepared for subsequent analysis.
Results: *FB* abundance was significantly decreased in H group compared with B, and increased in F group compared with H group. Histological findings revealed that hepatic triglyceride contents and number of neutrophil elastase positive cells, fibrotic area were significantly decreased in F group compared with those in H group. The serum endotoxin, AST, ALT T-cho, Cho-VLDL levels, and HOMA-R were significantly decreased in F group in comparison to H

group. In OGTT test, blood glucose level in 90 min and 120 min were ameliorated in F group compared with H group. Gene expression levels of TNF-a, collagen1a1, PPRAα, CPT1a1, MTP, IRS1, IRS2, PEPCK, and G6P in the liver were significantly ameliorated in group F compared with H group. Also, in gut-permeability analysis, significant increase in gut permeability was observed in H group in comparison to that in group B, whereas the increased gut permeability was abrogated in F group in comparison to that in group H. In colon mucosa, gene expression levels of TNF-a, OCLN, CLDN4, 8, 15 were improved in F group in comparison to those in H group. Gene expression levels of FOXP3 and TGF-β were significantly increased in F group compared with those in H group. In flowcytometry, significantly increased in CD4 + CD25 + FOXP3+ cells in lamina propria lymphocyte was observed in F group compared with H group. Administration of anti-FR4 antibody on B group leads Treg depletion, resulted in the increasing intestinal permeability in B group.

Conclusion: Our study indicated that *FB*-administration improves NASH pathogenesis via ameliorating gut-permeability by inducing Treg in colon. Our results suggest that *FB* could be a candidate agent for the treatment of NASH through the improving leaky-gut.

PS-087

What drives development of HCC in non-cirrhotic NAFLD?

A. Mahdi[1,2], M. Zaki[3,4], J. Lunec[3], Q. Anstee[1], D. Tiniakos[1], R. Shukla[3], F. Oakley[1], S. Cockell[5], H.L. Reeves[1,6]. *[1]Newcastle University Medical School, Institute of Cellular Medicine, Newcastle upon Tyne, United Kingdom; [2]College of Medicine, Al-Nahrain University, Department of pathology and forensic medicine, Baghdad, Iraq; [3]Newcastle University Medical School, Northern Institute for Cancer Research, Newcastle upon Tyne, United Kingdom; [4]Minia University, Faculty of Pharmacy, Biochemistry Department, Minia, Egypt; [5]Newcastle University Medical School, Bioinformatics Support Unit, Newcastle upon Tyne, United Kingdom; [6]The Newcastle upon Tyne NHS Foundation Trust, Department of Medicine, Newcastle upon Tyne, United Kingdom*
Email: h.l.reeves@ncl.ac.uk

Background and Aims: Although the relative risk of hepatocellular carcinoma (HCC) arising in patients with NAFLD is much lower in the absence of cirrhosis, given the prevalence of NAFLD, cases are rising significantly. The mechanisms involved are poorly understood and hamper the development of surveillance tools or preventive strategies.

Method: We fed 120 C3H/HeH mice, which develop obesity and impaired glucose tolerance with age, the American lifestyle (ALIOS) or control diet – for 12, 24 or 48 weeks, some supplemented with the antioxidant bucillamine(10 mg/kg/day). NAFLD/tumours, DNA damage and proliferation were assessed by a liver histopathologist, γ-H2AX and Ki-67 immunohistochemistry. RNA-Seq was performed in 50 liver tissues.

Results: Fasting blood glucose (mean 12.8 mmol/l) was not different between dietary groups at 48 weeks, but the ALIOS diet exacerbated increases in body and liver weight. The mice developed steatosis, ballooning, lobular inflammation and fibrosis. 27 of 47 mice (control 7/23; ALIOS 20/24) developed liver tumours – 2 were adenomas and 25 were HCC. Features highly significantly associated with tumour development (Table) included liver weight, steatosis grade and presence of lipogranulomas. Ki-67 elevation indicated a proliferative process contributing to liver weight and was also associated with tumour development, as were lobular inflammation, γ-H2AX positive nuclei and fibrosis. In mice fed control or ALIOS diet supplemented with bucillamine, NASH was absent, γ-H2AX reduced >10 fold and fibrosis markedly suppressed. Despite this, the numbers of HCC (control 5/11; ALIOS 9/11) and size were unchanged. Notably, bucillamine had little impact on liver weight, steatosis, lipogranulomas or Ki-67 positive nuclei. Unsupervised clustering of non-tumour tissues RNA-Seq data created two groups with 248 differentially expressed genes. Tumour development was highly enriched in the second cluster, in association with genes in the macrophage enriched metabolic network (MEMN) (72/248, 29%, q-value = 3.16E-53; Gene set enrichment analysis (GSEA)). Ingenuity pathway analysis (IPA) highlighted upregulated cell survival (p = 5.19E-11, Z-score = 5.308) and angiogenesis (p = 2.23E-12, Z-score = 2.452) gene expression.

Fibrosis stage (0/1/2/3)	6/8/6	1/14/11/1	0.064	0.355	**0.014**	↓	<0.001
NAS score (sum)				0.465	0.001	↓↓↓	<0.001
SAF score (sum)				0.467	0.001	↓↓↓	<0.001
H2AX positive nuclei (47 cases studied)				**0.353**	**0.016**	absent	<0.001
Ki-67 positive nuclei (24 cases studied)				**0.506**	**0.012**	**unchanged**	0.983

Conclusion: In this murine model of obesity related NAFLD and HCC, bucillamine treatment led to a clear amelioration of steatohepatitis but did not affect tumour burden. Therefore, NASH and DNA damage played a limited role in tumour development whilst liver weight, associated with steatosis grade, lipogranulomas and a proliferative state were key. IPA and GSEA analyses of non-tumour tissues supported a role for macrophages recruited to fat damaged hepatocytes (lipogranulomas) as promoting hepatocarcinogenesis in an obesity associated liver environment of enhanced hepatocyte proliferation.

PS-088

Hepatocyte-specific overexpression of FoxM1 transcription factor leads to spontaneous liver inflammation, fibrosis, and tumorigenesis in mice

T. Kurahashi, Y. Yoshida, S. Ogura, M. Egawa, K. Furuta, Y. Kamada, S. Kiso, T. Kodama, H. Hikita, R. Sakamori, T. Tatsumi, T. Takehara.
Osaka university, Gastroenterology and Hepatology, Suita, Japan
Email: takehara@gh.med.osaka-u.ac.jp

Background and Aims: Forkhead Box M1 (FoxM1) is a cell cycle-specific transcription factor that is overexpressed in a variety of cancers. Previously, we demonstrated that increased expression of FoxM1 is associated with a poor prognosis of patients with HCC. Although the role of FoxM1 in hepatocellular carcinoma (HCC) is well documented, its role in non-tumor hepatocytes remains unclear. To investigate this issue, we developed a new transgenic mouse model.

Method: We generated hepatocyte-specific FoxM1 conditional transgenic mice (TetO7-FoxM1/Rosa26-LSL-rtTA/Albumin-Cre: designated TG mice) using the Cre-loxP and Tet-on systems. TG and control mice (TetO7-FoxM1/Rosa26-LSL-rtTA: designated WT mice) with doxycycline (DOX) were treated to induce FoxM1 expression. Primary hepatocytes isolated from TG and WT mice were used.

Results: After treatment of DOX from the time of birth, TG mice showed increased levels of serum ALT [75.2 U/L in TG (n = 8) vs. 15.9 U/L in WT (n = 8), p < 0.05], and an increase in the number of TUNEL positive hepatocytes (p < 0.05) at 8 weeks of age. In addition, TG mice with 3 days-treatment of DOX showed increased levels of serum ALT (p < 0.01), increased gene expression of Ccl2 (p < 0.01) and infiltration of F4/80 positive macrophages in the livers of TG mice. This liver inflammation in TG mice was partially cancelled by depleting macrophages (p < 0.01). TG mice also showed an increased Siriusred-stained fibrotic area [5.6% in TG (n = 8) vs. 0.9% in WT (n = 8), p < 0.01] at 13 weeks of age, and spontaneous tumorigenesis [100% in TG (n = 10) vs. 0% in WT (n = 10), p < 0.01] at 48 weeks of age. Primary cultured hepatocytes from TG mice showed an increase in Ccl2 gene expression after induction of FoxM1. Consistently, chromatin immunoprecipitation analysis and luciferase gene reporter assay showed that FoxM1 was associated with a consensus binding site within murine Ccl2 promoter.

Conclusion: Overexpression of FoxM1 in hepatocytes causes spontaneous development of liver inflammation, fibrosis and tumorigenesis. Our data also suggest that FoxM1 might regulate inflammation-related hepatocarcinogenesis through the induction of chemokine expression.

HCV: Striving towards elimination

PS-089

Decentralized care is effective in the management of patients with hepatitis C in a public health care setting: The Punjab model

R.K. Dhiman[1], G. Grover[2], M. Premkumar[3], S. Rathi[1], M. Chopra[3], R. Kaur[3], S. Satsangi[3], S. Taneja[1], A. Duseja[4]. [1]*PGIMER, Hepatology, Chandigarh, India;* [2]*Program Officer, Department of Health and Family Welfare, Chandigarh, India;* [3]*PGIMER, Hepatolog, Chandigarh;* [4]*PGIMER, Chandigarh, India*
Email: rkpsdhiman@hotmail.com

Background and Aims: The prevalence of hepatitis C virus infection infection in Punjab, India is 3.29%, with an estimated burden of around 650,000 viremic chronic hepatitis C (CHC) patients. The Mukh Mantri Punjab Hepatitis C Relief Fund (MMPHCRF) was launched in June 2016 to provide free treatment to all CHC patients aiming to eliminate HCV from Punjab. We assessed the feasibility of decentralized care and efficacy and safety of 12 or 24 weeks of sofosbuvir (SOF) + ledipasvir (LDV) or SOF + daclatasvir (DCV) ± ribavirin (RBV) in the treatment of CHC patients in a public health care setting.
Methods: ***Decentralized care:*** All patients were evaluated and treated at 3 Government Medical Colleges (Amritsar, Faridkot and Patiala, India) and 22 District Hospitals; they were followed up to 12-weeks post-treatment to look for sustained viral response (SVR-12). ***Health care worker capacity building:*** Around 90 medical specialists were trained in a 4-hr predefined course, followed by online continued medical education sessions by regular PGIMER-INASL-Punjab Government Extension for Community Healthcare Outcomes (ECHO) Clinic conducted fortnightly. 50 pharmacists, 2 from each of the 25 centres, dispensed medicine as per specialist prescription. ***Data Management:*** 25 trained data entry operators and Clinton Health Access Initiative (CHAI) managed epidemiological data on CHC hotspots, high-risk groups, local service providers, etc. ***Monitoring:*** Medical Alerts were used for compliance monitoring. ***Study design:*** A cost-effective algorithm was developed using SOF-based regimens to treat all patients (Figure). The diagnosis of cirrhosis was based on clinical evidence or on liver stiffness measurement (LSM) ≥12.5 kPa on fibroscan.

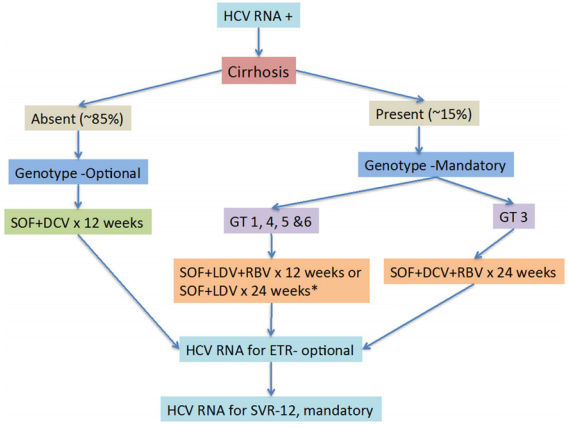

Figure: Algorithm for the treatment of chronic hepatitis C. *Ribavirin intolerant patients.

Results: We enrolled 29,371 patients (61.7% male; mean age 42 years) in 1 year, of which 19646 have completed treatment with SVR-12 of 92.5%. The program has attained maximum outreach to more vulnerable subgroups as 81.17% of these patients are from a rural background. The predominant genotype (G) was G3 (71.1%), with 14.3% cirrhotics. Cure rates in cirrhotics (93.1%) and non-cirrhotics (92.4%), and G3 (92.6%) vs non-G3 (93.1%) were comparable. Thus direct antiviral agent (DAA) based mass treatment of CHC has resulted in high cure rates irrespective of genotype, and presence of cirrhosis. On multivariate analysis only high liver stiffness measurement was a predictor of non-response. There were no major adverse events.
Conclusion: We have validated the efficacy and safety of generic all oral DAA regimens in a decentralized algorithm based public health model in Punjab, India with high cure rates regardless of genotype/presence of cirrhosis.

PS-090

Direct-acting antiviral treatment in sub-Saharan Africa: A prospective trial of Ledipasvir/Sofosbuvir for chronic Hepatitis C infection in Rwanda (the *SHARED* study)

N. Gupta[1], J. Kabahizi[2], C. Muvunyi[3], A. Mbituyumuremyi[4], J. Van Nuil[5], F. Shumbusho[3], F. Ntaganda[2], M.J. Damascene[4], C. Mukabatsinda[6], E. Musabeyezu[6], C. Ntirenganya[6], S. Nsanzimana[4], P. Grant[7]. [1]*Brigham & Women's Hospital, Division of Global Health Equity, Boston, United States;* [2]*Rwanda Military Hospital, Kigali, Rwanda;* [3]*University of Rwanda, Kigali, Rwanda;* [4]*Rwanda Biomedical Center, Kigali, Rwanda;* [5]*Partners In Health, Rwinkwavu, Rwanda;* [6]*University of Rwanda, Rwanda;* [7]*Stanford University, United States*
Email: ngupta@pih.org

Background and Aims: Direct-acting antivirals (DAAs) have not been prospectively studied or well-utilized in sub-Saharan Africa (SSA). We report preliminary results from a prospective study of ledipasvir/sofosbuvir (LDV/SOF) in Rwanda for adults with chronic hepatitis C virus (HCV) genotype (GT) 1 and GT4 infection.
Method: The "*Simplifying Hepatitis C Antiviral Therapy in Rwanda for Elsewhere in the Developing World*" (SHARED) study is a prospective trial in Rwanda evaluating the safety and efficacy of LDV/SOF (90 mg/400 mg once daily) for 12 weeks in 300 adults with HCV GT1 and/or GT4. Exclusion criteria include decompensated cirrhosis, HBV co-infection, uncontrolled HIV infection, and hepatocellular carcinoma. Sustained virologic response 12 weeks after completion of therapy (SVR12) is the primary efficacy outcome. HCV viral load and GT are determined using the Abbott testing platform.
Results: Among the 300 enrolled participants, median age is 64 (IQR 55, 72) and 63% are women. 30 (10.0%) participants are co-infected with HIV. Baseline median HCV viral load is 6.0 log10 IU/ml [IQR 5.6, 6.4]. 249 (80.3%) are reported to have GT4 only, 4 (1.3%) with GT1 only, and 47 (15.7%) with "mixed" GT1/4. Of the 164 patients who have completed study follow-up as of 30 October, 2017, 142 (86.7%) participants achieved SVR12. 16 of the 22 treatment failures were relapses after viral load <30 IU/ml at end of treatment. Risk factors for not achieving SVR12 included baseline HCV RNA >6.0 log10 (HR = 2.3; p = 0.036) and "mixed" GT1/4 (HR = 4.7; p < 0.001). Among the 11 participants reported with "mixed" GT1/4 with treatment failure, all except one were relapses. There have been no drug-related adverse events resulting in treatment discontinuation or study termination. Adherence by pill count and self-report was >98%.
Conclusion: Preliminary results suggest that LDV/SOF is a safe and effective treatment for HCV in Rwanda with a predominance of GT4. Given the association of "mixed" 1/4 GT with failure to achieve SVR12, sequencing of all viral isolates is underway to better understand the genetic heterogeneity and circulating resistance mutations of HCV GT4 infection in this region. Complete SVR12, safety data, and results of a reduced laboratory monitoring protocol for this group will be soon available. Overall, this study supports introduction and scale-up of treatment programs for HCV infection in Rwanda and similar low-income settings in SSA.

PS-091

HCV testing and linkage to care: Expanding access to HCV care through electronic health engagement

Z. Alam, D. Cook, H. Bui, L. Kausar, I. Alam. *Austin Hepatitis Center, Austin, United States*
Email: ztariq@linkagetocare.com

Background and Aims: There is an emerging epidemic of people who inject drugs (PWID), contract the hepatitis C virus (HCV), and fail to seek treatment for this curable illness. At least 75% of new HCV infections in the United States result from injection drug use. Since PWID are at an increased risk for contracting HCV, the Center for Disease Control (CDC) recommends HCV testing in this population. Therefore, we must increase education, screening, and linkage to care by working with methadone clinics, Sober Living Homes, and drug rehabilitation centers. One challenge in testing PWID is linkage to care and treatment following a positive test. Our aim is to link individuals that are HCV RNA positive to care, and utilize our electronic patient database management system (PDMS) with our Substance Abuse Treatment Center partners to fulfill the linkage portion.
Method: Longitudinal prospective cohort study with HCV screening at the above centers and utilization of a HIPPA compliant PDMS (www.linkagetocare.com). A centrally located Linkage to Care Specialist (LTCS) is notified immediately when an individual's information is entered in the system by the treatment center or self-referred. The LTCS educates the individual and proceeds to link them to care.
Results: January 2017 – October 2017, 1038 patients have gone through LTC; 503 HCV RNA positive patients referred (39% self-referred and 61% referred from 27 facilities in 19 states; 88% Texas); 57% were uninsured; 52% were between the ages of 21–40; 51% males. 398 (80%) patients were contacted by LTCS; 249 (70%) referred to a medical provider; 28% patients awaiting lab results; 2% lost contact. Patients were contacted by a LTCS within 48 hours after referral and twice before scheduling their first clinic appointment. 116 (47%) patients made it to their first appointment; 69 (60%) initiated HCV therapy; 40% were completing evaluation; 11 (16%) have finished HCV therapy; 92% were seen in office vs. 8% through telemedicine. Additionally, 47% of patients were from sober living homes, 47% from addiction treatment facilities and 6% from medical clinics.
Conclusion: Linkage to care is the missing link in treatment of chronic HCV. Our study accentuates a promising role for PWID patient engagement in electronic portals and LTCS as a tool in linking patients to the HCV care cascade. Hence, continued efforts are needed to increase and improve HCV patient electronic health engagement.

PS-092

Collocation of Buprenorphine with HCV treatment to improve adherence and reduce harm in PWID with HCV: Preliminary data from the ANCHOR study

E. Rosenthal[1], K. Hill[2], L. Nussdorf[2], P. Mathur[1], C. Gross[1], R. Silk[1], E. Akoth[1], D. Sternberg[3], N. Sidique[2], C. Chaudhury[4], B. Emmanuel[1], H. Masur[2], S. Kottilil[1], S. Kattakuzhy[1]. *[1]University of Maryland School of Medicine, Division of Clinical Care and Research, Institute of Human Virology, Baltimore, United States; [2]National Institutes of Health, Critical Care Medicine Department, Clinical Center, Bethesda, United States; [3]HIPS, Org; [4]National Institutes of Health, NIAID*
Email: nadeera.sidique@nih.gov

Background and Aims: People who inject drugs (PWID) have a significantly increased risk for acquisition of HCV and are progenitors of transmission. Studies of PWID have demonstrated decreased HCV acquisition with buprenorphine (bup) and improved HIV outcomes in patients who receive bup collocated with HIV care. Offering bup as part of HCV treatment may facilitate improvement in HCV treatment outcomes and reduce harms associated with injection drug use (IDU).
Method: ANCHOR study is a single center study embedded in an urban harm reduction center, evaluating treatment of HCV in PWID with chronic HCV, opioid use disorder (OUD), and IDU within 3 months of screening. Participants are treated with sofosbuvir/velpatasvir (SOF/VEL) and offered uptake of bup for OUD.
Results: 130 patients were screened and 71 enrolled and started SOF/VEL. Participants are predominantly male (76%), median 57 years old, black race (97%) and inject opioids once or more per day (65%). 47 (66%) patients were not on opioid agonist therapy (OAT) at screening, all of whom reported interest in bup. To date, 33 (70%) have started bup and 27 (82%) are retained on bup.
65 patients have reached week 4, 58 (89%) attended week 4 visit, and of those 55 (95%) had HCV VL < 200IU/ml at week 4. 62 (95%) patients received the second bottle of SOF/VEL. Patients on baseline OAT and those who started bup while on study were more likely to attend the week 4 visit than those not on any OAT (91% and 100% vs 55%; $p = 0.03$ and 0.0005). Patients retained on bup at week 8 were more likely to receive the third bottle of medication compared to participants not on any OAT (100% vs 82%; $p = 0.003$).
Patients who started bup during HCV treatment had a significant decline in drug use behaviors associated with HIV transmission risk (Darke HIV-Risk Taking Behaviour Scale) from day 0 to week 4 ($p = 0.004$) and day 0 to week 12 ($p = 0.0009$). No significant change was found in patients on baseline OAT or no OAT.
Data for 125 enrolled patients will be available at the time of EASL.
Conclusion: Preliminary results of the ANCHOR study support that PWID with HCV can be successfully initiated on bup during the course of HCV treatment, and that this intervention improves adherence and decreases drug use risks compared to those not on OAT. Collocating buprenorphine with HCV therapy may provide a critical opportunity to not only cure HCV, but simultaneously prevent reinfection and treat opioid use disorder in high-risk, marginalized PWID.

PS-093

HepFree: Screening migrant patients for viral hepatitis in primary care. A 90,000 patient randomised controlled trial indicates benefits are most obvious in older patients

S. Flanagan[1], V.J. Appleby[1], J. Gaviria[1], J. Kunkel[1], V. Madurasinghe[1], S. Eldridge[1], S. Moreea[2], K. Agarwal[3], E. Barnes[4], C. Griffiths[1], M. Pitt[5], A. Salmon[5], G. Foster[1]. *[1]Queen Mary University London, Blizard Institute, London, United Kingdom; [2]Bradford Institute for Health Research; [3]Kings College London; [4]University of Oxford, Nuffield Dept of Medicine, Oxford, United Kingdom; [5]University of Exeter, Medical School, Exeter, United Kingdom*
Email: stuart.flanagan@nhs.net

Background and Aims: Viral hepatitis prevalence is around 0.5% in the UK, but higher in migrant populations. No studies have identified strategies for testing and treating Hepatitis B (HBV) and Hepatitis C (HCV) in migrants in primary care. HepFree is a large, national screening trial involving 92,000 patients in control and intervention primary care practices. We report on characteristics and outcomes of patients attending for primary care viral hepatitis screening.
Methods: HepFree was a cluster randomised trial involving 58 primary care practices (8 control/50 interventional) in 3 areas of high density migrants (Bradford, East and South London) between 2013–2017. 59,390 eligible patients (aged over 18 and from a high-risk migrant population as per WHO prevalence by country) who had never tested for HBV/HCV were invited by letter for screening at intervention practices who were paid per patient tested. In control practices where local protocols applied, screening rates were measured in the 32,722 eligible adults.
Results: In intervention practices, of 59,390 invited patients, 11,611 (19.4%) tested for both HBsAg and HCV Ab, compared with 555/32,722 (1.7%) in control practices ($p = 0.011$). In intervention practices, 57.5% of tested patients were female. 32% of eligible patients from the Indian sub-continent (Bangladeshi, Indian or

Pakistani) were tested. 8.6% of eligible Black Afro-Caribbean patients were tested. 15% of patients aged 18–39 years were screened compared to 29% in patients older than 40 years. In control practices, testing rates were similar in the different ages (0.9% in patients aged <40 years, 1% in aged > 40 years). 115 patients (0.90%) tested HBsAg positive. 80 (69.5%) were male, 67 (58.2%) were East Asian, 26 (22.6%) Afro-Caribbean. 5 (4.35%) were eAg positive and 2 others (1.74%) delta positive. 6.1% had severe fibrosis or cirrhosis on ultrasound or transient elastography, mean age (MA) 46 years (range 18–83). 103 (0.81%) tested HCV Ab positive, of whom 38/103 (36.9%) were viraemic. 34 (89.5%) were SouthEast Asian, and 15.8% had severe fibrosis or cirrhosis, MA50 years (range 35–82). There were no cases of co-infection with HBV/HCV or HIV and no hepatocellular carcinoma. In 8 control practices, of 32,722 eligible patients 17/555 (3.1%) tested positive. Both testing and positivity rates were low in young (<40) indicating that screening in this group by GP invitation may not be cost-effective.

Conclusion: In this 92,000 patient study where doctors were encouraged and paid to test migrants almost 20% of eligible patients were tested. High rates of infection (1.7%) were found. Young patients are unlikely to present for testing and, if so, are unlikely to be positive. The converse is seen in older patients. These data indicate that screening in primary care should be targeted at older patients and alternative strategies applied for younger people where rates of infection are lower.

PS-094

Risk of liver fibrosis progression in patients with undiagnosed hepatitis C virus infection

D.E.M. Arraez[1], Y.N. Bujalance[2], F. Diaz-Flores[2], J.A.G. Dopico[2], E. Quintero[1], M. Hernandez-Guerra[1]. *[1]Hospital Universitario de Canarias, Gastroenterology and Hepatology Unit, Spain; [2]Hospital Universitario de Canarias, Central Laboratory Department, Spain*
Email: dalia_648@hotmail.com

Background and Aims: Hepatitis C virus (HCV) infected patients remain undiagnosed and untreated, and at risk for developing complications. Particularly, the characteristics and risk of fibrosis progression of HCV antibody-positive patients without RNA testing are unknown.

Method: We identified patients with a positive HCV antibody test performed during 2005–2007, and were classified based on whether RNA was performed during follow-up until Jan/2017 and RNA result. Clinical and laboratory variables were collected. Fibrosis stages were estimated by APRI score. We used chi-square test, Student´s t test, ANOVA and McNemar for statistical analysis.

Results: 38,246 HCV tests were performed during the studied period, of which 791 (2.01%) patients tested positive. At the end of the follow-up (median 128.6 months, range 109.8–145.9), in 49.43% (n = 391) of the subjects RNA was not tested, 13.02% (n = 103) had undetectable RNA and 37.55% (n = 297) had RNA > 15 UI. Patients who had not data for APRI calculation were excluded (n = 280). Patients without RNA testing (n = 122) compared with RNA undetectable (n = 92), were more frequently men (70% vs 47%; p = 0.001), alcohol users (53% vs 38%; p = 0.048), with lack of social support (50% vs 29%; p = 0.003) and showed higher percentage of basal significant fibrosis (≥F2) (26% vs 11%; p = 0.005). No differences were found in other evaluated variables that could have influenced in the evolution of liver fibrosis. During a median of 95.5 months (range 6.8–153.5) of follow-up, patients without RNA testing showed a significant increase in liver fibrosis (baseline median 1.1, range 0.5–6.2 vs final 1.7, range 0.5–9.3) compared with patients with undetectable RNA (baseline median 1.0, range 0.6–3.0 vs final 0.6, range 0.6–4.6), (p = 0.043). In addition, patients without RNA testing had a higher significant increase in the percentage of patients with ≥ F2 (p = 0.035) and cirrhosis (p = 0.022) at the end of the follow-up. The relative risk for ≥ F2 and cirrhosis in patients without RNA testing was 3.03 (95% CI: 1.54–5.98) and 4.31 (95% CI: 1.42–13.10), respectively.

Conclusion: In our cohort, patients with HCV antibody positivity without RNA testing are more likely to be socially excluded people. Given the increased risk of advanced fibrosis and progression to cirrhosis of these patients, urge support measures and strategies to linkage to care these difficult to treat patients.

PS-095

Marked reduction in the prevalence of hepatitis C viremia among people who inject drugs during 2nd year of the Treatment as Prevention (TraP HepC) program in Iceland

T. Tyrfingsson[1], V. Runarsdottir[1], I. Hansdottir[1,2], O.M. Bergmann[3], E.S. Björnsson[3,4], B. Johannsson[5], B. Sigurdardottir[5], R.H. Fridriksdottir[3], A. Löve[4,6], T.J. Löve[4,7], G. Sigmundsdottir[8], U.B. Hernandez[9], M. Heimisdottir[4,10], M. Gottfredsson[4,5,7], S. Olafsson[3,4]. *[1]SAA National Center for Addiction Medicine, Reykjavik, Iceland; [2]University of Iceland, Faculty of Psychology, School of Health Sciences, Reykjavik, Iceland; [3]Landspitali University Hospital, Department of Gastroenterology and Hepatology, Reykjavik, Iceland; [4]University of Iceland, Faculty of Medicine, School of Health Sciences, Reykjavik, Iceland; [5]Landspitali University Hospital, Department of Infectious Diseases, Reykjavik, Iceland; [6]Landspitali University Hospital, Department of Virology, Reykjavik, Iceland; [7]Landspitali University Hospital, Department of Science, Reykjavik, Iceland; [8]Directorate of Health, Chief Epidemiologist, Reykavik, Iceland; [9]Landspitali University Hospital, Department of science, Reykjavik, Iceland; [10]Landspitali University Hospital, Department of Finance, Reykjavik, Iceland*
Email: sigurdol@landspitali.is

Background and Aims: Iceland, with a population of 340,000, has a hepatitis C virus (HCV) seroprevalence of 0.3% and an estimated total of 800–1000 infected patients. Vogur Hospital, the countrýs largest addiction treatment center, is a key sentinel site where >90% of people who inject drugs (PWIDs), who account for the vast majority of infections, eventually seek treatment for their addiction. All admitted patients at this hospital with history of injection drug use (IDU) are screened for HCV. Therefore, Vogur provides an opportunity to monitor early trends in HCV prevalence in this important population. A nationwide treatment program was initiated in January 2016, aiming for elimination of chronic HCV infection as a public health threat.

Method: Starting in 01/2016 with the TraP HepC program, all patients with HCV are offered direct acting antiviral agents (DAA) treatment on a nationwide basis. The goal is to initiate treatment for every patient within 36 months (end-2018), aiming for elimination of domestic transmission of HCV. People with history of recent IDU, patients with advanced liver disease and prisoners are prioritized. Relapses and reinfections are promptly treated. We compared the prevalence of HCV viremia among PWID admitted to Vogur Hospital during the first six months of 2015 (pre-intervention), 2016 (first 5 months of intervention) and 2017 (after 11–17 months of nationwide intervention).

Results: During the first fifteen months of the program 554 individuals were evaluated with respect to HCV treatment, 56–70% of the estimated total patient population. DAAs were initiated for 518 patients, 362 SOF/LDV-based, 155 SOF/VEL-based, and one received another regimen. The mean age was 42 years (range 18–81), 68% were males (350). Recent (within 6 months) IDU was reported by 169 (37%). Overall, of those who initiated treatment, 473 (91.3%) completed treatment, whereas 45 (8.6%) discontinued during the first 15 months of the program. HCV RNA at >12 *weeks post treatment was negative in 96% of those who completed therapy and in 51% among those who discontinued. Patients reporting recent IDU were less likely to achieve cure, 87% vs 95%, p = 0.003. The prevalence of HCV viremia among PWID admitted for addiction treatment in the first six months of 2015, i.e. prior to TraP HepC was 42%, and 40% in the first half of 2016; however in early 2017 the prevalence had dropped by 64% compared to 2015, to 15%. The prevalence odds ratio

in 2017 compared to 2015 was 0.244 (95% confidence interval 0.155–0.386), p < 0.001.
Conclusion: A major scale-up in treatment for HCV across all patient groups has been successfully initiated in Iceland. DAA treatment in the setting of recent IDU, although challenging, was generally successful. This treatment effort was associated with a significant reduction in prevalence among PWID. This key population should be a focus of treatment scale-up to curtail spread of HCV.

PS-096
Hepatitis C care cascade in the country of Georgia after 2 years of starting national hepatitis C elimination program

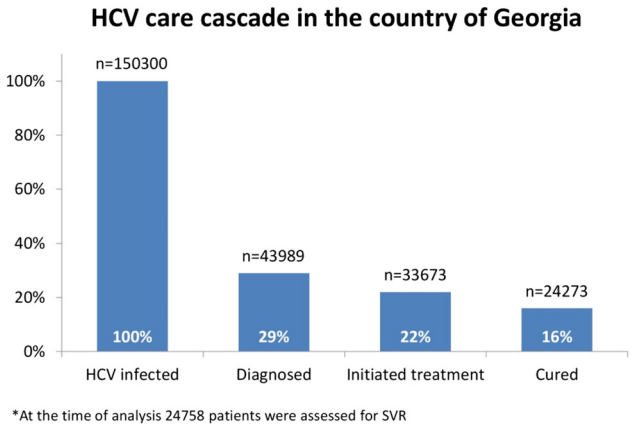
Email: tengizt@gol.ge

Background and Aims: In April 2015, in collaboration with U.S. CDC and commitment from Gilead Sciences to donate direct acting antivirals (DAAs), Georgia embarked on the world's first hepatitis C elimination program. The country set forth 90-95-95 targets to be achieved by 2020: (a) diagnose 90% of HCV-infected persons, (b) treat 95% of those diagnosed, and (c) cure 95% of those treated. We aimed to assess progress towards 90-95-95 targets after 2 years since the beginning of the elimination program.
Method: Four stages of hepatitis C care cascade were defined: (1) HCV infected, (2) diagnosed, (3) initiated treatment and (4) cured. The proportions of persons engaged in stages of care were quantified from the total estimated number of HCV-infected individuals. Population-based survey in 2015 estimated that around 150,000 adult people are infected with HCV in Georgia. Data on diagnosed, treated and cured patients were extracted from the national hepatitis C elimination program treatment databases for the period from April 28, 2015 through April 30, 2017. Sustained virologic response (SVR) i.e., cure were calculated using both per-protocol and modified intent-to-treat (mITT) analysis. Per-protocol approach included only those with complete SVR data, while in mITT analysis persons discontinuing treatment were also included. Persons who died or had no SVR test > 24 weeks after completing treatment were excluded from analysis.
Results: Among estimated 150000 adults living with chronic hepatitis C in Georgia, 43,989 (29.3%) were diagnosed and registered within the elimination program. 33,673 (22.4%) initiated treatment with DAA, and 24,273 (16.2%) achieved SVR (Figure). A total of 24,758 persons with complete SVR data and 601 persons who discontinued treatment, were included in treatment efficacy analysis (total 25,359 persons). Total SVR rate was 98.0% (24,273/24,758) in per-protocol analysis and 95.7% (24,273/25,359) in mITT analysis. SVR rate was 79.5% among persons receiving sofosbuvir (SOF)-based regimen, 98.5% among persons treated with ledipasvir/sofosbuvir (LDV/SOF), as initial regimen and 93.8% among persons re-treated with LDV/SOF after failure of initial SOF-based regimen.



Conclusion: Georgian hepatitis C treatment model ensures high cure rates already exceeding 2020 target with LDV/SOF and without newer generation DAAs. Scaling-up testing and diagnosis, along with effective linkage to treatment services are needed to achieve the goal of elimination.

Liver regeneration and tissue engineering

PS-097
Spatial sorting of hepatocytes reveals broad zonation of liver proteome
S. Ben-Moshe, K. Bahar Halpern, S. Itzkovitz. *Weizmann institute of science*
Email: shalev.itzkovitz@weizmann.ac.il

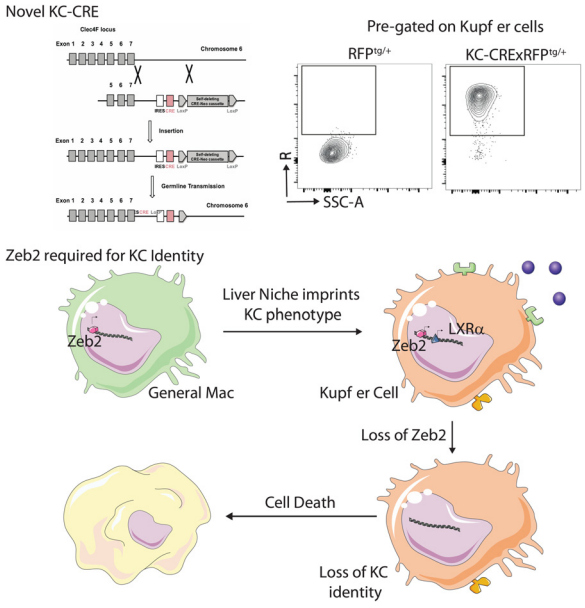
Background and Aims: The numerous metabolic and non-metabolic functions of the mammalian liver are carried out by hepatocytes in a region specific manner, depending on their position along the porto-central axis. Blood flow from the portal node to the central vein and Wnt signals secreted from the central vein create gradients of oxygen, nutrients, morphogens and hormones. These gradients impose different microenvironments, resulting in heterogeneity in gene expression. Cells positioned in different distances from the portal node and central vein are specialized for different metabolic functions. This phenomenon is termed liver zonation. Using spatially resolved single cell transcriptomics we have recently shown that around half of the liver genes are zonated, with expression level gradients peaking either in the portal layer, the central layer or even in the mid-lobule layers.
Method: Using these data, we identified two surface markers with discordant expression patterns. This allows for sorting of hepatocytes from different lobule layers using their combined levels. This spatial sorting of bulk populations enabled us to investigate the extent of zonation at the protein level, which is not yet attainable for single cells. LC-MS/MS on eight sorted different lobule layers revealed proteins zonation patterns.
Results: Zonation patterns were in general in accordance with those of the corresponding RNA. Interestingly, however, for some genes, proteins were found to be zonated, while their transcripts were not. Prominent metabolic pathways with clear protein but not RNA zonation are oxidative phosphorylation, glucose metabolism, lipid biosynthesis and proteasomal proteins.
Conclusion: This finding indicates that both transcriptional and translational regulatory mechanisms act together to establish zonation.

PS-098

Novel tools for dissecting the functions of Kupffer cells in homeostasis and disease reveal a role for the transcription factors Zeb2 and LXRa in maintaining Kupffer cell identity

C. Scott[1,2], W. T'jonck[1], D. Sichien[1], B. Johnny[1], L. Martens[1], H. Todorov[1], R. Cannoodt[1], P. De Baetselier[3], G. Berx[1], A. Beschin[3], Y. Saeys[1], M. Guilliams[3]. *[1]VIB-UGent, Center for Inflammation Research, Belgium; [2]University of Glasgow, Institute of Infection, Inflammation and Immunity, United Kingdom; [3]VIB-VUB, Center for Inflammation Research, Belgium*
Email: charlotte.scott@irc.vib-ugent.be

Background and Aims: Kupffer cells (KCs) are the most abundant macrophage (mf) population in the body. Despite this, their study remains in its infancy due to the lack of KC-specific tools. We aimed to generate new tools to specifically and unequivocally study KCs to determine their roles in homeostasis and disease, as well as investigate how these cells develop and are maintained in the liver environment.
Method: As heterogeneity has become a defining feature of different tissue mf populations, we compared the gene expression profiles of KCs with those of other mfs. This analysis identified the C-type lectin, Clec4F, to be a KC-restricted gene. Based on this, we constructed KC-DTR knock-in mice and KC-CRE mice enabling KCs to be specifically targeted for depletion or genetic manipulation. While investigating heterogeneity of tissue mfs, we also identified the conserved features of the mf lineage, including the transcription factor (TF) Zeb2, which is highly expressed by all mfs. Thus, we also sought to investigate the role of this TF in KC biology through crossing the new KC-CRE mouse to Zeb2$^{fl/fl}$ mice and examining the KC populations by flow cytometry and RNA sequencing (both bulk and single cell).
Results: KC-CRExROSA-RFP mice confirmed that the KC-CRE mice were working efficiently targeting ~95% of KCs in the liver with minimal off-target effects. Using KC-CRE mice alongside CD11c-CRE mice to target additional mf populations, we have shown that removal of Zeb2 from mfs, including KCs, results in loss of their tissue-specific identity and subsequently their death. Examination of the mechanisms involved revealed that loss of Zeb2 results in tissue-specific alterations in the transcriptional programs of the different mfs by altering expression of tissue-specific TFs. In KCs, loss of Zeb2 resulted in reduced expression of the TF LXRα. Confirming a role for LXRα, KC-CRExLXRα$^{fl/fl}$ mice revealed that LXRα expression is crucial for maintaining the KC population in the liver, with its loss, similarly to Zeb2, leading to KC death.



Conclusion: Taken together, we show here that using our novel tools we can now specifically target KCs for depletion and genetic manipulation and have identified the TF Zeb2, through the induction of LXRα, to be a crucial factor driving KC survival by maintaining KC identity.

PS-099

NAA25 and Tropomyosin regulate liver metabolic zonation, hepatocyte polarity and ploidy

L. Neri[1], V. Dominguez[2], J. Elurbide[1], M. Lasa[3], M. Ariz[4], A. Perez-Iturralde[1], B. Carte[1], L. Nicolas[5], E. Vicente[6], C.O. de Solorzano[4], A. Muñoz-Barrutia[5], B. Pintado[2], R. Aldabe[1]. *[1]CIMA, Gene therapy and regulation of gene expression, Pamplona, Spain; [2]CNB-CSIC, Transgenesis Unit, Madrid, Spain; [3]CIMA, Oncohematology, Pamplona; [4]CIMA, Imaging Platform, Pamplona; [5]Instituto de Investigación Sanitaria Gregorio Marañón, Biomedical Engineering Division, Madrid, Spain; [6]CIMA, Gene therapy and regulation of gene expression, Pamplona*
Email: raldabe@unav.es

Background and Aims: More than 15% of cellular proteins are acetylated in their first residue by the enzyme NatB. This enzymatic complex is composed by two subunits, the catalytic subunit NAA20 and the accessory subunit NAA25. Both subunits are overexpressed in human and mouse hepatocellular carcinoma (HCC) samples and downregulation of NatB subunits expression reduces cell proliferation, motility and tumorogenicity. Therefore this enzyme is a potential new target to fight HCC. We have genetically inactivated NatB accesory subunit, NAA25, in mice livers to identify the biological functions regulated by this enzyme in a healthy liver.
Method: To generate the conditional knock-out mouse we have used one ES clone provided by the German Gene Trap Consortium and to inactivate *mNAA25* in mice livers we crossed the obtained mice with B6.Cg-Tg(Alb-cre)21Mgn/J transgenic mice that express the recombinase CRE under the control of albumin promoter (mNAA25$^{\Delta hep/\Delta hep}$). Generated mice were bled and sacrificed at different time points to evaluate mice phenotype.
Results: mNAA25$^{\Delta hep/\Delta hep}$ are viable for more than 18 months without any macroscopic defect in their livers. However a biochemical analysis of 10–12 weeks old mice sera shows an increase of ammonia, ALP, bilirubin and bile salts concentration, reduced urea concentration without any other effect on other biochemical parameters like ALT, AST cholesterol, triglycerides, lactate and glucose. Once we analyzed liver sections we observed a defect of liver histology presenting mNAA25$^{\Delta hep/\Delta hep}$ mice bigger hepatocytes with bigger nuclei, a reduced number of binucleated cells and an increase of polyploidy hepatocytes. Inactivation of *mNAA25* in mouse hepatocytes activates β-catenin activity promoting an altered metabolic zonation. Consequently there is a decrease of arginase-1 positive hepatocytes and a proportional increase of Glutamine Synthetase positive hepatocytes, explaining the increase of ammonia observed in mice sera. Moreover, observed cholestasis in mNAA25$^{\Delta hep/\Delta hep}$ mice correlates with a defect in bile canaliculi structure and a defective transport of canalicular membrane proteins. It has been described that many of the cellular defects observed when NatB enzyme expression is inhibited are associated with defects of the actin cytoskeleton as one of NatB targets, tropomyosin, presents reduced its biological activity when it is not acetylated by NatB. Interestingly when we overexpressed tropomyosin 2.1 in mNAA25$^{\Delta hep/\Delta hep}$ livers we normalize several of the phenotypic defects observed in mNAA25$^{\Delta hep/\Delta hep}$ mice like: hepatocytes ploidy and hyperammonemia.
Conclusion: NAA25 and tropomyosin 2.1 are implicated in maintaining liver metabolic zonation, hepatocyte polarity and ploidy.

PS-100

A novel differentiation system to produce hepatocytes for disease modelling and drug screening

R. Tomaz, B. Wesley, K. Zacharis, D. Ortmann, L. Vallier. *Wellcome Trust – MRC Cambridge Stem Cell Institute, Department of Surgery, Cambridge, United Kingdom*
Email: rt466@cam.ac.uk

Background and Aims: Human pluripotent stem cells (hPSCs) have emerged has a promising tool for modelling diseases "in a dish", given their ability to differentiate into any tissue. Their growth capacity offers an unlimited supply of relevant cell types that can be used in drug screening. Differentiation conditions for hepatocyte-like cells (HLCs) have been successfully established. However, current methods mimic different steps of embryonic development and are limited by the lack of knowledge of signaling pathways operating in critical steps of differentiation/maturation, ultimately producing fetal-like cells. Forced expression of transcription factors (Forward Programming) has recently emerged as a robust and alternative route for conversion of hPSCs into somatic cell types, circumventing the need to mimic development. The aim of this study was to apply the forward programming system to the generation of hepatocytes *in vitro*.
Method: hPSCs were genetically engineered with an optimized inducible overexpression (OPTi-OX) platform. Cells were double targeted with the components of the Tet-ON system: a constitutively expressed transactivator responsive to doxycycline (dox) and an inducible promoter regulated by the transactivator driving the expression of the transgenes. The transgenes tested were a combination of four known hepatocyte-specific transcription factors: HNF4a, HNF1a, HNF6 and FOXA3.
Results: The four factors were robustly overexpressed in hPSCs upon treatment with 1 ug/ml of dox. Morphology changes between dox-treated and non-treated became apparent after 5 days in culture. After 15 days, dox-treated hPSCs expressing the four factors acquired a cobblestone morphology, binucleation, displayed CYP3A4 metabolic activity, and expressed hepatocyte markers such as Albumin, AFP and α1-Antitrypsin. Removal of one transcription factors was not detrimental for these functions, except for HNF4a, which was essential for the acquisition of the hepatocyte-like phenotype.
Conclusion: These results represent a first step towards the development of novel and faster methods for production of hepatocytes *in vitro*. In addition, this system can be further adapted in order to include additional transcription factors, with the potential to induce the acquisition of mature adult-like hepatocyte phenotype. Finally, these findings could be transferred to other cell types generated from hPSCs and thus provide a universal approach for generating mature cell types.

PS-101

3D bio-printing ofhuman hepatic tissue using human liver extracellular matrix as tissue-specificbioink

L. Frenguelli[1], Z. Zhang[2], L. Chikh[3], W. Al-Akkad[1], K. Rombouts[1], E. Gatenholm[3], M. Pinzani[1], H. Martinez[3], G. Mazza[4]. *[1]UCL, Institute for Liver and Digestive Health, London, United Kingdom; [2]University College London, Institute for Liver and Digestive Health, London, United Kingdom; [3]Cellink AB, Gothenburg, Sweden; [4]Institute for Liver and digestive he, London, United Kingdom*
Email: l.frenguelli@ucl.ac.uk

Background and Aims: Progress in 3D cell printing-based liver tissue engineering has been hampered by the lack of a biologically relevant bioink that mimics the 3D and biochemical structure of the liver. Decellularized extracellular matrix (ECM) represents an ideal source of bioink because it retains the structural and biochemical features of the native liver ECM. The aim of this study was to evaluate the bioprintability of human liver ECM under physiological conditions, to assess the in vitro biocompatibility with human hepatic cells and to model liver fibrosis *in vitro*.
Method: Decellularized human livers were lyophilized and solubilized using a protease-free protocol employing 0.5 M acetic acid. The solubilized ECM was mixed with cellulose-based bioink (CELLINK® Bioink) as support for bioprinting. Human hepatic cell lines (Hepg2 and LX2) were gently mixed with ECM bioink or CELLINK bioink (employed as control) using a CELLMIXER® directly into a cartridge before bioprinting. Tissue printing was performed in a BIO X 3D printer under physiological conditions (low extrusion pressure at 10 kPa and room temperature). Bioprinted tissues were maintained in 3D culture up to 14 days and exposed to TGFβ1 for 6 days in order to promote an *in vitro* fibrogenic process. The resultant bioprinted liver tissue was analysed by histology, viability assay and gene and protein expression.
Results: The printability of human liver ECM bioink was confirmed by line extrusion and spiral tests showing the precise deposition of the material with the desired spatial and temporal control. The combination of human liver ECM bioink with liver cell types resulted in an increased cell survival, engraftment and proliferation compared to cellulose-only bioink ($p < 0.001$). Pro-fibrogenic genes and proteins including αSMA ($p < 0.001$) and pro-COL1 ($p < 0.001$) were up-regulated in ECM liver bioink bioprinted LX2 cells after 6 days of TGFβ1 exposure. ECM bioink bioprinted Hepg2 cells showed spontaneous formation of spheroids after 14 days in culture with up-regulation of albumin gene expression and protein secretion after 14 days compared to 7 days ($p < 0.001$). The evaluation of both *in vitro* and *in vivo* biocompatibility with human primary hepatic cells is currently ongoing.
Conclusion: This is the first report describing the bioprinting of human hepatic tissue using human liver ECM as bioink. This is a key advance in the development of cell-instructive bioinks for the study of liver disease and for the development of 3D hepatic tissue for transplantation.

PS-102

Development of self-renewing 3D organoid culture from human fetal biliary tree stem cells (hBTSCs) as a potential system for regenerative medicine and disease modelling

S. Safarikia[1], V. Cardinale[2], G. Carpino[3], D. Costantini[4], S. DI Matteo[4], L. Nevi[4], D. Bosco[5], E. Gaudio[6], D. Alvaro[4]. *[1]Sapienza University of Rome, Department of Medicine and Medical Specialties, Rome, Italy; [2]Sapienza University of Rome, Department of Medico-Surgical Sciences and Biotechnologies, Rome, Italy; [3]University of Rome "Foro Italico", Department of Movement, Human and Health Sciences, Division of Health Sciences, Rome, Italy; [4]Sapienza University of Rome, Department of Medicine and Medical Specialties, Rome; [5]Sapienza University of Rome, Department of Experimental Medicine, Rome, Italy; [6]Sapienza University of Rome, Department of Anatomical, Histological, Forensic Medicine and Orthopedics Sciences, Rome, Italy*
Email: samira.safarikia@uniroma1.it

Background and Aims: 3D organoids represent an advanced culture technology in the field of stem cells and regenerative medicine, recapitulating embryonic development and the physiology of the tissue of origin. Adult or fetal biliary tree represent ideal cell sources of stem/progenitor cells to be used for the regenerative medicine of liver and pancreas. The aim of our study was to generate 3D organoid cultures of hBTSCs suitable for regenerative medicine of liver and pancreas and for *in vitro* disease modeling.
Method: The fetal biliary tree (n = 6, obtained from elective pregnancy termination) was digested, mechanically and enzymatically, to isolate *EpCAM/LGR5*-enriched hBTSCs. Cells were then embedded in Matrigel and cultured in an expansion organoid medium containing soluble factors typical of the stem cell niche including EGF, FGF, Noggin, R-Spondin1; these factors represent LGR5 ligands and Wnt agonists and favor the expansion of stem cells and maintenance of stemness. Culture medium was also supplemented with Forskolin, a cAMP activator, and with a TGFβR inhibitor, A83-01, to induce cell proliferation and arrest of differentiation. We analyzed

colony formation efficiency, organoid size and morphology, cell proliferation and, finally, gene expression by RT-qPCR.
Results: An average of 85 ± 7 million (n = 6) *EpCAM/LGR5* enriched fetal hBTSCs were obtained. The cells isolated from fetal biliary tree showed a high tendency to generate organoids with high colony formation efficiency (>90%). After 5 days in culture, the organoids were microscopically detected as spherical structures and after 7 days, they reached a macroscopically visible size. Cell proliferation in organoids was significantly higher compared to 2D conditions ($p < 0.05$). Fetal biliary tree organoids were composed of single layered cuboidal epithelium and inner cell masses. RT-qPCR analysis indicated that organoids expressed multipotency stem cell markers (SOX2, NANOG, OCT4), endodermal stem/progenitor cell markers (LGR5, EpCAM, PDX1, SOX17), hepatic, pancreatic and ductal markers (ALB, CYPA3, INS, CFTR, CK19) and stem/progenitor surface genes (NCAM, CD133, CD44), recapitulating major processes of self-organization during embryonic development. Specifically, organoids expressed a higher level of LGR5 compared to 2D cultures ($p < 0.05$). we have demonstrated expand organoids stably *in vitro* for at least two months when they remained phenotypically stable and suitable for regenerative medicine programs.
Conclusion: We have demonstrated that organoids expand clonogenically stable *in vitro* for at least two months, maintaining a stable phenotype of multipotent stem cells. This system has potential applications in regenerative medicine of liver and pancreas and in disease modeling.

PS-103
Development and characterization of a novel microtissue-based 3D human liver fibrosis model for anti-fibrotic drug discovery
R. Kostadinova, A. Neelakandhan, M. Kijanska, N. Zapiorkowska, S. Steiert, P. Guye, S. Messner. *InSphero AG, Schlieren, Switzerland*
Email: simon.messner@insphero.com

Background and Aims: Liver fibrosis is the excessive accumulation of extracellular matrix proteins such as collagen, which can lead to cirrhosis, liver failure and transplantation. Anti-fibrotic therapies aim at inhibiting the accumulation of fibrotic cells and preventing the deposition of extracellular matrix proteins. Although some therapeutics are effective in experimental animal models of liver fibrosis, there are currently no effective treatments against liver fibrosis on the market. The most frequently used model for *in vitro* liver fibrosis consist of simple mono-layer cultures of hepatic stellate cells (HSC), ignoring the role of hepatocyte injury or animal models of liver fibrosis, which are not predictive enough for the effect of the anti-fibrotic drugs in human. Our aim was to developand characterize of a physiological relevant 3D Human Liver Fibrosis Model, amenable for anti-fibrotic drug screening.
Method: An *in vitro* human liver model was engineered to incorporate all the relevant human liver cells such as hepatocytes, HSCs, Kupffer cells (KCs) and liver sinusoidal endothelial cells (LECs), all from primary origin. The resulting 3D InSight™ Human Liver Fibrosis model has been characterized under basal and induced liver fibrosis conditions on a morphological and phenotypic level by immuno-staining techniques and gene-expression analysis.
Results: Using the cell type specific markers and immunohistochemistry we demonstrated the presence of various cell types such as hepatocytes, HSC, KCs and LECs during the cultivation and treatment period. TGF-β1-treatment for 7 days of the 3D model activated the HSCs as detected by up to 6-fold increased expression of α-smooth muscle actin (α-SMA). The treatment of the tissues with TGF-β1 promoted the mRNA and protein expression of extracellular matrix gene expression such as collagen type I, III and IV and the pro-fibrotic markers such as platelet-derived growth factor beta (PDGF-β) and **lysyl** oxidase (Lox). Inhibition of fibrosis induction with anti-fibrotic drugs, such as ALK5-inhibitors or FXR-agonist obeticholic acid, effectively blocked fibrosis development.
Conclusion: We demonstrated that TGF-β1 treatment induces liver fibrosis in vitro and that this model system allows studying efficacy of anti-fibrotic drugs. The 3D Human Liver Fibrosis model is thus a novel, biologically relevant *in vitro* model of liver fibrosis, suitable for high-throughput efficacy screening of anti-fibrotic drugs.

PS-104
Hepatic differentiationof human induced pluripotent stem cells (iPSC) using 3D human liverextracellular matrix hydrogel
L. Frenguelli[1], R. Tomaz[2], W. Al-Akkad[1], M. Najimi[3], E. Sokal[3], M. Pinzani[1], L. Vallier[4], G. Mazza[5]. *[1]UCL, Institute for Liver and Digestive Health, London, United Kingdom; [2]Wellcome Trust-Medical Research Council Stem Cell Institute, Anne McLaren Laboratory and Department of Surgery, Cambridge University, Cambridge, United Kingdom; [3]Université Catholique de Louvain, 3Laboratory of Pediatric Hepatology & Cell Therapy, Institute of Experimental and Clinical Research, Louvain-la-Neuve, Belgium; [4]Wellcome Trust – MRC Cambridge Stem Cell Institute, Department of Surgery, Cambridge, United Kingdom; [5]Institute for Liver and digestive he, London, United Kingdom*
Email: l.frenguelli@ucl.ac.uk

Background and Aims: The development of patient-specific induced pluripotent stem cells (iPSCs) holds great promise for the realization of personalized regenerative medicine and *in vitro* disease models. A common limitation of hepatic lineages derived from iPSCs is a blunted phenotype compared with primary hepatocytes. Decellularized scaffolds composed by natural liver extracellular matrix (ECM) have recently been shown to maintain the phenotype of primary cells and to promote cell survival, proliferation and differentiation of stem cells.
The aim of this study was to evaluate the differentiation of human iPSC at different stage of differentiation towards hepatocyte-like cells by employing 3D human liver ECM hydrogel.
Method: Decellularized human livers were lyophilized and solubilized using a protease-free protocol employing 0.5 M acetic acid and sonication. The gelification of human ECM solution was induced by adding gellying polymers. Human iPSC were differentiated towards hepatocytes-like cells and reseeded into ECM hydrogel at 12 days (hepatoblast stage), 23 days (immature stage) and 30 days (mature stage) post-differentiation. 3D cell cultures were maintained *in vitro* up to 30 days for the hapatoblast and immature stage and 37 days for the mature stage. Primary human hepatocytes were used as control. 3D cultures were analysed by histology, immunofluorescence, viability assays, gene and protein expression.
Results: Human liver ECM hydrogel were successfully repopulated with human iPSC at all stages of differentiation as well as with primary hepatocytes. Viability was confirmed at the end of 3D *in vitro* differentiation. The metabolic activity of primary human hepatocytes cultured in 3D ECM hydrogels was improved at 7 days compared to 2D culture ($p < 0.01$). Immunofluorescence analysis confirmed expression of hepatic differentiation markers including A1AT and albumin. The highest level of differentiation was achieved when hepatoblast cells (12 days post-differentiation) were differentiated in vitro up to 30 days compared to shorter 3D differentiation time with both immature and mature stage. Further gene and protein expression analyses are ongoing.
Conclusion: This study demonstrated that hepatocyte-like cells derived via iPSC technology mature on 3D extracellular matrix ECM hydrogel. The differentiation can be improved if iPSC are cultured for longer period in 3D ECM hydrogel from the hepatoblast stage. This is a key advance in the development of personalised 3D technologies for the study of liver disease and for the understating of liver development.

NAFLD: Clinical and therapy

PS-105

Proof of concept study of an apoptosis-signal regulating kinase (ASK1) inhibitor (selonsertib) in combination with an acetyl-CoA carboxylase inhibitor (GS-0976) or a farnesoid X receptor agonist (GS-9674) in NASH

Harrison[10]. *[1]Texas Liver Institute, University of Texas Health San Antonio, San Antonio, United States; [2]Quality Medical Research, Nashville, United States; [3]Auckland Clinical Studies, Auckland, Auckland, New Zealand; [4]Ruane Clinical Research Group, Los Angeles, United States; [5]Gilead Sciences, Foster City, United States; [6]University of California at San Diego, San Diego, United States; [7]University of California Berkeley, Berkeley, United States; [8]Stanford University School of Medicine, Palo Alto, United States; [9]Cedars-Sinai Medical Center, Los Angeles, United States; [10]Pinnacle Clinical Research, San Antonio, United States*
Email: bryan.mccolgan@gilead.com

Background and Aims: Pre-clinical data suggest that combinations of an ASK1 inhibitor with an ACC inhibitor or FXR agonist are more effective than monotherapy. In this study we evaluated the safety and efficacy of these combinations in subjects with NASH.
Method: 70 subjects with NASH diagnosed by a hepatic proton density fat fraction (PDFF) ≥10% and liver stiffness ≥2.88 kPa by MRE, or biopsy consistent with NASH and stage 2–3 fibrosis were enrolled. Successive cohorts received monotherapy with SEL 18 mg, GS-0976 20 mg, or GS-9674 30 mg (n = 10/cohort), or combination therapy with SEL + GS-0976 (18/20 mg) or SEL + GS-9674 (18/30 mg) (n = 20/cohort) orally QD for 12 weeks. Centrally-read PDFF and MRE, and serum fibrosis markers were measured at baseline (BL), W4 and W12. Deuterated water was administered to measure fractional synthesis of lipids (*de novo* lipogenesis) and fibrosis-related markers (data are pending).
Results: Over 12 weeks, all regimens were safe and well-tolerated. Similar rates of AEs were observed between cohorts (Table). No subject discontinued treatment prematurely. Compared with BL, GS-0976 resulted in significant improvements in PDFF (p = 0.006) and TIMP-1 (p = 0.049), and non-significant reductions in ALT and PIII-NP (Table). GS-9674 monotherapy reduced PDFF (p = 0.010), GGT (p = 0.039), and ALT. The combination of SEL + GS-0976 led to significant reductions in PDFF (p < 0.001), ALT (p = 0.019), and PIII-NP (p = 0.057), whereas SEL + GS-9674 reduced GGT (p = 0.030).
Conclusion: In this proof of concept study in patients with NASH, 12-week treatment with the combinations of SEL + GS-0976 or SEL + GS-9674 was safe and led to improvements in hepatic steatosis, liver biochemistry, and fibrosis markers. Responses were similar with monotherapies. Studies of longer duration with histological assessment are required to better characterize the efficacy of combination versus monotherapies in NASH.

PS-106

Non-alcoholic fatty liver disease and relative risk of incident steatohepatitis, cirrhosis and hepatocellular carcinoma events in four European primary care databases

Email: myriam.n.alexander@gsk.com

Background and Aims: Non-alcoholic fatty liver disease (NAFLD) is a condition with no clinical symptoms that progresses in some patients to steatohepatitis (NASH), cirrhosis and hepatocellular carcinoma. Here, we identified NAFLD or NASH patients from 18 million patients' records; and estimated their risk of liver disease compared to individually matched patients.
Method: Primary care data were extracted from the UK, the Netherlands, Italy and Spain. Adult patients with a NAFLD or NASH diagnosis and without past liver disease or alcohol abuse were enrolled and followed up for incident cirrhosis and hepatocellular carcinoma events. Within a database, each NAFLD patient was matched to up to 100 "non-NAFLD" patients by practice site, gender, age ±5years, and visit recorded within±6 months. Hazard ratios were estimated using Cox models adjusted for age and smoking status, and stratified by matching. Estimates were pooled across studies by random effects meta-analyses.
Results: There were 136,457 recorded NAFLD/NASH patients enrolled in our study (2,674 NASH patients only available in Spain and UK) who experienced 408 recorded cirrhosis and 175 recorded hepatocellular carcinoma events (Figure 1). At baseline, NAFLD patients had elevated transaminases levels, and were more likely to have diabetes, hypertension and obesity than matched non-NAFLD. Follow-up varied from 2–5 years in the databases. Associations were significant with non-alcoholic cirrhosis and hepatocellular carcinoma; and were 2-3x higher in NASH only patients compared to NAFLD only or NAFLD/NASH. HRs were marginally reduced when adjusting in addition for body mass index. Associations were heterogeneous

Table: (abstract: PS-105): Safety and Relative (%) Changes in Imaging, Liver Biochemistry, and Serum Fibrosis Markers at W12[†]

	SEL 18 mg (n = 10)	GS-0976 20 mg (n = 10)	GS-9674 30 mg (n = 10)	SEL + GS-0976 18/20 mg (n = 20)	SEL + GS-9674 18/30 mg (n = 20)
MRI-PDFF	7.1 (−16.3, 28.9)	−42.7* (−52.3, −19.4)	−15.6* (−17.3, −12.7)	−32.0* (−45.3, −2.6)	−9.4 (−25.0, 18.7)

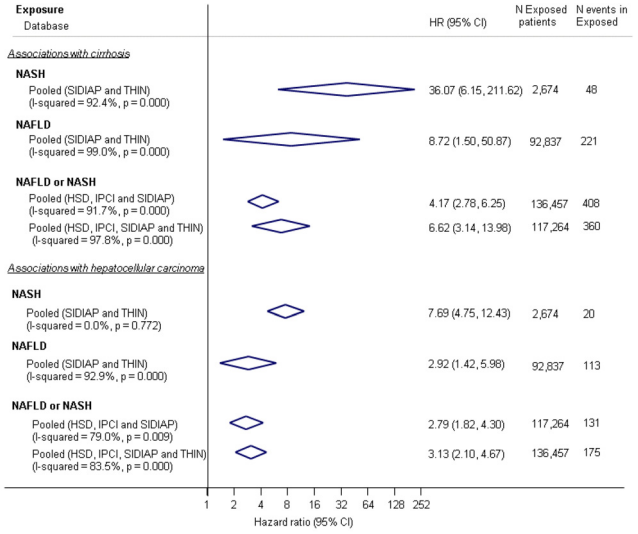
Grade 2 or higher AE	40% (4)	40% (4)	40% (4)	25% (5)	15% (3)

[†]All data are median (IQR) relative (%) changes from BL, or % (n).
*p < 0.05 vs. BL.

across databases: higher in the UK for incident cirrhosis; and higher in the UK and the Netherlands for hepatocellular carcinoma.



N: Number of; HR: Hazard ratio; CI: Confidence interval; THIN: The Health Improvement Network (UK); HSD: Health Search Database (Italy); SIDIAP: The Information System for Research in Primary Care (Spain); IPCI: The Integrated Primary Care Information (Netherlands). NAFLD and NASH were distinguishable in THIN and SIDIAP.

Figure: Association of NAFLD and NASH with incident liver outcomes.

Conclusion: A recorded NAFLD diagnosis is indicative of an increased risk of adverse liver outcomes; and the excess risk is graded according to severity with higher excesses in patients diagnosed as NASH. HR estimates concorded with previous studies. Heterogeneity across databases probably reflect medical practice, with the disease probably being diagnosed at a more advanced stage in the UK.

PS-107

Rare ceruloplasmin variants are associated with hyperferritinemia and increased hepatic iron in NAFLD patients: results from a NGS study

E. Corradini[1], I. Bernardis[2], P. Dongiovanni[3], E. Buzzetti[4], A. Caleffi[1], L. Artuso[2], S. Pelusi[3], E. Tenedini[2], E. Tagliafico[2], R. Rametta[3], A.L. Fracanzani[3], S. Fargion[3], A. Pietrangelo[4], L. Valenti[3]. *[1]University of Modena and Reggio Emilia, Division of Internal Medicine 2 and Center for Hemochromatosis, Modena, Italy; [2]University of Modena and Reggio Emilia, Center for Genome Research, Department of Medical and Surgical Sciences, Modena; [3]University of Milano, Fondazione IRCCS Ca' Granda Ospedale Policlinico di Milano, Department of Pathophysiology and Transplantation and Internal Medicine and Metabolic Diseases., Milan, Italy; [4]University Hospital Policlinico of Modena and University of Modena and Reggio Emilia, Division of Internal Medicine 2 and Center for Hemochromatosis, Modena, Italy*
Email: elena.corradini75@unimore.it

Background and Aims: Nonalcoholic fatty liver disease (NAFLD) is a multifactorial disease resulting from the interaction of genetic and environmental factors.
Hyperferritinemia has been associated with altered hepatic iron metabolism, increased hepatic iron stores and worse hepatic and cardiometabolic outcomes in patients with NAFLD and metabolic syndrome.
Our aim was to evaluate the prevalence of genetic variants of iron-related genes and their association with HyperFt and increased hepatic iron stores in NAFLD patients.
Method: From a published cohort of 347 subjects with histological NAFLD and available serum iron parameters, hepatic iron staining and genetic characterization, 23 cases with hyperferritinemia and positive iron staining (HyperFt) and 25 controls with lowest ferritin and negative iron staining (NormoFt) were selected.
Patients with beta-thalassemia trait, increased transferrin saturation, anemia, inflammation, and, within HyperFt group, carriers of HFE genotype at risk of iron overload or ferroportin mutations were excluded.
A custom AmpliSeq™ NGS panel of 33 genes associated with iron homeostasis was designed and tested. Literature and in silico predictions were used for prioritization of possibly pathogenic mutations.
Results: The two groups did not significantly differ in components of metabolic syndrome and severity of liver disease.
Potential pathogenic variants were found in 54% of HyperFT patients and in 4% of NormoFT patients ($p = 0.0001$), and ceruloplasmin (CP) resulted to be the most mutated gene, with the identification of 4 different variants harbored in heterozygosis by 6 HyperFt patients ($p < 0.01$) (Figure 1).

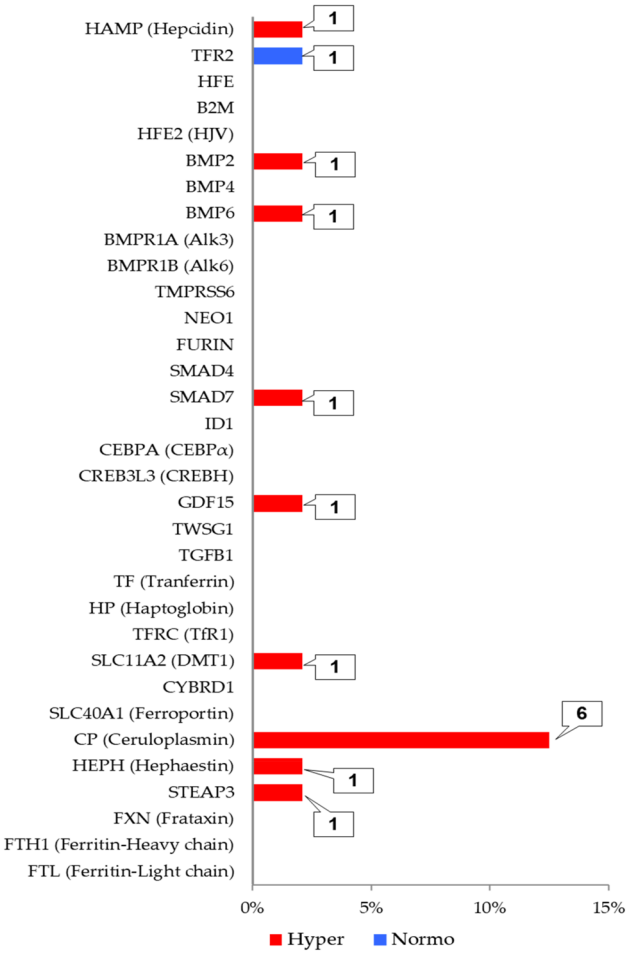


Figure 1: Number of patients carrying iron-genes pathogenic mutations in HyperFt and NormoFt group.

When polymorphisms possibly affecting iron metabolism such as TF c.829G > A or CP c.1652C > T were included in the analysis, 78% of HyperFt versus 38% of NormoFt patients resulted to have such variants ($p = 0.0016$). TMPRSS6 A736V distribution was not significantly different between IperFt and NormoFt patients.
When patients were checked for polymorphisms previously associated to advanced liver fibrosis or severe iron overload in HFE-hemochromatosis, such as PCSK7 rs2369918G > C and GNPAT rs11558492 (D519G), no significant difference in the distribution was found between the two groups.

Conclusion: Variants in non-HFE iron genes, particularly ceruloplasmin, seem associated with hyperferritinemia and increased hepatic iron stores in Italian NAFLD patients. Future studies are necessary to confirm these findings in larger cohorts and to evaluate their clinical relevance.

PS-108

The effect of intragastric balloon therapy on the intestinal microbiome in obese patients with non-alcoholic fatty liver disease, and correlations with anthropometric indices, nutritional factors, and serum immunological markers

VI Nguyen[1,2], P. Cordero[2], J. Li[2], C. Katar[2], C. Blumenthal[3], V. Male[4], A. Cuff[4], A. Wijeyesekera[5], J. Mcdonald[5], A. Perdones-Montero[5], E. Holmes[5], J. George[1], J.A. Oben[2]. *[1]Storr Liver Unit, Westmead Hospital and Westmead Millennium Institute, Sydney, Australia; [2]Institute for Liver and Digestive Health, University College London, London, United Kingdom; [3]Department of Nutrition and Dietetics, Westmead Hospital, Sydney, Australia; [4]Institute of Immunity and Transplantation, University College London, London, United Kingdom; [5]Division of Computational and Systems Medicine, Department of Surgery and Cancer, London, United Kingdom*
Email: vi.nguyen@nhs.net

Background and Aims: The prevalence of non-alcoholic fatty liver disease (NAFLD) closely parallels the obesity epidemic, and the rates of both are rising rapidly. There is growing interest in the role of the gut microbiota both in disease pathogenesis, and as potential novel therapies. The primary aim was to determine any changes in the intestinal microbiota in obese patients with NAFLD following assisted weight loss with an intragastric balloon (IGB). Secondary aims included: assessment of metabonomics and peripheral markers of inflammation, and examination for any correlations with gut microbial changes.
Method: Obese patients with NAFLD were prospectively recruited for IGB treatment. Clinical, anthropometric and nutrient data, serum biochemistry and inflammatory markers, and faecal samples for gut microbiota composition were collected at baseline, and at the end of IGB therapy (6 months).
Results: Thirty-four patients were recruited. The majority were female (70%) with an average age of 47 years. Mean baseline weight was 110.5 kg (BMI 39.4 kg/m^2), with median HOMA-IR 4.37 (1.65–4.51). Paired follow-up results were available for 28 patients: 15 successfully achieved ≥ 9.5% baseline weight loss (Group 1), while the remaining 13 patients (Group 2) did not. Significant improvements in several anthropometric and metabolic indices were observed in Group 1 (mean weight loss −17 kg, waist circumference reduction 15 cm, HOMA-IR reduction 3.05, $p < 0.01$ for all), but not in Group 2 (mean weight change −2.1 kg, HOMA-IR reduction of 1.17, $p = 0.1$). Those in Group 1 reported an average reduction in carbohydrate intake after the intervention (CHO intake in % Kilojuoles 54.5 to 49.1, $p = 0.04$), while consumption of sugar was increased in Group 2 (total sugars 77.8 g to 137.3 g, $p = 0.02$). There were no significant changes in inflammatory cytokines, but a few peripheral blood lymphocyte alterations were noted (significant increase in CD4 T-cells, and decline in NK cells in Group 1). No clinically significant changes in any gut microbial taxonomic units were observed following IGB therapy in both groups, nor were there any significant modifications in metabonomic outputs. A negative correlation with saturated fat intake and low level bacteria was observed (*Dorea*; $r = 0.28$, $p = 0.03$, and *Butyricoccus;* $r = 0.26$, $p = 0.04$).
Conclusion: In this cohort, no clinically significant alterations in the gut microflora or associated metabonomics was observed following IGB therapy, despite significant improvements in several metabolic, hepatic and immunological indices in those who achieved a substantial amount of weight loss.

PS-109

Usage of antiplatelet agents is inversely associated with liver fibrosis in patients with cardiovascular disease

K. Schwarzkopf[1], J. Bojunga[1], S. Rueschenbaum[1], Y. Martinez[1], M.M. Muecke[1], F. Seeger[2], F. Schoelzel[1], S. Zeuzem[3], M. Friedrich-Rust[1], C. Lange[1]. *[1]Department of Internal Medicine 1, J.W. Goethe-University Hospital, Frankfurt, Germany; [2]St. Elisabeth Hospital Ravensburg, Department of Cardiology, Ravensburg, Germany; [3]University of Frankfurt, Department of Medicine, Frankfurt, Germany*
Email: katharina.schwarzkopf@kgu.de

Background and Aims: In animal models platelets participate in the development of liver fibrosis, but little is known about the benefit of antiplatelet agents in preventing liver fibrosis in humans. We therefore aimed to explore the relationship between usage of antiplatelet agents and liver fibrosis in a prospective cohort study of patients at high risk of liver fibrosis and cardiovascular events.
Method: Consecutive patients undergoing elective coronary angiography at the University Hospital Frankfurt were prospectively included in the present study. Associations between usage of antiplatelet agents (acetyl salicylic acid, P2Y12 receptor antagonists) and liver fibrosis were assessed in regression models. Furthermore, the relationship between PDGF-β serum concentration, platelets, liver fibrosis and usage of antiplatelet agents was characterized.
Results: Out of 505 included patients, 337 (67%) received antiplatelet agents and 134 (27%) had liver fibrosis defined as a FibroScan® transient elastography value ≥7.9 kPa. Usage of antiplatelet agents was inversely associated with the presence of liver fibrosis in uni- and multivariate analyses (multivariate OR = 0.67, 95% CI = 0.0.51–0.89; $p = 0.006$). Usage of antiplatelet agents was inversely associated with FibroTest values as well (beta = –0.38, SD beta = 0.15, $p = 0.02$). Furthermore, there was a significant correlation between platelet counts and PDGF-β serum concentration (rho = 0.33, $p < 0.0001$), but PDGF-β serum levels were not affected by antiplatelet agents.

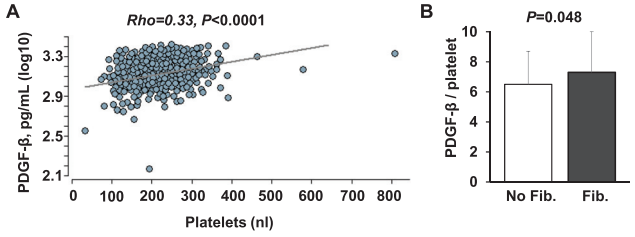

Figure: Relationship between PDGF-β serum concentration and platelet counts. (A) PDGF-β serum concentrations correlate with platelet counts, suggesting that platelets are a source of PDGF-β in humans. (B) The ratio of PDGF-β serum concentration divided through platelet count is higher in patients with liver fibrosis compared to patients without liver fibrosis. Fib., fibrosis.

Conclusion: There is a protective association between the usage of antiplatelet agents and occurrence of liver fibrosis. A randomized controlled trial is needed to explore the potential of antiplatelet agents as anti-fibrotic therapy in patients at risk for liver fibrosis progression.

PS-110

Steroidal and non-steroidal FXR agonists elicit clinically-relevant lipoprotein profiles in mice with chimeric humanized livers

R. Papazyan[1], K. Rigbolt[2], R. Lind[2], M. Feigh[2], J. Liu[3], B. Dong[3], E. Plummer[1], R.D. Lewis II[1], M. Roth[1], M. Young. *[1]Intercept Pharmaceuticals, Inc., San Diego, United States; [2]Gubra; [3]VA Palo Alto Health Care System, Palo Alto, United States*
Email: romeo.papazyan@interceptpharma.com

Background and Aims: Farnesoid X receptor (FXR) agonists are categorized into two major classes, steroidal or non-steroidal, that differ in their pharmacokinetic and possibly therapeutic properties.

Clinical and preclinical data comparing non-steroidal compounds with the first-in-class steroidal compound obeticholic acid (OCA) are lacking. Further complicating these issues, preclinical rodent models do not adequately reproduce the clinical response to FXR activation, particularly in cholesterol metabolism and the elevated circulating low-density lipoprotein cholesterol (LDL-c) associated with OCA or chenodeoxycholic acid administration in humans. It was previously shown that mice with chimeric humanized liver reproduce the human effects of OCA on circulating cholesterol. To compare the actions of steroidal and non-steroidal FXR agonists on cholesterol metabolism, chimeric mice were treated with OCA or two non-steroidal FXR agonists, INT-2228 and INT-2231, in this study.

Method: The effects of OCA (10 mg/kg/day) were evaluated in PXB chimeric mice (>80% human hepatocytes; PXB mice, PhoenixBio) as well as SCID mice (PXB background) as non-chimeric controls. In a second cohort, chimeric mice were administered vehicle (1% CMC), 10 mg/kg/day of OCA, 0.3 mg/kg/day of INT-2228, or 30 mg/kg BID of INT-2231 for 14 days. Genome-wide gene expression levels in the liver were assessed by RNA-sequencing and key genes were validated by quantitative PCR. Western blot analysis was performed for metabolic proteins associated with hepatic cholesterol metabolism. Serum lipoprotein fractions were analyzed by HPLC.

Results: Gene expression profiling in chimeric mice treated with OCA, INT-2228, or INT-2231 showed similar effects on hepatic FXR target genes, including downregulation of CYP7A1 and upregulation of NR0B2, SLC51B, and ABCB11. Furthermore, pathway analysis revealed significant downregulation of hepatic cholesterol genes (e.g. LDLR, HMGCR, HMGCS1, and MVK) across all agonist-treated groups. Consistent with the transcriptional response, protein levels of cleaved (activated) sterol regulatory element-binding protein 2 and LDLR were reduced in chimeric mice, but not in control mice. Importantly, both classes of compounds elicited similar increases (66–89%) in circulating LDL-c levels ($p < 0.001$ vs vehicle).

Conclusion: Similar to the effects of OCA, non-steroidal FXR agonists directly activate hepatic FXR and increase circulating levels of LDL-c. We conclude that changes in cholesterol metabolism and elevated LDL–c are a class effect of FXR activation.

PS-111
Preclinical and first-in human development of SGM-1019, a first-in-class novel small molecule modulator of inflammasome activity for the treatment of nonalcoholic steatohepatitis (NASH)

K. Dabbagh, G. Steven Dodson, L. Yamamoto, B. Baeza-Raja, A.W. Goodyear. *Second Genome, Inc, South San Francisco*
Email: karim@secondgenome.com

Background and Aims: Preclinical studies suggest that inflammasome activation in response to diverse stimuli drives liver inflammation and fibrosis in models of NASH. These stimuli include cellular damage in the liver and bacterial products that originate from the gastro-intestinal tract that appear to be increased in the context of western diets associated with chronic liver diseases. The study aimed to confirm that inflammasome activity in rodent NASH models and efficacy of inflammasome inhibition to reduce inflammation and fibrosis in the liver. We also sought to demonstrate the safety and pharmacological activity of SGM-1019, a novel small molecule inhibitor of inflammasome activation, in a non-human primate (NHP) model of liver inflammation and fibrosis, and in healthy human volunteers enrolled in a phase I clinical study.

Methods: Inflammasome activity in animals fed a high fat diet (HFD) was evaluated by measuring IL-1β levels from *ex vivo* stimulated whole blood and in *ex vivo* liver culture supernatants. The effect of inflammasome blockade on the development of liver inflammation and fibrosis was evaluated in the streptozotocin (STZ)-HFD-induced steatosis model of NASH following 10 weeks of treatment. The efficacy of SGM-1019 was evaluated in a 6-week carbon tetrachloride (CCl_4) exposure model of liver fibrosis in NHP. We also evaluated the pharmacokinetics, safety and pharmacodynamic effects of SGM-1019 on inflammasome activation in a phase I single and multiple ascending dose trial in healthy human volunteers.

Results: HFD fed rodents displayed enhanced whole blood IL-1β responses to LPS/ATP stimulation *in vitro* (581 pg/ml chow, 2685 pg/ml HFD, $p < 0.0001$). Cultured liver slices from these animals also displayed increased IL-1β secretion (6.58 pg/ml chow, 73.6 pg/ml HFD, $p < 0.001$) that was inhibited by inflammasome blockers (34.6 pg/mg IB-1 $p < 0.01$; 33.1 pg/ml IB-2 $p < 0.05$). 10-week treatment of diabetic mice on a HFD (STZ-HFD) treated with an inhibitor of inflammasome activation reduced liver histological fibrosis scores by 44% (2 vs 1.125, $p = 0.01$). Furthermore, in a 6-week NHP CCl_4 model, bi-daily SGM-1019 treatment for 4 weeks improved total histology scores ($p < 0.01$) driven primarily by improvements in fibrosis, hepatocyte degeneration and inflammation. Finally, SGM-1019 was safe and well tolerated in healthy human volunteers dosed for 2 weeks at all doses evaluated. Pharmacodynamic evaluation demonstrated that at the doses tested, SGM-1019 significantly inhibited inflammasome activation over the dosing period as measured by IL-1β release from *ex vivo* stimulated whole blood.

Conclusion: These studies demonstrate that the inflammasome plays a critical role in the pathogenesis of liver fibrosis and NASH, and that inhibition of inflammasome activation with SGM-1019 is a novel and potentially safe and effective way of treating patients with chronic liver diseases.

PS-112
Web-based counseling for NAFLD. Final results

A. Mazzotti, M.T. Caletti, L. Brodosi, L. Montesi, G.M. Reggiani. *Unit of Metabolic Diseases & Clinical Dietetics – S. Orsola-Malpighi Hospital, Dpt. Medical & Surgical Sciences, "Alma Mater" University, Bologna, Italy*
Email: giulio.marchesini@unibo.it

Background and Aims: Lifestyle changes are mandatory in NAFLD, but difficult to implement in busy Liver Units. We tested the feasibility and effectiveness of a web-based educational intervention aimed at lifestyle changes in NAFLD.

Method: According to our protocol, following diagnosis and motivational interviewing, NAFLD cases are invited to enter a multidisciplinary, 5-wk group-based lifestyle modification program, aimed at healthy diet and habitual physical activity, carried out by physicians, dieticians, psychologists. From 2010 to 2015, 716 subjects were observed (age 52 ± SD13) and 438 completed the program in 3 months (group cohort-GC). We developed a web-based intervention, accessed via userid and password, for individuals who could not enter GC because of logistics, job- or time-constraints (web cohort-WC, n = 278). Also the web intervention includes 5 modules, with interactive games, off-line contact with the Center, and questionnaires to investigate motivation, competence and learning. During follow-up, all subjects were only treated for comorbidities, with no specific therapy for liver disease. Surrogate markers of NAFLD severity were tested at 6-12-24-mo follow-up. Primary outcome was 10% weight loss; secondary outcomes were changes in BMI, ALT, surrogate markers (Fatty liver index-FLI, Fib-4, NAFLD Fibrosis score-NFS). WC results were tested for non-inferiority; comparison vs. GC was made by repeated-measures ANOVA.

Results: WC and GC had similar BMI (33 kg/m^2), with a higher prevalence of males (67% vs. 45%), younger age and higher education in WC. Attrition was higher in WC (OR, 2.46, 95%CI 1.68–3.61), associated with female gender, normal ALT at entry and no-diabetes. BMI decreased in both groups by nearly 2 points; the 10% weight loss target was attained in 14% (WC: 12% vs. 15% in GC, p = NS); another 20–28% attained a 5% loss. All liver enzymes decreased significantly, irrespective of treatment, but ALT normalized more frequently in WC (27% at 12-and 24-mo vs. 13% and 17% in GC). The web treatment increased the rate of ALT normalization at 6 months (OR. 2.34; 95%CI, 1.27–4.30), and 12 months (OR, 2.22; 1.33–3.73), not at 24 months (OR, 1.62; 0.94–2.78; p = 0.080), after adjustment for gender, education level, employment status, age, BMI at baseline and

presence of T2DM. FLI decreased significantly in both groups, more markedly in WC (p = 0.034); Fib-4 and NFS decreased, but only Fib-4 changes were significant in both groups.
Conclusion: The study demonstrates the feasibility, long-term effectiveness and non-inferiority of a web-program, similar to an intense group-based lifestyle counselling, in achieving 10% weight loss in subjects on active follow-up. This threshold was previously associated with improvement in fibrosis in studies where the effects of lifestyle changes were measured at NAFLD histology.

Viral hepatitis: Basic science

PS-113
Characterization of host and viral proteins involved in the chromatinization of the hepatitis B virus minichromosome
M. Locatelli[1,2], J. Fresquet[1], S. Maadadi[1], J.P. Quivy[3], B. Testoni[1,2], F. Zoulim[1,2,4,5]. *[1]INSERM U1052, CNRS UMR-5286, Cancer Research Center of Lyon (CRCL), Lyon, France; [2]Université Claude-Bernard (UCBL), University of Lyon, Lyon, France; [3]Institut Curie, PSL Research University, CNRS, UMR 3664, Paris, France; [4]Laboratoire d'excellence (LabEx), DEVweCAN, Lyon, France; [5]Hospices Civils de Lyon (HCL), Lyon, France*
Email: fabien.zoulim@inserm.fr

Background and Aims: The key obstacle to cure chronic HBV infection is the persistence of the covalently closed circular DNA (cccDNA) in the liver. Upon entry into hepatocytes, the partially double stranded viral DNA (relaxed circular (rc)DNA) is released into the nucleus, where it is repaired and wrapped by histones to form an episomal chromatinized structure. To elucidate the still poorly understood mechanisms leading to cccDNA formation and chromatinization, we investigated the involvement of host factors belonging to nucleosome assembly pathways in the early establishment of cccDNA pool in infected cells.
Method: cccDNA appearance was studied by qPCR and Southern Blotting (SB) at early time points (i.e. between 30 minutes and 72 hours) post-infection in HepG2-NTCP cells and primary human hepatocytes (PHH) infected with wild type or HBx-deficient viruses. qPCR quantification of viral RNAs and DNA after siRNA was used to evaluate the impact of the knock-down of specific cellular proteins involved in chromatin remodeling on HBV replication.
Results: Knock-down of ATRX, ASF, BLM and CAF-1p60 before virus inoculation did not show any effect on viral replication or cccDNA appearance. In contrast, silencing of DAXX, CAF-1 p150 and HIRA decreased viral replication and, in the case of HIRA, led to a significant impairment of cccDNA accumulation, both in qPCR and SB. rcDNA levels remained unaffected, indicating either a possible incomplete or delayed rcDNA to cccDNA transition. Chromatin Immunoprecipitation analysis showed that HIRA was bound to cccDNA already at 2 h post-infection and that its recruitment was concomitant with the deposition of histone H3.3 and the binding of HBV capsid protein (HBc), independently from HBx protein expression (using an HBx-defective virus). By co-immunoprecipitation and Proximity Ligation assay experiments, we showed that HIRA was able to interact with HBc in infected hepatocytes and in an HepaRG cell line expressing HBc in an inducible manner.
Conclusion: Our results suggest that chromatinization of incoming viral DNA is a very early event, requiring the nucleosome assembly pathways and, particularly, the histone chaperone HIRA, representing a first step toward the identification of new therapeutic targets to impair cccDNA establishment.

PS-114
Exhaustion of virus-specific and total B cellpopulations by HBV infection

Email: a0133558@u.nus.edu

Background and Aims: Despite the importance of HBV serology in disease classification, B cell biology has been poorly characterized in chronic hepatitis B (CHB) patients. Vast quantities (50–300 μg/ml) of subviral particles containing envelope component (HBsAg) are secreted during HBV infection, yet the host immune system does not mount an effective humoral response. Here we determined the impact of CHB on global and HBV-specific B cells.
Method: Total and HBsAg-specific B cells (identified by double staining with recombinant HBsAg labelled with DyLight-550 or -650) were analyzed by flow cytometry. Peripheral blood samples were obtained from HBV vaccinated subjects (n = 17), patients with resolved (anti-HBs+; n = 17), acute (longitudinal, n = 7) and chronic (different categories, n = 95) HBV infection. HBsAg, HBV-DNA and transaminase levels were quantified in all patients. Immune gene expression and capacity of antibody production of sorted memory B cell subtypes from healthy and CHB patients were analyzed by NanoString, ELISA and ELISPOT. Sorted HBsAg-specific B cells from healthy vaccinated subjects and CHB patients were studied for their ability to differentiate into antibody producing B cells.
Results: Only HBsAg-binding but not double-negative B cells from vaccinated subjects were able to produce anti-HBs after differentiation into plasma cells. In addition, HBsAg-specific plasmablasts were transiently detected following HBV booster vaccination, both demonstrating that the staining protocol identifies bona-fide anti-HBs specific B cells. Surprisingly, their frequency was comparable in CHB patients and vaccinated individuals. Global B cell analysis revealed an enrichment of atypical memory B cells (exhaustion properties, inability to produce IgG) in CHB patients, which was further augmented among HBsAg-binding cells. Transcriptional profiling found suppression of signalling pathways e.g. NF-κB and overall increased expression of genes associated with reduced functionality in CHB patients. Importantly, sorted HBsAg-binding B cells from CHB patients were unable to produce anti-HBs, despite >80% displaying a classical memory phenotype. Addition of recombinant HBsAg or serum of CHB patients to B cells from vaccinated healthy donors inhibited their ability to produce anti-HBs or limited its detection.
Conclusion: General and HBsAg-specific B cell analysis demonstrated their exhausted phenotype and reduced functionality in CHB patients. These features might contribute to anti-HBs seronegativity and persistence of HBV infection.

PS-115

Rescuing hepatitis-B-specific T cell responses by modulating cholesterol metabolism

N. Schmidt[1], L.J. Pallett[2], A. Schurich[1], K. Suveizdyte[1], O.E. Amin[1], F. Froghi[3], B.R. Davidson[3], R. Gillmore[4], T. Meyer[4,5], W. Rosenberg[3], M. Maini[1]. [1]*UCL, Infection & Immunity, London, United Kingdom;* [2]*Division of Infection & Immunity, London, United Kingdom;* [3]*UCL, Institute of Liver and Digestive Health, London, United Kingdom;* [4]*Royal Free Hospital, Oncology, London, United Kingdom;* [5]*UCL, Cancer Institute, London, United Kingdom*
Email: m.maini@ucl.ac.uk

Background and Aims: Immunotherapeutic approaches to boost HBV-specific T cells with antiviral potential require a multipronged approach to optimise these highly defective responses. A recent study demonstrated *in vitro* and *in vivo* enhancement of anti-tumour CD8 T cell efficacy by inhibition of acyl-coenzyme A:cholesterol acyltransferases (ACAT) to promote plasma membrane/lipid raft cholesterol accumulation, resulting in improved T cell receptor (TCR) clustering/signalling (*Yang et al, Nature* 2016). Since HBV-specific CD8 T cells have also been proposed to have changes in their lipid raft composition impairing MHC/peptide binding (*Reignat et al, JEM* 2002), our study aim was to investigate their potential for rescue by modulation of cholesterol metabolism.
Methods: HBV-specific T cells in PBMC were expanded from patients with chronic HBV (CHB) +/− ACAT inhibitor Avasimibe +/− PD-1 blockade. Intrahepatic lymphocytes (IHL) and tumour infiltrating lymphocytes (TIL) were stimulated with HBV peptides or anti-CD3/CD28 +/− Avasimibe.
Results Avasimibe improved effector function of HBV-specific CD8 T cells in more than 50% of patient PBMC (n = 21), with striking enhancements in some cases (maximum increase from 0.29% to 9.09% $IFNy^+CD8$, 0.33% to 4.39% TNF^+CD8 T cells). Similar effects were seen for HBV-specific CD4 T cells, with increased activation markers on responding CD4/CD8 T cells. Importantly, Avasimibe addition just 24 hours before restimulation increased binding of HLA-A2/HBV dextramers, and effector function, without changes in T cell proliferation (Ki-67, cell trace dye dilution). CD36, a high affinity transporter for long chain fatty acids, and Carnitine palmitoyltransferase 1 alpha (CPT1a), the rate limiting enzyme for mitochondrial beta-oxidation of long chain fatty acids, were both significantly increased after ACAT inhibition. Combining Avasimibe with PD-1 blockade showed a non-redundant and/or synergistic effect in PBMC from selected patients. Preliminary data indicate that the effector function of IHL and PBMC and TIL from some patients with hepatocellular carcinoma (HCC) can also be rescued.
Conclusion: We show that ACAT inhibitors, capable of re-programming cholesterol metabolism to enhance immune synapse formation, can rescue immediate effector function in HBV-specific T cells from patients with CHB or HCC. Synergism with PD-1 blockade suggests this may be a promising adjunctive approach for functional cure.

PS-116

Hepatitis E virus triggers mitochondrial fusion to promote viral replication

Y. Wang[1], W. Wang[2], S. Wang[1], M. Peppelenbosch[2], J. Zhao[1], Q. Pan[2]. [1]*302 hospital, Department of Pathology and Hepatology, Beijing, China;* [2]*Erasmus MC-University Medical Center, Department of Gastroenterology and Hepatology, Rotterdam, Netherlands*
Email: yijinwang927015@163.com

Background and Aims: Although hepatitis E virus (HEV) infection is generally self-limiting, severe complications and chronic hepatitis have been reported in special populations. Mitochondrial dysfunctions in hepatitis patients have been reported in many clinical studies. Liver cells contain abundant copies of mitochondria, and mitochondrial morphological dynamics, including the processes of fusion and fission, play important roles in physiology and pathogenesis. This study aims to understand mitochondrial morphological alteration in response to HEV infection and its implication in HEV replication.
Method: Liver biopsies of 17 patients with positive anti-HEV immunoglobulin (Ig) M and 5 control patients with hepatic hemangioma were reviewed for mitochondrial morphology by confocal immunofluorescent imaging. Human liver Huh-7 cells were used to model HEV infection *in vitro* and mitochondrial dynamics were observed by electron microscope and confocal immunofluorescent imaging. Lentiviral mediated RNAi was applied to silence genes that regulate mitochondrial dynamics. Viral replication was analyzed by quantitative real-time polymerase chain in reaction (qPCR).
Results: Immunofluorescent staining of liver biopsies showed that 11 out of 17 (65%) HEV infected patients presented aggregated and fused mitochondria; whereas mitochondria in all 5 uninfected control patients displayed uniform and spotty distribution. Ultrastructural analysis of HEV-infected Huh7 cells by transmission electron microscopy displayed elongated mitochondria (mitochondrial fusion) with obscure cristae. In contrast, mitochondria in uninfected cells displayed short and rod-like mitochondria with clear cristae. Consistently, confocal observation of HEV-infected cells by immunofluorescence substantiated tubular mitochondria, in contrast to dispersive and fragmented mitochondria in uninfected cells. Optic Atrophy 1 (OPA1) and mitofusion 1 (Mfn1) are the well-known positive regulators of mitochondrial fusion. In OPA1 and Mfn1 silencing cells, both the uninfected and HEV-infected cells presented fragmented mitochondria because of the impairment of the fusion machinery. Importantly, silencing of OPA1 or Mfn1 resulted in significant decrease of HEV RNA, suggesting that HEV-induced mitochondrial fusion facilitates viral infection. Further, exogenous mitochondrial dynamic regulator, ginsenoside Rg3 (G-Rg3), which had been reported to abrogate hepatitis C induced mitochondrial fission, was used to treat stable HEV infected cells. Importantly, G-Rg3 was able to promote HEV replication significantly.
Conclusion: HEV infection results in mitochondrial fusion which facilitates viral replication. Targeting mitochondrial dynamics represents a viable option for antiviral drug development against HEV.

A microRNA screen uncovers O-Linked N-Acetylglucosamine transferase as a host factor involved in hepatitis C virus morphogenesis

S. Bandiera[1], S. Pernot[2], K. Herzog[2], C. Fauvelle[2], A. Weiss[3], S. Durand[2], W. Raffelsberger[3], L. Brino[3], T. Baumert[2], M. Zeisel[2]. [1]*Inserm U1110, Strasbourg;* [2]*Inserm U1110, Strasbourg, France;* [3]*IGBMC, Illkirch CEDEX, France*
Email: katharina.herzog@etu.unistra.fr

Background and Aims: Infection of human hepatocytes by the hepatitis C virus (HCV) is a multistep process involving both viral and host factors. Among the host factors involved in the HCV replication cycle there are microRNAs (miRNAs), a class of small non-coding RNAs that post-transcriptionally regulate gene expression in virtually every biological process. Given that miRNAs were indicated to regulate between 30% and 75% of all human genes but their role in HCV infection has never been systematically explored, we sought to exploit miRNAs as a tool for loss-of-function studies of HCV-host interactions and investigate novel factors modulating HCV infection.
Method: To systematically uncover human miRNAs affecting the HCV replication cycle, we performed a two-step functional high-throughput miRNA mimic screen in Huh7.5.1 cells infected with

recombinant cell culture-derived HCV (genotype 2a). miRNA targeting was studied using a combination of computational and functional approaches.
Results: We identified 186 miRNAs that affect HCV entry/replication, and 309 miRNAs that affect viral assembly/release. Since HCV assembly and release are currently the least well-characterized steps of the viral replication cycle, we focused on miRNA hits that modulated late steps of the HCV replication cycle. We uncovered miR-501-3p and miR-619-3p as novel modulators of HCV assembly/infectivity. Furthermore, we discovered that these miRNAs control O-linked N-acetylglucosamine transferase (OGT) protein expression in Huh7.5.1 cells. Finally, by performing functional investigation using RNA interference, we showed that OGT contributes to regulate HCV morphogenesis in liver cells.
Conclusion: In conclusion, by identifying OGT as a novel host factor regulating HCV morphogenesis, our study advanced our current understanding of the HCV-host interactions. Given that OGT was previously shown to contribute to altered metabolism in liver cancer, our results may also unravel a role of OGT as a driver for HCV-induced liver disease and hepatocarcinogenesis.

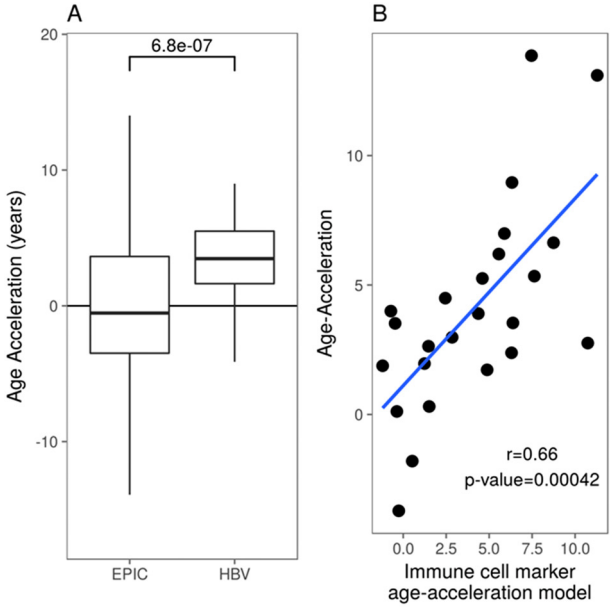
PS-118
The capacity of persistent HCV infection to regulate alloreactive T cells responses is reversed following viral eradication
E. Merritt[1], K. Childs[1], I. Carey[2], K. Agarwal[2], A. Sanchez-Fueyo[1], M. Martinez-Llordella[1]. [1]*King's College London, Liver Science Department, MRC Transplant Centre, London, United Kingdom;* [2]*King's College Hospital, Liver Science Department, London, United Kingdom*
Email: marc.martinez-llordella@kcl.ac.uk

Background and Aims: Selected liver transplant recipients can discontinue immunosuppression and maintain allograft tolerance despite persistent hepatitis C virus (HCV) infection. This phenomenon is associated with increased HCV-induced CD8+ T cell exhaustion, suggesting that HCV infection might exert beneficial effects by restraining anti-donor responses instead of increasing alloreactivity by heterologous immunity. The current availability of directly-acting anti-viral (DAA) agents offers a unique setting to study the effect of viral heterologous immunity on alloreactive T cell responses. Here we aim to investigate whether HCV-specific immunity influences anti-donor reactivity and contributes to the formation of a pro-tolerogenic microenvironment in liver allograft recipients.
Method: We have developed an in vitro assay to investigate to what extent HCV-specific T-cells cross-react with HLA antigens. T cell lines from HCV-infected non-transplanted (n = 12) and liver transplant recipients (n = 16) were derived from FACS sorted HCV-dextramer positive (HCV+) and negative (HCV-) CD8 T cells. HCV- and HCV+ T cell lines were stimulated with K562 cell lines expressing either syngeneic, 3rd party or donor HLA molecules. Alloreactivity was further investigated in HCV-infected liver transplant recipients (n = 10) before and 6 months after DAA treatment employing T cell lines and PBMCs. In addition, we assessed the relationships between the immunophenotype of circulating T cells (activation, exhaustion and regulation markers), the magnitude of endogenous type I interferon responses (serum CXCL10), and the breadth of donor-specific immune responses.
Results: We have revealed the cross-reactivity of HCV-specific CD8 T cells with allogeneic HLA molecules. In liver transplanted recipients, we detected an enrichment of donor HLA-reactive cells among the HCV+ clones compared to 3rd party HLAs (21% and 13% respectively). The increased expression of the exhaustion markers CTLA4 and PD1 in CD8 T cells and serum levels of CXCL10 significantly correlated with a reduction in donor-specific alloreactivity ($p = 0.024$ and $p = 0.035$, respectively). HCV clearance resulted in a reduction in the CD8 T cell exhaustion phenotype ($p = 0.037$). Moreover, the extent of anti-donor HLA alloreactivity increased 6 months after successful DAA treatment ($p = 0.024$). The use of PD1/CTLA4 co-blockade augmented donor-specific responses, but exclusively before viral clearance, indicating that T cell exhaustion induced by HCV infection regulates T cell alloreactivity.
Conclusion: We have documented for the first time the effects of HCV-induced heterologous immunity on allogeneic T cell responses. These findings have practical implications for the management of HCV infection following liver transplantation, and contribute to our understanding on the immunological effects of HCV eradication employing DAA.

PS-119
DNA methylation and immune cell markers demonstrate evidence of accelerated aging in patients with chronic HBV infection, with improvement during treatment
Y. Gindin[1], A. Gaggar[1], S. Kottilil[2], Z. Jiang[1], J.G. Mchutchison[1], M. Subramanian[1], H. Janssen[3], A. Lok[4], C. Ferrari[5]. [1]*Gilead Sciences Inc.;* [2]*University of Maryland School of Medicine, Institute of Human Virology;* [3]*University Health Network, Toronto, Canada;* [4]*University of Michigan Health System, Division of Gastroenterology and Hepatology, United States;* [5]*University of Parma, Unit of Infectious Diseases and Hepatology, Laboratory of Viral Immunopathology, Azienda Ospedaliero-Universitaria di Parma, and Department of Medicine and Surgery, Italy*
Email: yevgeniy.gindin@gilead.com

Background and Aims: DNA methylation (DNAm) levels are a measure of human biologic age and a set of 353 genomic markers in whole blood has been shown to be associated with accelerated aging and overall mortality in several disease states. Here, we evaluated blood DNAm and a novel immune marker model to assess biological age acceleration in patients with chronic HBV infection (CHB) and explored the effects of viral suppression on immune-imputed model of age acceleration.
Method: DNA methylation was assessed using the Infinium HumanMethylation450K BeadChip from patients with CHB virally suppressed on an oral antiviral (n = 54) and publicly available age-matched healthy control samples (n = 288). Age acceleration was calculated in CHB patients as the difference between an individual's DNAm age and one calculated from a linear model derived using the healthy control samples. Separately, peripheral blood immunophenotyping data were collected serially over 48 weeks for HBV patients who were initiated on TDF therapy (n = 195). A novel model to infer age acceleration from blood marker data was built using a regularized regression method (elastic net) from an independent dataset and validated in this study. The elastic net model identified a set of 16 immune markers, along with their coefficients, as optimal predictors of age acceleration.
Results: Age acceleration is significantly higher (median = 3.5 years; $p = 6.8 \times 10^{-7}$) in virally-suppressed patients with CHB compared to that of an independent set of normal controls (Figure 1A). For these 54 CHB subjects, age acceleration inferred from peripheral blood immunophenotyping is concordant with DNAm-based measure ($r = 0.66$, $p = 4.2 \times 10^{-4}$) (Figure 1B). Using immunophenotyping-inferred age acceleration from CHB subjects not on treatment (n = 195), age acceleration showed a significant decrease ($p = 0.0062$) after initiating antiviral therapy, with a 0.5 year median reduction in age < acceleration by Week 48 (Figure 1C). The decrease in age acceleration with antiviral therapy is associated with the decrease in relative abundance of activated T-cell subsets ($p < 0.001$).

Conclusion: Patients with CHB exhibit age acceleration, even after viral suppression. Cellular activation markers accurately predict age acceleration and could be causally related to the age acceleration process. A reduction in age acceleration as derived from immuno-phenotyping suggests potential benefit of antiviral therapy and warrants further investigation.



PS-120

Hepatitis C virus leaves epigenetic signature post cure by direct-acting antivirals that is linked to distinct mutation signature

M. Gal-Tanamy[1], S. Perez[2], A. Lavi-Itzkovitz[2], A. Kaspi[3], A. Davidovich[2], A. Tobar[4], A. Livoff[5], A. Nimer[6], E. Solomonov[7], A. El-Osta[3], G. Yaari[8], S.M. Stemmer[9], I. Haviv[1], M. Gal-Tanamy[1]. *[1]Bar-Ilan University, Faculty of Medicine, Israel; [2]Bar-Ilan University, Faculty of Medicine, Safet; [3]Monash University, Department of Diabetes, Australia; [4]Rabin Medical Center, Institute of Pathology, Israel; [5]Barzilay Medical Center, Department of Pathology, Israel; [6]Western Galilee Medical Center, Faculty of Medicine, Israel; [7]Ziv Medical Center, Department of Surgery, Israel; [8]Bar-Ilan University, Faculty of Engineering, Israel; [9]Rabin Medical Center, Davidoff Center, Israel*
Email: mgtanamy@gmail.com

Background and Aims: Hepatitis C virus (HCV) is a leading cause of hepatocellular carcinoma (HCC). While direct acting antivirals (DAAs) therapy for HCV efficiently eradicate the infection, epidemiological studies show that sustained virological response (SVR) following anti-HCV treatment does not eliminate the risk for HCC.
We hypothesize that HCV infection promotes epigenetic alternations that induce host gene expression program that is involved in cellular networks that are essential to HCV life cycle and are implicated in oncogenesis. Moreover, HCV leaves an "epigenetic signature" on the host chromatin that is not fully recovered following virus eradication after treatment with DAAs and can be reverted by epigenetic modifier drugs.
Method: The patterns of gene expression and genome-wide histone modifications for active and repressed chromatin were evaluated in HCV-infected hepatocytes before treatment and following one month of viral eradication by treatment with DAAs. To explore the link between genome wide chromatin organization and genomic signature we studied mutational signature by detecting low-frequency passenger mutations in 64 HCC samples from three etiology groups – HBV, HCV, or other.
Results: We demonstrated that HCV infection induces epigenetic changes that reprogram host gene expression and persist as "epigenetic signature" following virus eradication. Treatment of HCV-cured cells with inhibitors for different epigenetic modifiers reverted the epigenetic signature and the HCV-induced oncogenic phenotypes of cell invasion that remain persistent following DAAs treatment. Moreover, we found enrichment of C to T mutations in HCC liver biopsies on HCV etiology, compared to other HCC etiologies that may reflect the known signature of APOBEC that we observed to be upregulated in HCV infected and cured cells, and the down regulation of the base excision repair pathway that is responsible for its repair.
Conclusion: These results demonstrate that HCV-induced epigenetic missregulation that is essential for the HCV life cycle that persists following its eradication. This HCV "hit and run" scenario may explain why some chronic HCV infected patients do proceed to develop HCC after HCV eradication. Our discoveries provide a new insight into the outcomes of HCV infection and HCC development, also following SVR, and establish a novel mechanistic link between virus etiology and cancer genome.

Background and Aims: The efficacy and safety of Glecaprevir/Pibrentasvir (G/P) among Hepatitis C Virus (HCV) infected patients have been only investigated in clinical trials, no real-life data are available yet. The aim of the study was to investigate the effectiveness and safety of G/P in an Italian real-life setting.
Method: All HCV Italians consecutively treated with G/P within the Lombardy web-based Navigator-II Network were analysed. G/P was administered according to drug label (12 or 16 weeks). Fibrosis was determined histologically or non-invasively, through liver stiffness measurement (LSM). Sustained Virological Response 4 (SVR4) was defined as undetectable HCV-RNA 4 weeks after the end of treatment (EOT).
Results: Between October 2017 and January 2018, 723 patients (49% males) were treated with G/P. Their age was 58 (21-89) years, BMI 23.9 (15.8-39.7) Kg/m^2 and LSM 6.1 (2.5-43.0) kPa. Fibrosis was F0 in 17%, F1 in 45%, F2 in 22%, F3 in 9% and F4 in 7%. 16% of them were IFN-experienced. HCV-RNA was 1,102,600 (21-38,300,000) IU/ml, and HCV genotype 1 in 50% (35% HCV – 1b), 2 in 28%, 3 in 9% and 4 in 12%. HBV or HIV coinfection were reported in 0.3% and 6%, respectively. eGFR was 90.2 (47.0-272.5) ml/min (30% CKD1, 42% CKD2, 8% CKD3, 1% CKD4, 1% CKD5), PLT 209 (46-812) x 10^3/mm^3, ALT 50 (8-568) U/l, albumin 4.3 (2.7-5.9) g/dl, bilirubin 0.66 (0.14-4.50) mg/dl. Planned treatment duration was 8 weeks in 89%. HCV-RNA was undetected in 71% and 98% of the patients at week 4 and EOT, respectively. EOT responses were independent on fibrosis (F4 vs. non-F4: 100% *vs.* 97%, p=1.0), PLT (< 150 *vs.* ≥150 x 10^3/mm^3: 100% *vs.* 97%, p=0.64), HCV-RNA (<800,000 *vs.* ≥800,000 IU/ml: 99% *vs.* 97%, p=0.64), CKD stage (1 *vs.* 2 *vs.* 3 *vs.* 4: 95% *vs.* 97% *vs.* 100% *vs.* 100%, p=0.98), HIV (yes *vs.* no: 97% *vs.* 100%, p=1.0), age (<75 *vs.* ≥75: 97% *vs.* 100%, p=1.0), treatment duration (8 *vs.* 12/16-weeks: 97% *vs.* 100%, p=1.0) or center capability (<30 *vs.* >30 patients: 97% *vs.* 97%, p=1.0). The lowest EOT rates were observed in HCV-1 patients (HCV-1 *vs.* others: 96% *vs.* 99%, p=0.003). In the subset of patients with available off-treatment responses, the SVR4 rates were 100%. No treatment-related adverse events were reported, only one patient had to prematurely discontinue G/P.
Conclusion: In a large real-life Italian cohort of HCV patients, the virological responses and the safety profile to G/P were excellent. Full SVR results will be reported at ILC 2018.

GS-014

NGM282 improves fibrosis and NASH-related histology in 12 weeks in patients with biopsy-confirmed NASH, which is preceded by significant decreases in hepatic steatosis, liver transaminases and fibrosis markers at 6 weeks

S. Harrison[1], S. Rossi[2], M. Bashir[3], C. Guy[4], R. Banerjee[5], M. Jaros[6], S. Owers[1], B. Baxter[2], L. Ling[2], A. Depaoli[2]. [1]*Pinnacle Clinical Research, Research Department, San Antonio, United States;* [2]*NGM Bio, Clinical Research, San Francisco, United States;* [3]*Duke University, Department of Radiology, Durham, United States;* [4]*Duke University, Department of Pathology, Durham, United States;* [5]*Perspectum Diagnostics, Oxford, United Kingdom;* [6]*Summit Analytical, Denver, United States*
Email: srossi@ngmbio.com

Background and Aims: NGM282 is a non-tumorigenic analogue of human FGF19 demonstrating rapid and significant reductions in hepatic steatosis, liver transaminases and fibrosis markers after 12w of treatment with 3 and 6mg compared to placebo. The translation of these acute non-invasive changes to improvements in histology was evaluated with the addition of a 12w biopsy. MRI-PDFF, liver transaminases, Pro-C3 and multi-parametric imaging with Liver*Multi*Scan™ (LMS) were assessed at baseline, 6w and 12w to assess earlier treatment responses.
Method: Twenty-two subjects were enrolled and received NGM282 3mg daily for 12w. Key inclusion criteria included biopsy-proven NASH within 3m of screening, NAS ≥ 4 (at least 1pt in each component), stage 1–3 fibrosis and absolute liver fat content (LFC) by MRI-PDFF ≥ 8%. The primary endpoint was a reduction in absolute LFC ≥ 5%. Interim efficacy and safety were assessed on 16 subjects completing 12w of treatment. Liver biopsies were performed at screening and 12w, which were then blinded and read by an independent hepatopathologist using the NASH CRN criteria.
Results: Baseline absolute LFC (17%), ALT (84 IU) and liver inflammation-fibrosis (LIF) score by LMS (2.76) were consistent with NASH activity on biopsy. Absolute LFC changed by –9.5% and –10.9% at

ELSEVIER

6w and 12w, respectively, with 100% meeting the primary endpoint. The decrease in relative LFC was 66% at 12w, with 100% achieving a clinically-meaningful ≥30% decrease. ALT significantly decreased by 38 IU at 2w and 53 IU by 12w. Importantly, fibrosis improved by ≥1 stage in 8 (50%) subjects, with 3 subjects improving by two stages (all Stage 3 to 1). NAS was decreased by ≥2 points (including at least 1 point of inflammation or ballooning) in 10 (63%) subjects, with 8 (50%) meeting the regulatory agency-endorsed histologic endpoints used in current Phase 3 studies. Steatosis was completely resolved in 8 (50%) subjects with all others decreasing to Stage 1 steatosis. Pro-C3 levels were significantly decreased by 6w and remained suppressed through 12w, with the greatest magnitude observed in subjects with fibrosis changes. LIF score decreased by −0.68 at 12w, consistent with the profound changes in MRI-PDFF, biomarkers and histology. LDL increased by a similar magnitude to previous studies but was mitigated within 2–4w by a statin. The most common adverse events were mild loose/frequent stools and injection site reactions.
Conclusion: Treatment of NASH with NGM282 for 12w results in unprecedented improvements in liver histology, and is preceded by significant improvements in liver transaminases, Pro-C3 and imaging by 6w. These data warrant further evaluation of NGM282 in late stage trials.

GS-015

Primary spontaneous bacterial peritonitis prophylaxis is associated with greater ICU admission and 30-day mortality compared to secondary spontaneous bacterial peritonitis prophylaxis

J.S. Bajaj[1], P. Tandon[2], J. O'leary[3], F. Wong[4], S. Biggins[5], G. Garcia-Tsao[6], P. Kamath[7], B. Maliakkal[8], M. Fallon[9], P.J. Thuluvath[10], J. Lai[11], R. Subramanian[12], H.E. Vargas[13], L. Thacker[14], R. Reddy[15]. *[1]Virginia Commonwealth University and McGuire VAMC, Gastroenterology, Hepatology and Nutrition, Richmond, United States; [2]University of Alberta, Edmonton, Canada; [3]Baylor University Medical Center, Dallas, United States; [4]University of Toronto, Medicine, Toronto, Canada; [5]University of Washington, Seattle, United States; [6]Yale University, New Haven, United States; [7]Mayo Clinic, Rochester, United States; [8]University of Tennessee, Memphis, United States; [9]University of Arizona, Phoenix, United States; [10]Mercy Medical Center & University of Maryland School of Medicine, Baltimore, United States; [11]University of California, Division of Gastroenterology, San Francisco, United States; [12]Emory University, Atlanta, United States; [13]Mayo Clinic, Scottsdale, United States; [14]Virginia Commonwealth University, Richmond, United States; [15]University of Pennsylvania, Philadelphia, United States*
Email: jasmohan.bajaj@vcuhealth.org

Background and Aims: Spontaneous bacterial peritonitis (SBP) is a major cause of death in cirrhosis and, while secondary prophylaxis (2°) is recommended to prevent recurrence, the value of long-term primary prophylaxis (1°) is uncertain, particularly given the possibility of generating antibiotic-resistant bacteria. We aimed to compare the outcomes in patients with cirrhosis on 1° *vs.* those on 2° prophylaxis for SBP in a large inpatient cohort.
Method: NACSELD (North American Consortium for Study of End-Stage Liver Disease) consists of inpatients with cirrhosis admitted non-electively in 14 centers. Cirrhosis details, reasons for admission and medications along with inpatient and 30-day course are recorded prospectively. We compared the outcomes (ICU admission, ACLF development as per NACSELD diagnostic criteria, 30-day mortality) between groups on 1° *vs.* 2° prophylaxis with propensity matching based on MELD score and serum albumin.
Results: 2731 cirrhotic pts were included of which 2239 were not on SBP prophylaxis, 305 were on 1° and 187 were on 2° SBP prophylaxis. After MELD and albumin matching 154 patients remained in each SBP prophylaxis group (Table). A significantly higher number of patients on 2° prophylaxis had previous admission, were admitted with infection, especially SBP and had admission hepatic encephalopathy and refractory ascites. Patients on 1° prophylaxis patients were more likely to have SIRS on admission and their rate of ICU admission and 30-day mortality was higher than in the 2° prophylaxis group. ACLF, nosocomial, fungal and second infections were similar between groups.
Conclusion: Despite being on primary or secondary SBP prophylaxis, a significant number of patients developed SBP. Unexpectedly, patients on 1° had poorer outcomes than those on 2° prophylaxis when propensity matched for MELD score and serum albumin. The value of SBP prophylaxis (both primary and secondary) in current times requires re-evaluation.

Mean ± SD and numbers (%)	Primary prophylaxis (n = 154)	Secondary prophylaxis (n = 154)	p-value
Age (years)	56.71 (10.39)	56.17 (9.92)	0.70

A phase 1/2, randomized, placebo controlled and open label extension studies of Givosiran and investigational RNA interference therapeutic, in patients with acute intermittent porphyria

E. Sardh[1], M. Balwani[2], P. Harper[3], P. Stein[4], D. Rees[4], J. Bloomer[5], D.M. Bissell[6], C. Parket[7], J. Phillips[8], H. Bonkovsky[9], R. Desnick[10], N. Al-Tawil[11], S. Rock[12], C. Penz[12], A. Chan[12], W. Querbes[12], A. Simon[12], K. Anderson[13]. *[1]Karolinska University Hospital, Centre of Inherited Metabolic Diseases CMMS; [2]Icahn School of Medicine at Mount Sinai; [3]Karolinska University Hospital, Karolinska Institute, Porphyria Centre Sweden; [4]King's College Hospital; [5]University of Alabama; [6]University of California; [7]University of Utah, Department of Internal Medicine, Salt Lake City, United States; [8]University of Utah; [9]Wake Forest University, School of Medicine, Winston-Salem, United States; [10]Mount Sinai, Icahn School of Medicine, Department of Genetics and Genomic Sciences, New York, United States; [11]Karolinska Trial Alliance Phase 1 Unit; [12]Alnylam; [13]University of Texas Medical Branch*
Email: srock@alnylam.com

Background and Aims: Acute hepatic porphyrias (AHP) are a family of rare genetic diseases due to mutations in the enzymes responsible for heme synthesis. Central to the pathophysiology of all AHP is the induction of aminolevulinic acid synthase 1 (ALAS1), the rate limiting step in heme synthesis, which can lead to accumulation of the neurotoxic heme intermediates aminolevulinic acid (ALA) and porphobilinogen (PBG) that are causal for acute neurovisceral attacks and chronic symptoms. Givosiran is an investigational RNA interference (RNAi) therapeutic targeting liver ALAS1 to reduce ALA and PBG accumulation in AHP patients and ameliorate disease manifestations.
Methods: A phase 1, multinational, randomized, placebo-controlled, study was conducted in 3 parts; Part A single ascending dose, Part B multiple ascending dose and Part C multiple dose study to evaluate

the safety, tolerability, pharmacokinetics, and pharmacodynamics of subcutaneously administered givosiran in AIP patients. Part C also had exploratory analyses of clinical activity, including the impact of givosiran on porphyria attacks and heme treatment (ClinicalTrials.gov Identifier: NCT02452372). Patients completing Phase 1 were eligible to enrol in the open label extension study (NCT0294983).
Results: As of May 2017, givosiran was generally well tolerated in Part C (Cohorts 1–3), with no serious adverse events or clinically significant laboratory abnormalities related to study drug. Circulating ALAS1 mRNA levels had a mean (SEM) maximal reduction of 70% ± 3% relative to baseline, with concomitant ALA and PBG reductions of 77% and 76% compared to baseline, respectively, at the 2.5 mg/kg monthly dose. Patients treated with givosiran had a 73% mean decrease in the annualized attack rate (requiring hospitalization, urgent care, or hemin) compared to placebo, and a 73% mean decrease in the annualized number of hemin doses in the treatment versus run-in period. As of May 2017, the safety profile in patients in the OLE (n = 8) was consistent with that observed in Part C, as was the maintenance of clinical activity seen in the Phase 1.
Conclusions: Givosiran was generally well-tolerated and resulted in rapid, dose-dependent, and durable lowering of neurotoxic intermediates ALA and PBG. Importantly, this ALA and PBG lowering was associated with marked reductions in both the annualized attack rate and annualized hemin use. Complete Phase 1 study data will be presented along with interim study data from the Phase 1/2 OLE study.

GS-017

Reduction in the incidence of hepatitis C-related decompensated cirrhosis associated with national scale-up of direct-acting antiviral therapies targeting patients with advanced liver fibrosis

S. Hutchinson[1], H. Valerio[1], J. Dillon[2], R. Fox[3], H. Innes[1], A. Weir[4], S. Barclay[5], S. Mcdonald[1], N. Kennedy[6], A. Fraser[7], A. Stanley[5], P. Bramley[8], P. Hayes[9], D. Goldberg[4]. Email: sharon.hutchinson2@nhs.net

Background and Aims: Direct-acting antivirals (DAAs) for chronic hepatitis C virus (HCV) have been shown to be highly effective in terminating active infection. Evidence of the impact of DAAs in averting severe liver morbidity at the population level is however lacking. Scotland, like most other countries, prioritized DAAs (following first licensing in May 2014) to patients with advanced liver fibrosis, but also set an ambitious target to reduce the incidence of HCV-related decompensated cirrhosis (DC) by 75% by 2020. Unlike most other countries, Scotland has national surveillance of HCV treatment and disease; thus, we aimed to examine the early impact of DAAs on HCV-related DC at the population level.
Method: Data on the number and characteristics of persons initiated on HCV therapy in Scotland up to March 2017 were obtained from the Scottish HCV Clinical database. Record-linkage of Scotland's HCV Diagnosis database to the national inpatient hospital database generated data on the numbers of persons with a chronic HCV diagnosis that had presented and been admitted to hospital for the first time with DC (defined as ascites, hepatic encephalopathy, hepatorenal syndrome or bleeding varices) during 2000–2016.
Results: In the three years since the introduction of DAAs (April-14 to March-17), 4,800 people were initiated on HCV therapy in Scotland, involving: 54% with genotype 1 and 38% genotype 3; 24% with F2/3 fibrosis stage, 27% compensated and 5% decompensated cirrhosis; 83% treated with DAAs; and 94% with a sustained viral response (SVR) (based on 3240 with available data to date). The number initiated on therapy was 1.6-fold and 2.8-fold higher in this period (April-14 to March-17), compared to the preceding three years, for all patients and those with compensated cirrhosis, respectively. Between 2013 and 2016, we observed a 29% reduction in first-time presentations for DC among all persons previously diagnosed with chronic HCV (Fig 1); a larger reduction (39%) was observed among those with chronic HCV at the time of DC admission. However, first-time admissions for DC doubled from 10 in 2013 to 20 in 2016 among persons who had attained SVR prior to DC presentation.

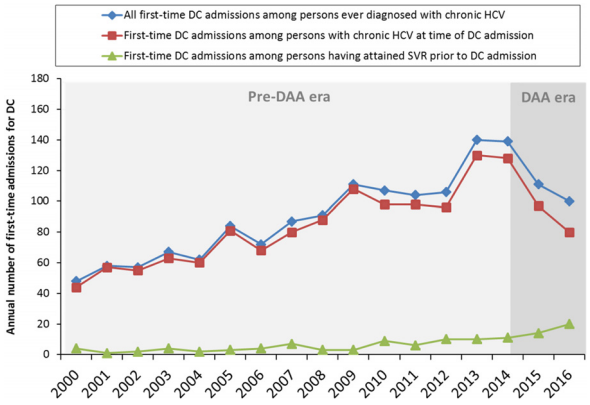

Figure 1: Annual number of first-time hospital admissions for decompensated cirrhosis (DC) in Scotland during 2000–16, among persons previously diagnosed with chronic HCV infection.

Conclusion: These data provide the first country-level evidence of the immediate impact that DAAs can have in averting HCV-related DC. Greater emphasis needs to be placed however on addressing comorbidities that pose a continued risk of liver disease progression among those attaining SVR.

Email: brian.mcnabb@gilead.com

Background and Aims: Based on early registry and cohort study results, patients with cirrhosis who achieve SVR with DAA therapy experience improvements in hepatocellular carcinoma risk, liver-related morbidity, and mortality. However, follow-up time for these studies is generally short. This analysis from the Gilead Cirrhosis Registry evaluates long-term outcomes in patients with cirrhosis who achieved SVR following treatment with a sofosbuvir-(SOF) based regimen.
Methods: Patients with cirrhosis who achieved SVR after receiving a SOF-based regimen were eligible to be enrolled within 60 weeks of

completing a treatment study or transfer from another SVR registry study, or within 2 years of achieving SVR following treatment in clinical practice. Enrolled patients return for visits every 24 weeks for up to 5 years for laboratory, clinical, and radiographic assessments of durability of SVR and clinical aspects of liver disease (HCC, CTP score, MELD score, signs of liver decompensation, liver fibrosis, transplantation, and death). Here we report select parameters. All parameters will be presented at conference proceedings.

Results: As of 5 OCT 2017, 1564 patients have been enrolled in the cirrhosis registry. Mean age (range) is 59 (26–86) years, 68% are male, and 84% and 15% of patients had pretreatment CTP scores A and B + C, respectively. Median (range) of registry follow-up time was 53 (<1–144) weeks. Overall, there were 55 observed events of HCC, in 3,922 person-years (PYs) of follow-up since the start of DAA treatment (34 cases in 3,292 PYs of follow-up for CTP A patients and 21 in 601 PYs of follow-up for CTP B + C patients). Overall, there have been 20 liver transplantations and 5 liver-related deaths. CTP class changes from pretreatment throughout the registry study are presented in the Table. Overall, patients with pretreatment CTP A cirrhosis maintained CTP A status (99% at registry week 96) while patients with pretreatment CTP B or C cirrhosis showed improvement (67% of CTP B and 86% of CTP C patients had CTP A cirrhosis at registry week 96). There were 3 virologic failures (1 reinfection and 2 without baseline samples to distinguish reinfection from relapse by sequencing).

Pretreatment CTP Class, n (%)	Registry Baseline			Registry Week 48			Registry Week 96		
	CTP A	CTP B	CTP C	CTP A	CTP B	CTP C	CTP A	CTP B	CTP C
CTP A, n = 1318	1211/1250 (97)	37/1250 (3)	2/1250 (<1)	768/793 (97)	24/793 (3)	1/793 (<1)	256/260 (99)	4/260 (2)	0/260
CTP B, n = 201	127/187 (68)	60/187 (32)	0/187	95/151 (63)	55/151 (36)	1/151 (<1)	32/48 (67)	16/48 (33)	0/48
CTP C, n = 26	10/21 (48)	11/21 (52)	0/21	13/19 (68)	6/19 (32)	0/19	6/7 (86)	0/7	1/7 (14)

Conclusion: In this ongoing registry of patients with cirrhosis who achieved SVR after treatment with a SOF-based regimen, HCC was uncommon and occurred more often in patients with decompensated cirrhosis. The majority of patients maintained or improved their CTP category relative to pretreatment through up to week 96.

Email: audreycoilly@gmail.com

Background and aims: Acute liver failure (ALF) of unknown cause represents between 10% to 50% of ALF, worldwide. Their prognosis is poorer compared to those when a cause is identified. To date, no study has specifically focused on the prognosis of these patients. The main objective was to determine the factors associated with liver transplantation (LT)-free survival at 3 months.

Method: This prospective multicentre HASIPRO study included patients from 26 French centres between Jun 13 and Dec 16. The inclusion criteria were (1) severe ALF defined by an INR >1.5, (2) no obvious cause at admission, especially viral hepatitis A and B and drug exposure that could be involved. The quantitative variables are presented in median ± IQR.

Results: This study included 70 patients (median age: 44 y.o, 66% of female gender). At baseline, 26% of patients had grade ≥1 hepatic encephalopathy. The main biological characteristics were: ALT 1324 [426–3105] IU/L, total bilirubin 203 [74–336] μmol/L, INR 2.7 [1.9–4.2] and MELD score 27 [21–35]. Fifty-six (80%) patients were hospitalized in ICU, requiring in 40%, 28% and 13% mechanical ventilation, vasopressor agents and extra-renal dialysis, respectively. Overall and LT-free survivals were 86% and 45%, respectively (Figure 1). Of the 30 transplant patients, 46% fulfilled the KCH and/or Clichy-Villejuif criteria for LT. The sensibility, specificity, positive, negative predictive values were 43, 96, 93, 56% and 4, 93, 50, 32% for KCH and Clichy-Villejuif criteria, respectively.

One cause could be determined in 55 (76%) patients after 3 months of follow-up, mainly 16 (23%) autoimmune hepatitis, 7 (10%) DILI, 5 (7%) viral hepatitis (including 3 HEV).

In multivariate analysis, baseline criteria significantly associated with LT-free survival at 3 months were:

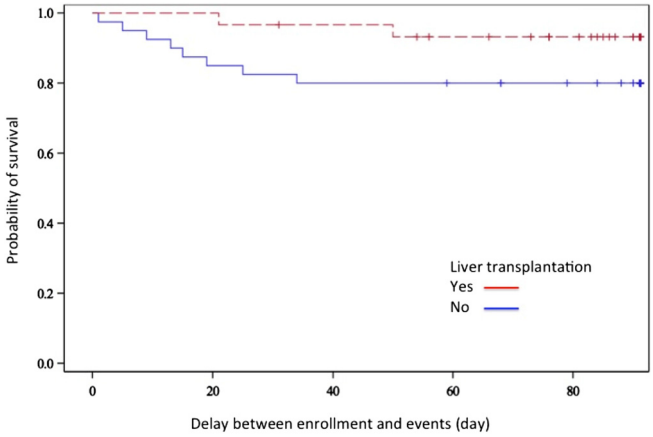

Figure 1: Three-months survival among 70 patients with ALF of unknown cause.

Conclusion: Severe ALF of unknown cause represents a proper nosological entity grouping miscellaneous causes. The prognosis is poor and LT-free survival rate is of 45% at 3 months. The usual transplantation criteria for fulminant hepatitis are not fulfilled in more than half of the patients. Therefore, it is mandatory to establish

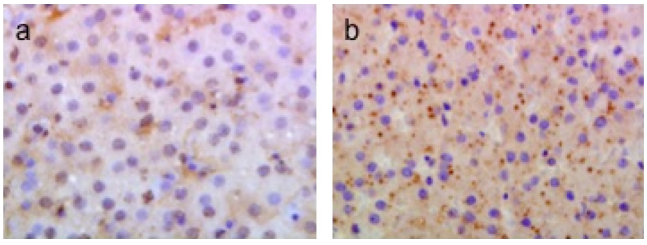
new and dynamic criteria for this population that will be presented at the meeting.

PS-122

Platelet aggregation contributing to reperfusion injury can be prevented by normothermic ex vivo liver perfusion prior to liver transplantation

D. Kollmann[1], I. Linares[1], S. Ganesh[1], R. Rosales[1], Mátyás Hamar[1], P. Urbanellis[1], A. Wiebe[1], P. Yip[2], O. Adeyi[3], M. Selzner[1], N. Selzner[1].
[1]Toronto General Hospital, Department of Surgery, Toronto Organ Preservation Laboratory, Toronto, Canada; [2]Toronto General Hospital, Laboratory Medicine Program and Department of Laboratory Medicine and Pathobiology, Toronto, Canada; [3]Toronto General Hospital, Laboratory Medicine and Pathobiology, Toronto, Canada
Email: Dagmar.kollmann@meduniwien.ac.at

Background and Aims: Normothermic ex vivo liver perfusion (NEVLP) is a rapidly evolving method of graft preservation used as an alternative to static cold storage (SCS). The role of platelets in hepatic sinusoidal endothelial cell (SEC) injury after ischemia and reperfusion has been reported mainly in SCS settings. In this study, the impact of NEVLP vs SCS on platelet aggregation and platelet-mediated SEC injury has been investigated.
Method: Pig liver transplantation (PLT) was performed with donor livers either subjected to 8hrs of SCS (SCS-group) or to NEVLP (NEVLP-group) prior to transplantation (n = 5/group). Liver biopsies were obtained 3hrs post-PLT and stained for H&E, CD31 and CD61. Platelet aggregation was scored as clumps per 5 20x HPF units (Figure 1). CD31 was scored on a scale of 1–4 (none to minimal loss of staining = 1 – diffuse loss of staining = 4). Liver enzymes, platelet counts, Platelet-factor-4 (PF-4), TGF-β and Hyaluronic Acid (HA) levels as well as other parameters (Prothrombin Time, INR, Hemoglobin) were measured during a 3-day survival period.
Results: All pigs survived for 3 days. The NEVLP-group showed significantly less ischemic injury with lower AST on postoperative day (POD)1 (581 vs. 1675 U/l, p = 0.003) & POD2 (190 vs. 1198 U/l, p = 0.005). Platelet count recovery was faster in the NEVLP- vs. SCS-group (% of baseline) at 12hrs after PLT (67% vs. 31%; p = 0.019) & at 24hrs (72% vs. 21%; p = 0.007). Intrahepatic sequestration of platelets was higher in the SCS group, with significantly more aggregation in liver sinusoids: SCS mean # clumps/5 HPF = 70 ± 46 vs. NEVLP = 4 ± 1.6, p = 0.039. Platelet aggregation correlated with SEC injury: mean SCS CD31 score = 3.6 ± 1 vs. NEVLP = 1.9 ± 0.2; p = 0.018. Consistently, HA levels were significantly higher in the SCS- vs. NEVLP-group (HA levels POD1: 1196 ± 438 vs. 193 ± 65 µg/ml, p = 0.005). Also, PF-4 levels increased in SCS, but not in NEVLP at 24hrs (SCS vs. NEVLP: 204 ng/ml vs. 104 ng/ml, p = 0.006). Both groups expressed increased TGF-ß but the increase was higher in the SCS-group and remained significantly higher at POD3 (7.4 vs. 5.3 ng/µl, p = 0.026).



Conclusion: This study demonstrates intrahepatic platelet aggregation as a contributor to and a measure of SEC injury. Platelet aggregation after reperfusion was prevented by normothermic perfusion of the grafts prior to transplantation. Therefore, NEVLP prior to transplantation allows a faster recovery of the platelet count after transplantation and might protect the liver from platelet induced SEC injury.

PS-123

The main determinant of circulating exosomal miRNA profile across a spectrum of patients with liver injury is the degree of liver failure

S. Mastoridis, V. Patel, C. Woodhouse, M. Martinez-Llordella, A. Sanchez-Fueyo. *King's College London, Institute of Liver Studies, London*
Email: sotiris.mastoridis@googlemail.com

Background and Aims: Exosomes are nanosized vesicles released by most liver cell-subsets, and are recognised to be important mediators of intercellular communication. Exosomes can alter the liver's microenvironment and exert systemic effects by transferring to other cells miRNAs contained within their protective phospholipid bilayer membrane. While liver injury is known to be associated with drastic changes in the circulating exosome and miRNA repertoires, the extent to which this is a disease-specific phenomenon and/or a response to liver cell death, liver failure, or systemic inflammation is unclear. A thorough understanding of this process is required to clarify the role of exosomes/miRNA in the pathogenesis of liver failure syndromes and their potential utility as diagnostic and prognostic biomarkers.
Method: Plasma was collected from healthy controls (HC; n = 20) and patients with acute-on-chronic liver failure (ACLF; n = 19), stable cirrhosis (SC; n = 18), decompensated cirrhosis (DC; n = 19), acute liver failure (ALF; n = 20), and non-liver sepsis (SEP; n = 10). Exosomes were isolated by size-exclusion chromatography (SEC) and their presence validated by electron microscopy, Western blot, and nanoparticle tracking analysis. miRNA was extracted from exosome isolates and a comprehensive miRnome analysis using 800 probes was performed by the Nanostring™ nCounter platform. Statistical analyses were performed using SPSS and the Limma (v3.10.2) package for R statistical environment.

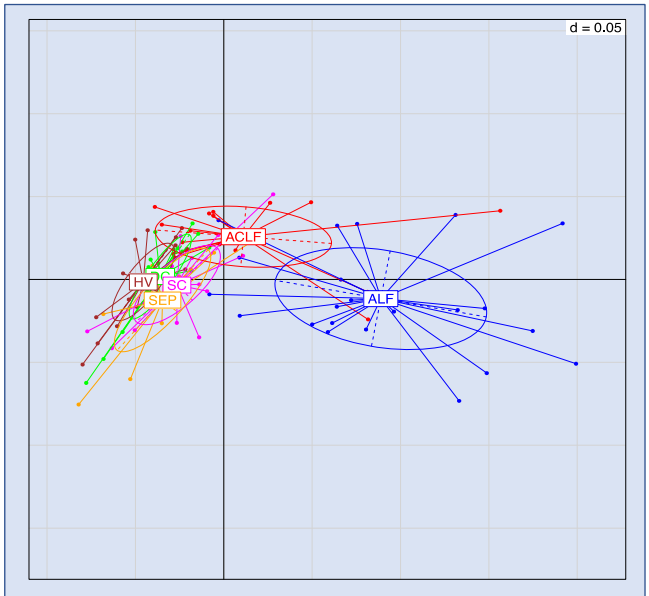


Figure 1: Principal Component Analysis (PCA) of exosomal miRNA expression profiles among six groups of study.

Results: Significantly differentially expressed exosomal miRNA were identified between all patient groups and the healthy controls. An unsupervised principal component analysis (Figure 1) revealed that the ALF and ACLF groups diverged the most from the control group. A correlation analysis showed that MELD score and other markers reflecting the degree of liver failure (e.g. Bilirubin, INR, Child-Pugh score) influenced the largest number of exosomal miRNA species, with much weaker effects exerted by broader sepsis/organ-failure

scores such as SOFA. Highly differentially expressed miRNA in LF patients' exosomes included those known to be highly expressed by liver tissue (e.g. miR-122–5p).
Conclusion: Liver damage is associated with distinct circulating exosomal miRNA profiles. This mainly correlates with the degree of liver dysfunction and not with the aetiology of liver injury, presence of sepsis or systemic inflammatory responses. Our data are the first to study exosomes and their content across a wide-spectrum of liver diseases and underlying aetiologies. Strong correlation of these miRNA with MELD-score points indirectly to their prognostic potential. Further analyses of our cohorts' clinical outcomes-data are in progress in order to clarify these associations and their functional downstream consequences.

PS-124

Early and late liver-related mortality following drug induced liver injury from amoxicillin-clavulanate

H. Tillmann[1,2], C.M. Hunt[3,4], M. Austen[5], J. Williams[5], A. Suzuki[3,4,6].
[1]Greenville VA Health Care Center, Greenville, NC, United States; [2]East Carolina University, Medicine, Division Gastroenterology, Hepatology and Nutrition, Greenville, NC, United States; [3]Duke University, Gastroenterology, Durham, NC, United States; [4]Durham VA Medical Center, HSR&D, Durham, NC, United States; [5]Central Arkansas Veterans Healthcare System, HSR&D, Little Rock, AR, United States; [6]Durham VA Medical Center, Gastroenterology, Durham, NC, United States
Email: tillmannh14@ecu.edu

Background and Aims: Amoxicillin/clavulanate (AMX/CLA) is one of the most common drugs resulting in drug induced liver injury (DILI) associated with a 17–39% hospitalization rate and 3–5% mortality rate. In the Veterans Health Administration (VHA) 2004–2014, 847,749 first AMX/CLA exposures were associated with a 0.14% DILI incidence in patients without baseline liver disease. We further assessed liver-related mortality in this population related to injury pattern and age.

	Early mortality <6 months	Late mortality (6–24 months)
Mortality by injury pattern		
Hepatocellular, not severe	2/248 (0.8%, CI 0.2–2.8%)	0/39
Severe hepatocellular [ALT > 5xULN & bili > 2xULN]	**23/62 (37.1%, CI 26.1%–49.6%)**	0/39
Mixed	4/125 (3.2%, CI 1.3–7.9%)	1/121 (0.8%, CI 0.2–4%)
Cholestatic	26/683 (3.8%, CI 2.6–5.5%)	**11/657 (1.6%, CI 0.9–2.9%)**
Controls	290/807781 (0.036%, CI 0.032–0.04%)	824/807,471 (0.1%, CI 0.09–0.11%)
Mortality by age in years		
18–45	1/121 (0.82%, CI 0.19–4.4%)	1/120 (0.83%, CI: 0.02–4.5%)
46–55	1/152 (0.66%, CI 0.16–3.5%)	3/151 (1.96%; CI: 0.7–5.6%)
56–65	17/391 (4.35%, CI 2.6–6.9%)	3/374 (0.8%; CI: 0.03%-2.3%)
66–75	16/246 (6.5%, CI 4.0–10.3%)	4/230 (1.7%; CI: 0.7–4.4%)
Age ≥76	20/225 (8.9%, CI 5.8–13.3%)	2/205 (1%; CI: 0.3–3.5%)

Method: AMX/CLA DILI was defined by ALT > 5x upper limits normal (ULN) or ALP >2xULN during the high-risk period (AMX/CLA initiation to 30 days following its discontinuation or the first 90 days after AMX/CLA initiation, whichever shorter), after excluding other causes of acute liver injury with ICD-9 codes and serology. Serious hepatocellular AMX/CLA DILI was defined by ALT > 5xULN and bilirubin > 2xULN. Liver related mortality was defined as death associated with bilirubin > 2 ULN and INR > 1.5, with early death (<6 months) and late death (6 months to 2 years of DILI). Liver-related mortality was examined by DILI phenotype and age in AMX/CLA DILI cases and AMX/CLA-treated controls without DILI.
Results: Early liver-related death occurred in 55/1135 (4.85%) DILI cases vs. 290/807,781 (0.04%) controls ($p < 0.001$). Importantly, the hepatocellular injury was significantly associated with early mortality only if being severe defined by Bilirubin > 2 ULN (see Table). An additional 13/1080 (1.2%) DILI cases and 824/807,471 (0.1%) controls ($p < 0.001$) exhibited late liver-related mortality; cholestatic DILI comprised nearly all late DILI deaths (see Table). Furthermore, age over 55 was associated with early mortality (53/862 (6.1%) / vs. 2/273 (0.7%), $p < 0.001$) yet not late liver-related mortality.
Conclusion: Nearly 5% of AMX/CLA DILI patients suffered early liver-related mortality, with highest percentage in Hy's law cases, and lowest in hepatocellular cases without significant bilirubin elevation. Death disproportionally affected the older population. Cholestatic liver injury was associated with late-liver related mortality.

PS-125

Orthotopic liver transplantation of xenogeneic livers repopulated with autologous hepatocytes: proof of normal function and consistent survival

Stéphanie Lacotte[1], G. Oldani[2], A. Peloso[2], L.A. Orci[2], V. Delaune[2], S. Vijgen[2], L. Rubbia-Brandt[2], C. Toso[2]. *[1]Centre Médical Universitaire, Genève, Switzerland; [2]University Hospital of Geneva, Genève, Switzerland*
Email: oldani@gmail.com

Background and Aims: Generation of transplantable patient-like organs in animals may solve the problem of organ shortage and potentially extend the indications for liver transplantation. However, the efficacy of this approach is yet to be demonstrated even in preclinical studies involving small animals. We challenged this idea by transplanting mouse-rat chimeric livers into baby rats, in orthotopic position. Grafts and animals survival was assessed along with liver synthetic function.
Method: Chimeric livers were created by transplanting Lewis rat hepatocytes into FRG® mice (C57Bl/6 Fah-/-/Rag2-/-/Il2rg-/-). The organs obtained were transplanted into 3-week old female Lewis rats (45 ± 3 g) without or with immunosuppression (IS) (Tacrolimus 0.6 mg/kg/day, during 56 or 112 days). The intensity of rejection was assessed by weekly graft biopsies and peripheral blood immune cells activation. Rat and mouse albumin production was measured once a week. Wild type C57Bl/6 mice were used as control donors.
Results: All non-immunosuppressed recipients experienced acute rejection and died between day 8 and 11 after transplantation.
Under calcineurin inhibitor monotherapy all chimeric liver recipients survived in good health, having normal development and weight gain. Banff score was 2–3, rejection being mostly driven by cholangiocytes. Rat albumin production was within physiologic ranges. Chimeric livers grew on average 670% (from 1.3 ± 0.2 g to 8.7 ± 1.4 g), in line with syngeneic rat controls.
By contrast, pure xenogeneic controls showed impaired growth and died before or shortly after the immunosuppression was stopped, in the 56-day IS group ($p = 0.0014$). In the 112-day IS group they all died while still on Tacrolimus ($p = 0.0013$). Banff score was never inferior to 6, rejection involving all epithelia.
Four months after implantation into rats, chimeric livers were partially repopulated by rat cholangiocytes and portal endothelial cells.
Conclusion: This is the first report showing robust survival of orthotopically transplanted chimeric livers. Moreover, the transplanted organs sustained and were able to follow normal animal growth and development after transplantation.

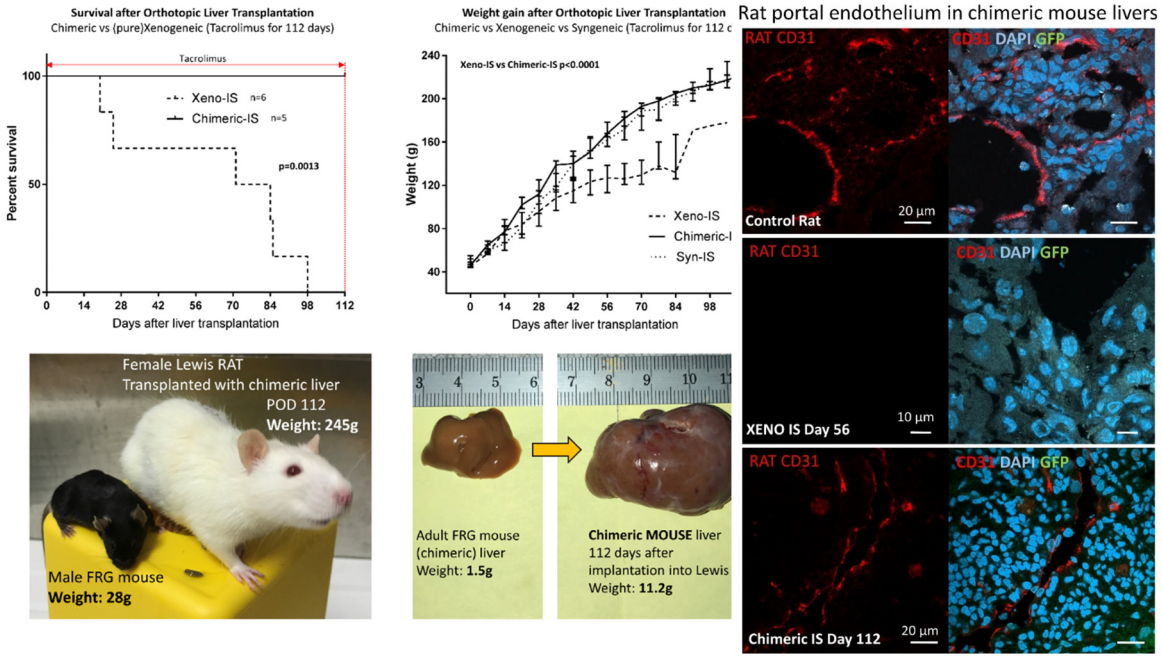

Figure: (abstract: PS-125)

PS-126

Following clinical liver transplantation, the majority of circulating cells exhibiting donor MHC are "cross-dressed" not "passenger" leukocytes

S. Mastoridis, A. Sanchez-Fueyo, M. Martinez-Llordella. *King's College London, Department of Liver Studies, London*
Email: sotiris.mastoridis@googlemail.com

Background and Aims: The dogma that following solid organ transplantation (SOT) allospecific immune responses are the consequence of graft-derived antigen presenting cells (APCs), or "passenger leukocytes", presenting donor MHC to naïve T cells has been recently challenged. Rather, mounting data from animal models of SOT highlight the salience of the semi-direct pathway of allorecognition, whereby T cell alloreactivity is triggered by recipient APCs that present intact donor MHC on their surfaces. These "cross-dressed" APCs acquire donor MHC either by direct cell contact and trogocytosis, or via allograft-derived extracellular vesicles (EVs). Our aim is to ascertain the presence of cross-dressed cells in the context of clinical liver transplantation and to establish whether this correlates with the presence of donor-derived EVs.

Methods: Peripheral blood mononuclear cells (PBMC) and platelet-poor plasma were collected from liver transplant recipients (n = 5) pre-transplant, and at post-transplant days 1, 4, 10, and 90. Donor splenocytes were collected at the time of graft harvest. HLA genotyping enabled the selection of appropriate donor-/recipient-specific HLA monoclonal antibody pairs. Advanced imaging flow cytometry with Amnis' ImageStream was used to perform phenotypic analyses of PBMC and EVs according to previously described methods. Statistical analyses were performed with GraphPad Prism 7.0.

Results: The percentage of PBMCs displaying donor MHC peaked at day 1 post-transplantation, and declined until undetectable at 90 days. In all cases, the majority of cells expressing donor MHC also expressed recipient MHC (cross-dressed). CD14+, CD16+ and CD11c+ cells accounted for the majority of cross-dressed cells, while proportions of these subsets expressing only donor-MHC (passenger leukocytes) were significantly lower ($p < 0.01$). EVs expressing donor HLA peaked at day 1 following transplantation (0.24–9.05% of total small EVs). Donor EVs formed a higher percentage of total EVs in those recipients exhibiting greatest proportions of cross-dressing at day 1 ($p < 0.001$).

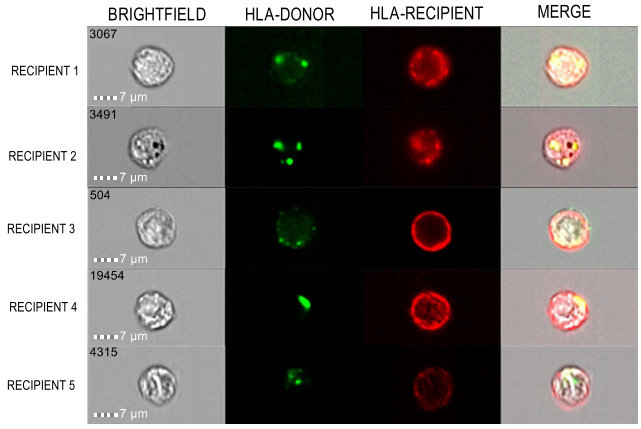

Figure 1: Recipient CD14+ cells acquire donor HLA. FACS staining performed at day 1 post-liver transplantation, with representative ImageStream™ images from 5 different transplant recipients shown.

Conclusion: This work represents the first investigation, to our knowledge, of cross-dressing in peripheral leukocytes following liver transplantation. It corroborates findings from experimental models showing cross-dressing to occur in the setting of SOT, with the predominance of "cross-dressed" over "passenger" leukocytes suggesting that in the clinical context too, these cells may play an important role. Our data suggest that the kinetics of EV release in the early post-operative period are associated with the appearance of cross-dressed cells. The functional properties of cross-dressed recipient APCs in clinical liver transplantation constitutes the basis of ongoing work.

PS-127

Intestinal microbiota modulates susceptibility to acetaminophen induced acute liver injury

C. Elfers[1], K.M. Schneider[1], A. Mohs[1], L. Lijun[1], E.J. Galvez[2], T. Strowig[2], I. Bergheim[3], E. Latz[4], C. Trautwein[1]. [1]*University Hospital RWTH Aachen, Department of Medicine III, Aachen, Germany;* [2]*Helmholtz Centre for Infection Research, Braunschweig, Germany;* [3]*University of*

Vienna, Department of Nutritional Sciences, Vienna, Austria; [4]University of Bonn, Institute of Innate Immunity, Bonn, Germany
Email: kmschneider@ukaachen.de

Background and Aims: Acetaminophen (APAP) poisoning represents the leading cause of acute liver failure (ALF) in western countries. Whereas the link between intestinal dysbiosis and chronic liver disease is well established, insight into the role of gut-liver crosstalk for drug induced liver injury (DILI) remains scarce. Here, we hypothesized that intestinal microbiota may affect the outcome of APAP induced liver failure.
Method: Male 6–8 week old wildtype (WT) and *Nlrp6*$^{-/-}$ mice were injected with a sublethal dose of APAP to induce DILI. 12 hours after injection, a comprehensive analysis of liver injury was performed based on liver functions tests (LFTs), histology, flow cytometry immunophenotyping (FACS) and 16S rRNA-based microbiota profiling. Moreover, microbiota of WT and *Nlrp6*$^{-/-}$ mice was modulated by fecal microbiota transfer (FMT).
Results: APAP administration induced significantly increased liver injury in *Nlrp6*$^{-/-}$ mice compared to WT controls as evidenced by LFTs and histological assessment, which revealed necrosis as the predominant form of cell death. Enhanced DILI in *Nlrp6*$^{-/-}$ mice was associated with markedly increased infiltration of Ly6C^{hi} monocyte derived macrophages (MoMFs) as demonstrated by FACS analysis. Interestingly, microbiota of *Nlrp6*$^{-/-}$ mice was less diverse and did not undergo a major change upon DILI. In contrast, acute liver injury in WT mice prompted a massive change in microbiota composition and a reduction of microbial diversity. These changes were associated with an expansion of colonic mucus layers in WT mice. This potentially protective response did not appear in *Nlrp6*$^{-/-}$ mice, which presented significantly increased serum endotoxin levels after APAP administration. Strikingly, WT mice gavaged with microbiota from *Nlrp6*$^{-/-}$ mice displayed significantly increased liver injury upon APAP treatment and resembled the inflammatory phenotype of *Nlrp6*$^{-/-}$ mice. Specifically, FMT skewed MoMF polarization in WT mice toward a Ly6C^{hi} inflammatory phenotype suggesting a critical function of MoMF as sensors of gut-derived signals orchestrating the inflammatory response.
Conclusion: Our data suggest an important, yet unknown function of intestinal microbiota and gut-liver crosstalk during acute liver injury. Intestinal dysbiosis – as seen in *Nlrp6*$^{-/-}$ mice and transferrable to healthy WT controls via FMT - aggravated liver injury upon APAP administration by promoting pro-inflammatory Ly6C^{hi} macrophage polarization.

Autoimmune and cholestasis 2

PS-128
Statins are associated with reduced mortality and morbidity in primary sclerosing cholangitis (PSC)

K. Stokkeland[1,2], J. Höijer[3], M. Bottai[3], K. Söderberg Löfdal[4,5], A.M. Bergquist[1,6]. *[1]Karolinska Institutet, Department of Medicine Huddinge, Unit of Gastroenterology and Rheumatology, Stockholm, Sweden; [2]Visby Hospital, Department of Medicine, Visby, Sweden; [3]Karolinska Institutet, Unit of Biostatistics, IMM, Stockholm, Sweden; [4]Karolinska Institutet, Division of Clinical Pharmacology, Department of Laboratory Medicine, Stockholm, Sweden; [5]Karolinska University Hospital, Department of Clinical Pharmacology, Stockholm, Sweden; [6]Karolinska University Hospital, Unit of Hepatology, Center of Digestive Diseases, Stockholm, Sweden*
Email: knut.stokkeland@gotland.se

Background and Aims: There is increasing evidence that statins is beneficial in chronic liver and cholestatic liver disease. The aim was to study the impact of exposure of different drugs including statins on death, liver transplantation, liver cancer and variceal bleeding in patients with primary sclerosing cholangitis.
Method: We performed a register-based cohort study of patients with a diagnosis of PSC between 2005 and 2016 in Sweden (n = 2 914). PSC was defined using the combination of the ICD-10 codes for cholangitis (K830) and either ulcerative colitis, UC (K51), or Crohn's disease, CD (K50). Data from the Patient Register, the Prescribed Drug Register, the Death Certificate Register were used. Use of drugs with possible positive effects on liver disease and its progression were studied. Outcomes were, death, liver transplantation (LT), liver cancer and bleeding esophageal varices.
Results: Mean age (IQR) at PSC diagnosis was 41.4 (25.6–56.1) years. The total follow up time were 11 769 years and 3.4% was transplanted and 19.9% died during the study period. There were 58% of the patients who had UC, 13% had CD and 29% had been diagnosed with both CD and UC during the study. Frequency of drug use were: UDCA 60.2%, 5-ASA 74.4%, azathioprine/mercaptopurins 33.7%, antibiotics 91%, antimycotics 12.1%, metronidazole 34.2%, corticosteroids 69.3% and statins 13.9%. Hazard ratios (CI: 95%) for all-cause mortality and the combined endpoints death or LT and death or LT, liver cancer or variceal bleeding are shown in Table 1.

Table 1: Hazard ratios (CI:95%) for death, liver transplantation or variceal bleeding with use of different drugs in 2914 patients with PSC

	All-cause mortality (N = 2 914)	Death or LT (N = 2 794)	Death, LT, liver cancer or variceal bleeding (N = 2 740)
UDCA	1.04 (0.87–1.25)	1.34 (1.12–1.62)	1.45 (1.24–2.80)
5-ASA	0.91 (0.77–1.09)	0.90 (0.74–1.09)	0.97 (0.80–1.18)
Azathioprine	0.66 (0.52–0.84)	0.65 (0.50–0.83)	0.72 (0.56–0.93)
Antibiotics	1.70 (1.27–2.29)	2.27 (1.70–3.05)	1.99 (1.52–2.61)
Antimycotics	2.78 (2.24–3.44)	3.13 (2.48–3.94)	2.43 (1.88–3.13)
Metronidazole	1.27 (1.06–1.53)	1.20 (0.99–1.47)	1.31 (1.07–1.59)
Corticosteroids	1.94 (1.60–2.34)	2.14 (1.75–2.60)	1.68 (1.39–2.04)
Statins	0.68 (0.54–0.88)	0.50 (0.28–0.66)	0.54 (0.41–0.71)

Conclusion: Statins and azathioprine use were associated with decreased risks of death, liver transplantation and variceal bleeding in patients with PSC. UDCA was not associated with a reduced mortality.

PS-129
Usefulness of serum metabolic profiling in the search of novel diagnostic biomarkers for primary sclerosing cholangitis, intrahepatic cholangiocarcinoma and hepatocellular carcinoma

Email: jjgmarin@usal.es

Background and Aims: In patients with primary sclerosing cholangitis (PSC), a condition with increased risk of developing intrahepatic cholangiocarcinoma (iCCA), the progression of the disease to a

malignant lesion often escapes detection. Moreover, in some cases, the differential diagnosis between iCCA and hepatocellular carcinoma (HCC) is difficult. Since early diagnosis of iCCA and HCC by non-invasive methods remains a challenge and the analysis of low-molecular weight metabolites, by new high-throughput techniques, provides a potential source of information to identify novel biomarkers, here we have investigated whether serum metabolomics profiles can be useful to discriminate in the diagnosis of iCCA and PSC or HCC.

Method: Chloroform/methanol and methanol extracts obtained from the serum of patients with PSC, iCCA, or HCC and healthy individuals (n = 20 in each group) were analyzed using ultra-performance liquid chromatography coupled to mass spectrometry (UHPLC-MS).

Results: Using this approach 438 metabolites were identified. Significant changes in the levels of several compounds belonging to different chemical families were found in all the comparisons. Thus, levels of 151 metabolites were altered in PSC versus controls and 49 of them (mainly phosphatidylcholines and lysophosphatidylcholines) were significantly different compared to iCCA. A diagnostic model was built through linear discriminant analyses. An algorithm consisting of PC(34:3) + histidine accurately permitted to differentiate PSC and iCCA. The proposed model yielded an area under the receiver operating characteristic curve (AUROC) of 0.990, 100% sensitivity, 70% specificity and 85% accuracy. Concentrations of 148 metabolites were significantly altered in HCC versus controls, and 16 of them (amino acids, sphingomyelins, diacylglycerols and triacylglycerols), were significantly different compared to iCCA. Levels of 52 metabolites were significantly altered in iCCA versus controls and, of them, 4 amino acids permitted to discriminate iCCA from HCC. An algorithm consisting of glycine + aspartic acid permitted to differentiate both types of tumors with an AUROC of 0.885, a sensitivity of 95%, a specificity of 65%, and an accuracy of 80%.

Conclusion: Specific changes in serum metabolite concentrations useful to distinguish iCCA from PSC or HCC have been identified. Validation studies are needed to determine the actual clinical value of these biomarkers in the diagnosis of these liver diseases.

Fra-2 transgenic mice develop a phenotype of spontaneous primary sclerosing cholangitis

F. Steinbach[1], S. Rosigkeit[1], E. Wagner[2], E. Bockamp[1], D. Schuppan[1,3].
[1]*University Medical Center Mainz, 1Institute of Translational Immunology and Research center for Immune Therapy, Mainz, Germany;* [2]*Spanish National Cancer Research Center, 2BBVA Foundation-CNIO Cancer Cell Biology Program, Madrid, Spain;* [3]*Division of Gastroenterology, Beth Israel Deaconess Medical Center, Harvard Medical School, Division of Gastroenterology and Hepatology, Boston, United States*
Email: detlef.schuppan@unimedizin-mainz.de

Background and Aims: Primary sclerosing cholangitis (PSC) is a chronic liver disease characterized by inflammation and fibrosis of the bile ducts. We have developed a transgenic mouse that overexpresses Fra-2, an alternative component of the transcription factor AP-1 which is responsible for cell proliferation, inflammation, wound healing. Interestingly, Fra-2 drives dermal fibrosis and serves as a novel model of systemic sclerosis affecting the skin and lungs. Here, we describe a novel phenotype developing in older Fra-2 transgenic mice that display core features of PSC.

Method: Fra-2 mice were bred from heterozygous males and wildtype females as described (Eferl et al., 2008). Newborn heterozygous Fra-2 and control mice were maintained for up to 16 weeks. Mice were sacrificed at age 11 and 16 weeks. Liver histology was scored on H&E stained sections, and liver collagen determined via hydroxyproline (HYP) quantification and Sirius Red morphometry. Immune cell infiltration and the expression of the fibrosis promoting cholangiocyte integrin αvβ6 were examined by immunohistochemistry (IHC).

Results: At 11 and especially 16 weeks of age, mice had developed stage 3–4 fibrosis with prominent periportal ductular proliferations surrounded by a rim of connective tissue. Sirius red stained collagen was upregulated 5fold in Fra-2 transgenic vs wildtype control mice which corresponded with biochemical collagen deposition as determined by HYP content. Fibrosis in Fra-2 transgenic mice was characterized by a prominent immune cell infiltration surrounding actively proliferating ductular structures. Ductular structures strongly expressed the integrin αvβ6, an activator of TGFβ1, as observed in human PSC.

Conclusion: Fra-2 is a master transcription factor of fibrogenic gene expression. Apart from skin and lung fibrosis, its overexpression induces rapidly progressive biliary fibrosis resembling PSC. Apart from these mice serving as a valuable preclinical model to evaluate therapies for PSC, Fra-2 itself appears to be an important molecular target for antifibrotic therapies in PSC.

Email: adrien.guillot@nih.gov

Background and Aims: Kupffer cells represent the liver resident macrophage population. Following tissue injury and together with infiltrating monocytes, they are thought to play critical roles in controlling the inflammatory environment and favoring tissue repair. Ductular reactions, which consist of immune infiltrates, fibrogenesis and cholangiocytes proliferation in liver portal areas, are observed in chronic liver diseases; however, the mechanisms underlying cholangiocyte injury and regeneration remain obscure due to the lack of a model with specific cholangiocyte injury. Thus, our studies aim to provide a conditional and cell specific model, leading to acute biliary cell death and allowing for the study of subsequent immune response and bile duct regeneration.

Method: For this purpose, we generated transgenic mice expressing a tamoxifen inducible Cre recombinase inducing human CD59 (hCD59) protein expression in Sox9-positive cells. Injected intermedilysin (ILY) toxin specifically binds to hCD59 to lyse the targeted cells with no off-target effects. Cre-negative hCD59-floxed littermates were used as negative controls. Mice expressing GFP under the CX3CR1 promoter were used to trace infiltrating monocytes. Kupffer cells and recruited monocytes were also identified by immunohistochemistry by using anti-Clec4f and anti-Iba-1 antibodies. Liver injury was shown by TUNEL staining, serum analysis, and bile acid quantitation. Biliary cell proliferation was evaluated by BrdU incorporation in pan-cytokeratin positive cells. Macrophages were depleted by injecting clodronate-loaded liposome prior to ILY injection.

Results: Following tamoxifen injection, we observed that hCD59 expression was restricted to bile duct cells. ILY injection led to a specific biliary epithelial cell death in this transgenic line. Subsequently, bile duct injury was associated with intense inflammatory cell recruitment around portal areas, mostly GFP-positive and Clec4f-negative infiltrated monocytes, while Kupffer cells did not accumulate in damaged portal areas. Lastly in our model, macrophage depletion reduced biliary cell regeneration as well as portal fibrogenesis, and intrahepatic bile acid accumulation although biliary cell injury was identical.

Conclusion: The hCD59-Sox9Cre mice represent an innovative, cell specific, and conditional model to study acute biliary cell injury and subsequent bile duct regeneration and repopulation. By using this model, we demonstrated that recruited monocytes play an important role in promoting ductular reaction, as well as cholestasis.

Email: jesper.andersen@bric.ku.dk

Background and Aims: A characteristic hallmark of cholangiocarcinoma (CCA) is its genomic heterogeneity, which inevitably manifests in therapeutic resistance. The molecular mechanisms driving tumorigenesis, and the basis for why CCA malignancies demonstrate resistance remains unclear. We elucidate the deregulated miR landscape in a CCA patient cohort characterizing the miR involvement in disease onset and role in eliciting drug resistance.
Method: Illumina small RNAseq (miRseq) was performed at high coverage (avg. 30M reads) in 212 fresh frozen samples. Also, for *in vitro* modeling, 18 CCA and normal cell lines were analyzed. Patient-matched gene expression and mutational profiles of all CCA samples were generated. Integration of deregulated miR and aberrant gene expression was performed. High throughput screening (HTS) of >2,700 miR mimics was analyzed in primary normal human cholangiocyte (NHC) and patient-derived CCA cells evaluating their role in regulating proliferation and morphology. Gemcitabine resistant CCA cell lines were established to elucidate the role of miRs in drug refractory disease.
Results: To distinguish deregulated miR expression in CCA, samples were divided into intrahepatic (iCCA, n = 99), perihilar (pCCA, n = 10) and distal disease (dCCA, n = 18), including matched adjacent tissues (n = 63) and normal controls (n = 23). Determination of deregulated miRs was performed by a well-established miR workflow (miRDeep2/DEseq2). Data was processed with cutoffs of Padj. < 0.01 and IFC > 2. We have defined a total of 29 significant miRs (19 up and 10 down) in tumor samples compared to matched adjacent tissues (AUC = 0.99). Correlation of aberrantly expressed miRs and *best fit* model system was evaluated to manipulate select miRs and by HTS. Gene expression and mutational profiles of CCAs and adjacent normal tissue were analyzed and integrated with miRs. In the miR mimics library screen siAKT (decreased proliferation) and taurocholic acid (increased proliferation) were used as controls. Morphological changes were analyzed by fluorescent phalloidin membrane staining. Screening of NHC cells revealed 50 miRs that significantly increased the normal proliferation rate, of which mir-26b is a positive control known to be elevated in CCA. Additionally, 35 miRs significantly inhibited cellular proliferation and will be evaluated further as putative targets in CCA.
Conclusion: The results obtained in this study provide new biological and molecular knowledge on CCA heterogeneity and lead to improve the current understanding of the pathobiology of miR-driven chemoresistance. Further analyses focused on identifying novel drug targets will bring miR biology forward as a therapeutic aim in CCA.

PS-133

Novel role of amphiregulin in bile acids metabolism and protection from cholestatic liver injury

Email: maavila@unav.es

Background and Aims: Many acute and chronic liver diseases are accompanied by cholestasis. Intrahepatic accumulation of bile acids (BAs) may cause hepatocytes and cholangiocytes death. Upon liver injury, a potent protective and regenerative response is mounted to restore the architecture and function of the organ. However, when this reparative reaction chronifies liver fibrosis and tumorigenesis may ensue. A better understanding of this reaction is required to devise hepatoprotective strategies, as well as antifibrogenic and antineoplastic therapies. The epidermal growth factor receptor (EGFR) signaling system is essential for regeneration after most types of experimental liver injury, including cholestatic injury. EGFR can be activated by a wide family of growth factors, among which amphiregulin (AR) was identified as a key mediator of liver regeneration. Here we have studied the role of AR during cholestatic liver injury and the mutual regulation of AR expression and BA synthesis.
Method: We used two models of cholestatic liver injury: bile duct ligation (BDL) and oral alpha-naphtyl-isothiocyanate (ANIT) administration in wild type (AR-WT) and AR knockout (AR-KO) mice. AR expression was examined in: (i) livers from patients with primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC); (ii) mice and cultured liver cells treated with BAs; and (iii) farnesoid X receptor knockout mice (FXR-KO) after BDL. The cytoprotective capacity of AR was evaluated in vitro and in vivo.
Results: AR mRNA and protein were up-regulated in the liver of PBC and PSC patients (hepatocytes and cholangiocytes). Oral BA administration to mice induces ileal and hepatic AR expression, and cholestyramine feeding reduces postprandial ileal and liver AR upregulation. AR-KO mice display higher Cyp7a1 expression and intrahepatic BA concentrations than AR-WT mice. Liver AR expression was markedly enhanced in BDL and ANIT groups of AR-WT mice. Liver damage was markedly exacerbated in AR-KOs. BAs induced AR expression in cultured liver cells partially through FXR. Consistently, after BDL FXR-KO mice show reduced liver AR expression than FXR-WT. AR treatment protected from BDL-induced liver injury and from BAs toxicity in cultured liver cells.
Conclusion: AR participates in BA homeostasis under physiological conditions. Liver AR expression is activated during cholestasis partially through FXR. AR plays an important role in protecting the liver from BA induced toxicity.

Email: katewilly@hotmail.com

Background and Aims: Vedolizumab (VDZ) appears to be an attractive option for treating Primary Sclerosing Cholangitis (PSC) as it targets gut-homing lymphocytes which have been linked with the pathophysiology of PSC. VDZ has been proven to be beneficial in inflammatory bowel disease (IBD) but there is little data on the effect of VDZ in PSC/IBD.
Method: A retrospective audit was carried out by the International PSC Study Group of patients with PSC who had received VDZ for their IBD. General demographics and variables pertaining to liver enzymes and IBD response were obtained, comparing baseline with day 42, and last follow-up. Patients receiving VDZ post-liver transplant were not included. Paired T-tests were used for comparisons pre- and post-VDZ, and, unless otherwise stated, data stated as means with 95%CI.
Results: 60 patients with PSC/IBD received VDZ from 11 centres in North America and Europe. 37 (61.7%) were male, with mean age at PSC diagnosis 30y (range 13–86) and mean age at IBD diagnosis 25y (range 9–62). 54 (90.0%) patients had classical PSC, 4 (6.7%) had small-duct PSC, and 2 (3.3%) had PSC-AIH overlap; 15 (25.0%) had cirrhosis. 40 (66.7%) had UC, 15 (25.0%) had Crohn's disease, 4 (6.7%) had IBD-unspecified, and 1 had unknown IBD subtype. 35 patients (58.3%) were on concomitant ursodeoxycholic acid. 33 (55.0%) had previously had anti-TNF therapy, 21 (35.5%) were anti-TNF naïve, and 6 had unknown anti-TNF status.
The median duration of VDZ was 363 days (range 14–2609). VDZ was ceased in 28 patients (46.7%) during the study period, mostly for lack of efficacy (21, 75%), with 3 stopping for adverse reactions, 3 for other reasons (compliance, insurance), 1 unknown.
The mean ALP at baseline was 2.38xULN (1.82–2.94) vs. 2.59xULN at Day 42 (1.93–3.24, p = 0.32), and at last follow-up (whilst still on VDZ) was 2.76xULN (2.09–3.44, p = 0.06 vs. baseline). When comparing with ALP at baseline, the proportion of patients who had any drop in ALP was 43.9% at day 42 (mean drop −20.2%, −4.0 to −26.31) and 50.9% at last follow-up (mean drop −22.6%, −15.1 to −30.2), whilst only 5.3% dropped ALP by at least 40% at day 42 (8.8% at last follow up).
There was a rise in mean ALT at baseline vs. last follow-up: 61.6IU/L (49.1–74.1) vs. 79.8IU/L (61.9–97.6, p = 0.0078), and a similar rise in AST: 56.9IU/L (43.4–70.4) vs. 71.9IU/L (54.6–89.1, p = 0.055).
44 patients had data available for endoscopic IBD response. 25 (56.8%) improved, compared with 19 (43.2%) who had unchanged or worsened endoscopic appearance. Of those who had an IBD response, 60.0% had an ALP drop from baseline to last follow up compared with only 42.1% in IBD non-responders, but this was not statistically significant (p = 0.36).
Conclusion: Whilst VDZ appears moderately effective for IBD in PSC/IBD, there was no effect on ALP response, (though a trend towards ALP rise), and there was a small rise in ALT. These observations may be due to the natural course of the underlying PSC.

Cirrhosis: Portal hypertension, and complication

PS-135

A spleen stiffness measurement-based model for recognition of high risk varices: Baveno VI criteria and beyond

F. Ravaioli[1], A. Colecchia[1,2], G. Marasco[1], A. Colli[3], E. Dajti[1], A. DI Biase[4], M. L. B. Reggiani[1], A. Berzigotti[5], M. Pinzani[6], D. Email: antonio.colecchia@aovr.veneto.it

Background and Aims: Recently, Baveno VI guidelines suggested that esophagogastroduodenoscopy (EGD) can be avoided in patients with cACLD who have a liver stiffness measurement (LSM) <20 kPa and platelet count >150,000/mm^3. We aimed to assess the performance of spleen stiffness measurement (SSM) in ruling out patients with high risk varices (HRV); we also aimed to validate Baveno VI criteria in a large population and assess how the sequential use of Baveno VI criteria and SSM could safely avoid the need for endoscopy.
Method: We retrospectively analysed 498 cACLD patients who had undergone LSM/SSM by transient elastography (TE), platelet count and EGDs from 2012 to 2016 referred to our tertiary centre. We performed multivariate analysis and split validation to define the role of SSM in predicting HRV. The derivation dataset consisted of 54 randomly selected cases and 129 randomly selected controls from the original datasets of 100 cases and 398 controls; consequently, the validation dataset includes 46 cases and 123 controls.
Results: At the multivariate analysis, SSM (OR = 1.108; 95%CI = 1.072–1.145), LSM (OR = 1.068; 95%CI = 1.042–1.096), platelet count (OR = 0.985; 95%CI = 0.979–0.993) and Child-Pugh B (OR = 3.066; 95%CI = 1.654–5.692) were independent predictors of HRV. With the aim of identifying, by SSM ROC curves, the most accurate SSM cut-off to rule out patients with HRV [corresponding to a low probability (<5%) of HRV presence], a cut-off ≤ 46 kPa was chosen. The performance of SSM (≤46 kPa) in ruling out HRV showed a sensitivity of 97.8%, a specificity of 44.9%, NPV of 98.9% and an LR- of 0.05. Applying the newly identified SSM cut-off (≤46 kPa) or Baveno VI criteria, 36.7% and 21.7% of patients in the validation cohort could have avoided EGD, with HRV being missed in 1% in both cases. The combination of SSM with Baveno VI criteria would have made it possible to avoid an additional 22.5% of EGDs if compared with Baveno VI criteria alone, thus reaching a final value of 44.2% of avoided EGD, with <5% missed HRV.
Conclusion: Our study indicates that SSM is not only an independent predictor of the presence of HRV but is also an accurate and non-invasive test for ruling out HRV and that combining it with Baveno VI criteria in a simple sequential algorithm makes it possible to safely avoid a significant larger proportion of unnecessary endoscopies.

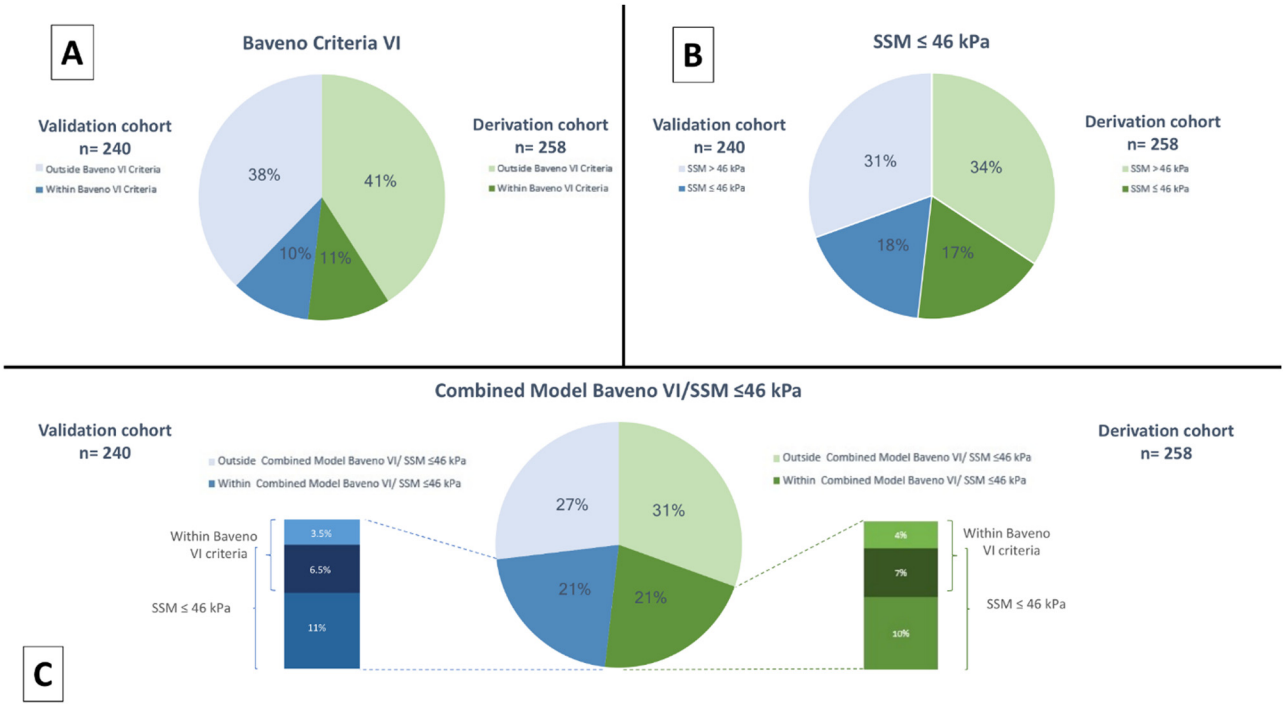

Figure: (abstract: PS-135): Rate of spared endoscopies by each of the considered non-invasive models. All percentages (%) are referred to the entire population (n = 498), represented as the combination of the derivation and validation cohort. In the new combined model Baveno VI/SSM ≤ 46 kPa, the rate of the spared endoscopies is reported also in the column graphs as the sum of the patients that fulfill only the Baveno VI Criteria (SSM > 46 kPa), patients with SSM ≤ 46 kPa (and outside Baveno VI Criteria) and patients that would have avoided endoscopy according to both models (in overlapping area).

PS-136

Non-invasive measurement of HVPG using graph analysis of dynamic contrast-enhanced ultrasound: the CLEVER study

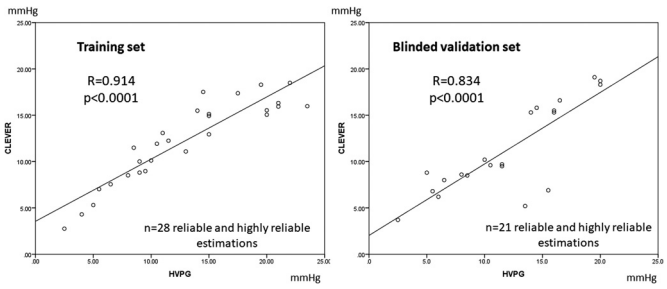
Email: annalisa.berzigotti@insel.ch

Background and Aims: Hepatic venous pressure gradient (HVPG) is the standard-of-care method to assess portal pressure in patients with chronic liver disease (CLD). HVPG has a strong independent prognostic value, but it is invasive, which limits its routine use. Non-invasive methods providing an accurate estimate of HVPG are an unmet need in hepatology. Preliminary data suggested that graph analysis of dynamic contrast enhanced ultrasonography (DCE-US) of the liver allows calculating the degree of derangement of the hepatic microcirculation and mirrors the severity of portal hypertension (Amat-Roldan et al. Radiology 2015). The EC-funded prospective CLEVER study (FP7-IAPP-GA-2013-612273-CLEVER) aimed at developing a novel automatized software based on DCE-US able to improve prognostication in cirrhosis. Here we report the applicability and diagnostic accuracy of the CLEVER software to assess portal hypertension as compared to HVPG in a large population of patients with CLD studied in one of the participating centers.

Method: The present results were obtained in a subgroup of 152 patients with CLD undergoing clinically indicated HVPG measurement who had DCE-US for CLEVER assessment on the same day. 90 secs after starting a continuous infusion of 4.8 ml of SonoVue (Bracco, Switzerland) lasting 3 min, one or more videoclips of the right hepatic lobe parenchyma were recorded, including microbubble disruption and reperfusion (20 seconds clips; Acuson Sequoia). The CLEVER software estimates the HVPG by offline graph model analysis of the vascular connectomes on the microbubbles reperfusion images. 83 patients (training set) were used to develop 5 equipment-calibrated models for HVPG estimation. The computer algorithm automatically selects the best HVPG prediction model, and provides a grading of reliability of the HVPG estimation ("poorly reliable", "reliable" or "highly reliable"). 69 patients were used as blinded validation set.

Results: The CLEVER software was able to provide portal pressure estimations from CEUS videos in 85/152 patients (56%). Applicability increased when >2 videoclips were acquired: 51% with one acquisition, 56% with 2, 81% with 3, and 100% with 4.

Reliability and correlation with HVPG. In the training set 28/50 patients (range of HVPG 2.5–26 mmHg) had reliable or highly reliable CLEVER results. In them, the correlation between HVPG and the CLEVER estimation was excellent: R = 0.914, p < 0.0001. In the validation set 21/35 patients had reliable or highly reliable results. The correlation between HVPG and CLEVER output was R = 0.834, p < 0.0001 (Figure).



Conclusion: We developed and validated the DCE-US based CLEVER software which allows an accurate non-invasive estimation of portal pressure in patients with CLD. Multiple acquisitions during the same contrast infusion are required to increase the applicability of the method.

PS-137

Effect of B-blockers on the systemic hemodynamics of decompensated cirrhosis and survival

Villanueva[1,2]. *[1]Hospital de la Santa Creu i Sant Pau, Gastroenterology and Hepatology department, Barcelona, Spain; [2]Centro de Investigación Biomédica en Red en el Área temática de Enfermedades Hepáticas, Spain; [3]Hospital Universitari Arnau de Vilanova, Gastroenterology and Hepatology department, Spain*
Email: ealvaradot@santpau.cat

Background and Aims: Whether β-blockers can be harmful in cirrhosis is currently debatable. Different circulatory changes occur in advanced cirrhosis, including an intensification of hyperdynamic circulation. Because maintenance of blood pressure and cardiac output is essential in advanced cirrhosis, the effect of β-blockers on such hemodynamic parameters can be detrimental. The aim of this study was to evaluate whether the effect of β-blockers on the systemic hemodynamic of advanced cirrhosis may influence survival.
Method: From January 2005 to January 2016 patients with cirrhosis and ascites who had high-risk esophageal varices without previous bleeding, referred for primary prophylaxis, were consecutively included in the study. A hepatic and systemic hemodynamic assessment was performed at baseline and again 1–3 months later, under treatment with non-selective β-blockers (NSBB), either propranolol or carvedilol.
Results: Among 403 patients with varices referred, 190 with ascites were included. The mean Child-Pugh score was 8 (IQR, 7–9), mean MELD was 13 (IQR, 10–15) and age was 61 years (IQR, 53–68). During a follow-up of 36 months (IQR, 16–62), 27 patients (14%) had variceal bleeding, 31 (16%) hepatorenal syndrome, 38 (20%) SBP, 31 (15) developed a HCC, 18 (9%) had OLT and 73 (38%) died. As compared with patients surviving, those who died were older (64 ± 10 *vs.* 59 ± 9 y, p = 0.001), had lower baseline albumin (30 ± 4 *vs.* 32 ± 5 G/L, p = 0.007) and worse Child-Pugh (8.1 ± 1.5 *vs.* 7.1 ± 1.5, p = 0.01). Baseline hemodynamic parameters were similar between both groups, except for a higher HVPG in those who died (20.6 ± 4 *vs.* 18.9 ± 4, p = 0.03). However, at the control 1–3 months of treatment with NSBB patients who died had a higher decrease of cardiac output (CO) from baseline (19 ± 13 *vs.* 14 ± 17%, p = 0.05) with a lower final value (5.7 ± 1.5 *vs.* 6.6 ± 1.5 L/min, p = 0.01) and had lower mean arterial pressure (MAP: 76 ± 9 vs 85 ± 15 mmHg, p = 0.01) than survivors. By Cox regression analysis, age, baseline Child-Pugh and HVPG and CO at 1–3 months were independent predictors of dead. The probability of death was higher in patients with a CO < 5 L/min at 1–3 months of treatment with NSBB than in those with CO ≥ 5 L/min (death risk of 19% *vs.* 5% at 1 year and 42% *vs.* 15% at 3 years, p < 0.001 by log-rank).
Conclusion: Among patients with decompensated cirrhotic treated with NSBB, those who died have lower CO and MAP under treatment with NSBB than those surviving (in addition to worse liver function and higher HVPG at baseline). CO had an independent prognostic value and the risk of death was higher in patients with CO < 5 L/min. Our results suggest that monitoring CO under treatment with NSBB can be helpful to improve outcomes.

PS-138

The global prevalence of Wilson disease from next-generation sequencing data

S. Brackley[1], J. Gao[1], J. Mann[2]. *[1]University of Cambridge, School of Clinical Medicine, Cambridge, United Kingdom; [2]University of Cambridge, Department of Paediatrics, Cambridge, United Kingdom*
Email: smb202@cam.ac.uk

Background and Aims: Wilson Disease (WD) is an autosomal recessive disorder of copper metabolism, caused by mutations in the ATP7B gene. Its prevalence is widely quoted as 1 in 30,000, but this figure predates the discovery of the gene responsible and recent estimates have been much higher. We aimed to: (1) meta-analyse previous prevalence estimates for WD, and (2) estimate the prevalence of WD across ethnicities from population sequencing data, using a validated method.
Method: MEDLINE and EMBASE were systematically searched for articles related to Wilson disease. Previous prevalence estimates were meta-analysed using an inverse variance model with a double arcsin transformation.
ClinVar and the University of Alberta WD database were used to identify disease-causing mutations in ATP7B. Coding sequence nucleotide changes for each variant were identified and converted to human genome coordinates (hg38) using the Mutalyzer program (https://mutalyzer.nl/). Variants were then filtered for those previously defined as "disease variants" and, for missense mutations, "deleterious" or "damaging" on SIFT and Polyphen-2 respectively. The Ensembl Variant Effect Predictor (https://ensembl.org/Tools/VEP) was used to annotate variants with allele frequencies from gnomAD and 1000G data sets. A pooled global prevalence estimate was generated using the Hardy-Weinberg equation. In addition, we estimated the prevalence for 8 separate ethnicities.
Results: 1,003 abstracts were screened and 12 studies were included, reporting population prevalences ranging from 0.4 to 135 per 100,000. Meta-analysis of previous data gave an estimate of 5.54 per 100,000 (95% CI 5.45–5.63).
787 unique variants in ATP7B were identified. 569 were classified as disease-causing variants, of which 539 were categorised as pathogenic after excluding missense mutations likely to be tolerant by SIFT/Polyphen-2 analysis. 155 mutations had been identified in gnomAD. Based on these allele frequencies, the overall prevalence of WD was 13.90 per 100,000 (95% CI 12.63–15.31). East Asian ethnicity had the highest estimated prevalence (37.56 per 100,000 (95% CI 28.23–50.09)) compared to only 1.75 per 100,000 (95% CI 1.00–3.00) in the African-American population.

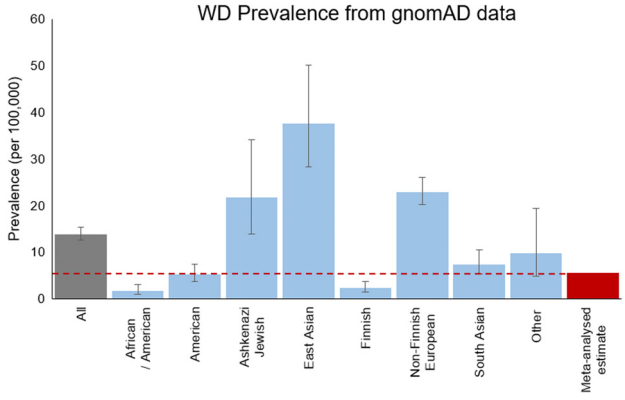


Figure: Estimated prevalence of WD by ethnicity as calculated from gnomAD allele frequency data (blue, error bars indicate 95% CI) compared to meta-analysis of current literature (red).

Conclusion: These data provide the first global prevalence estimate of Wilson disease in addition to an unbiased description of the multi-ethnic risk. This has implication for genetic counselling and clinical suspicion of the disorder across ethnicities.

Email: justinboike@gmail.com

Background and Aims: Transjugular intrahepatic portosystemic shunt (TIPS) is an effective treatment for complications of portal hypertension but is associated with risk of hepatic decompensation. Prior data have demonstrated 30-day survival ranging between 46%–88% but these studies have been limited to single center experience and included non-contemporary experience. We aimed to assess contemporary practice patterns and outcomes following TIPS placement among a multi-center sample of patients with cirrhosis in the United States.

Methods: This was a multi-center retrospective cohort study of all patients with cirrhosis who underwent TIPS placement from 2010 through 2015 with outcomes through 2016 across nine tertiary academic medical centers. Kaplan-Meier estimates with log rank test were used to estimate overall and transplant-free survival across quartiles of model of end-stage liver disease (MELD) score. Patients were censored at date of death, transplantation, or last follow-up.

Results: TIPS recipients (n = 1146) were mean age of 57 (standard deviation 9.9) years old, 61% male, 92% Caucasian and 84% non-Hispanic. Mean MELD score was 16 (SD 6.6) and median 15 (range 6.4–58.5); 34% of recipients had alcohol-induced cirrhosis, 30% Hepatitis C, 20% non-alcoholic fatty liver disease, and 16% other. Indications for TIPS were ascites (40%), variceal hemorrhage (31%), combination of ascites and variceal bleeding history (10%), hepato-hydrothorax (6%), treatment of portal vein thrombosis (5%), and other (7%). Covered stents were used in 89%, revision was required in 31% and liver transplantation subsequently performed in 21% of patients. Transplant-free survival at 30, 90, and 365 days was 81%, 70%, 54% with a mean survival of 2.7 years. Increasing MELD quartiles above the median was inversely associated with 30 and 90-day survival (Figure 1a, p = 0.003). After 90 days, the probability of survival was significantly improved for those with MELD scores less than 19 compared to those in highest MELD quartile (Figure 1b, p < 0.0001).

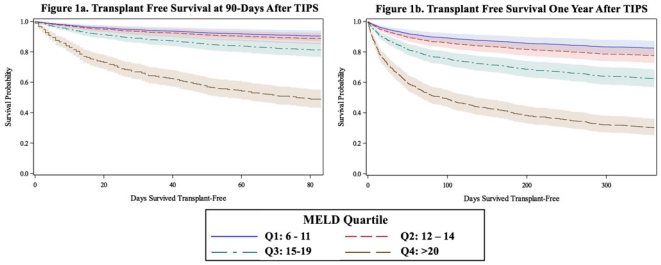

Figure: Kaplan-Meier curves with 95% confidence intervals of transplant-free survival for MELD quartiles at 90-days after TIPS (1a) and one year after TIPS (1b).

Conclusion: In a large U.S. multicenter cohort of TIPS recipients, 30-day and 90-day survival is excellent in recipients with MELD less than 19. These findings provide the liver community with important information to assist in the management of portal hypertensive complications in patients with cirrhosis and challenge the historical MELD cutoff of 15 for undergoing TIPS.

PS-140

Early-TIPS improves survival in cirrhotic patients with high-risk varical bleeding: Results of a China multicenter observational study

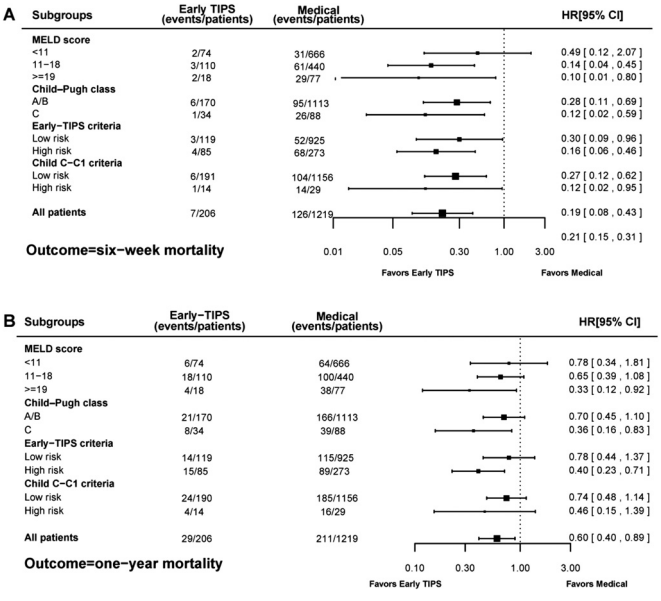
Email: hangh@fmmu.edu.cn

Background and Aims: Early TIPS has been shown to improve survival in high-risk patients (Child B + active bleeding at endoscopy or Child C10–13, early-TIPS criteria) with cirrhosis and acute variceal bleeding (AVB).However, it has been suggested that early-TIPS criteria may overestimate the risk in a significant proportion of patients and

the survival benefit conferred by early TIPS in such patients has been questioned. Alternative criteria have been proposed to refine the criteria to identify candidates for early-TIPS, such as model for end-stage liver disease (MELD) score ≥19 (MELD19 criteria) and Child-Pugh class C with plasma level of creatinine ≥1 mg/dl (ChildC–C1 criteria). The present study aimed to evaluate the role of early TIPS in a large cohort of patients with AVB to validate these systems of risk analysis

Method: A total 1425 cirrhotic patients (90% Child A/B) with AVB who received standard treatment (medical group, n = 1219), or early TIPS (placed within 72 hours from admission, n = 206) and had no exclusion criteria (HCC beyond Milan, age >75, creatinine ≥3 mg/dl, complete PVT or Child >13) were retrospectively included from 12 academic hospitals in China from 2010 to 2016. Fine and Gray competing risk analysis were used to compare the outcomes between early-TIPS group and medical group after adjusting for important baseline characteristics or by using propensity score.

Results: Among 1425 patients with AVB, the 6-week and 1-year mortality were 3.4% and 14.1% in early-TIPS group versus 14.1% and 17.3% in medical group, respectively. Among 95 (7%) patients classified as high risk by the MELD19 criteria, early-TIPS group had a lower risk of mortality in both at 6 weeks (11.1% *vs.* 37.7%, adjust HR = 0.10; 95% CI: 0.01–0.80) and 1 year (22.2% *vs.* 49.4%, adjust HR = 0.33; 95% CI: 0.12–0.92). Similar results were observed among the 358 (25%) patients classified as high risk by the early TIPS criteria (4.7% *vs.* 24.9% at 6-week and 17.6% *vs.* 32.6% at one year, p < 0.001). Among the 43 (3%) patients classified as high risk by the ChildC–C1 criteria, early-TIPS group had a lower risk of 6-week mortality (7.1% *vs.* 48.3%, adjust HR = 0.12; 95% CI: 0.02–0.95) but similar risk of 1-year mortality (28.6% *vs.* 55.2%, adjust HR = 0.46; 95% CI: 0.15–1.39) compared to medical group.



Conclusion: Early-TIPS improves both short and long term survival in high risk variceal bleeder identified by MELD19 criteria and early-TIPS criteria but only short-term survival per ChildC-C1 criteria.

PS-141

Resistance training improves muscle size and muscle strength in liver cirrhosis – a randomized controlled trial

L. Aamann[1], G. Dam[1], M. Borre[1], A. Drljevic-Nielsen[2], K. Overgaard[3], H. Andersen[4], H. Vilstrup[1], N.K. Aagaard[1]. *[1]Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark; [2]Aarhus University Hospital, Department of Radiology, Aarhus, Denmark; [3]Aarhus University, Department of Public Health - Sport Science, Aarhus, Denmark; [4]Aarhus University Hospital, Department of Neurology, Aarhus, Denmark*
Email: luise.aamann@gmail.com

Background and Aims: Sarcopenia in liver cirrhosis leads to diminished muscle strength and quality of life (QoL) and increases mortality. Resistance training and adequate protein intake reduce muscle wasting and improve physical performance in other chronic diseases. We evaluated the effect of resistance training on muscle size and strength, physical performance and QoL in cirrhotic patients on a standard high protein diet.

Method: Thirty-nine patients (exercise n = 20, control = 19) with Child Pugh A/B cirrhosis were allocated to resistance training in groups of five or a control group. A dietitian guided all patients. If recorded daily protein consumption was less than 1.2 of protein/kg/day, supplements were provided.

The exercise group conducted supervised resistance training one hour three times weekly for 12 weeks. Muscle cross sectional area (CSA) was measured by magnetic resonance imaging of m. quadriceps (scan at 60% of femur length) and muscle strength by isokinetic knee extension peak torque at velocity of 90 degrees/sec. The short form questionnaire (SF-36) and 6-minute walk test (6MWT) tested QoL and performance. Outcomes were assessed at baseline and follow-up by blinded investigators.

Results: Thirty-five patients completed the study (exercise n = 19, control = 15). Protein intake including supplements was equal in both groups.

In the exercise group, CSA of m. quadriceps increased by 616 mm^2 (5,847 mm^2 to 6,462 mm^2; ±398SD; p < 0.001), compared to 92 mm^2 (5,585 mm^2 to 5,677 mm^2; ±453SD; p = 0.45) in controls. At study end, the exercise group had a higher gain in CSA of 524 mm^2 (95% CI 222–826) compared to controls (p < 0.001).

Correspondingly, the peak torque increased in the exercise group by 15 Nm (119–134 Nm; ±16SD; p < 0.001) versus controls, who increased by 4 Nm (106–110 Nm; ±14SD; p = 0.30). Thus, the exercise group had a strength gain 11 Nm (95% CI: 0–22) greater compared to controls (p = 0.05).

The exercise group improved the mental component score (SF-36) by 4.1 (49.9–54.0; ±6.2SD; p = 0.01) and 6MWT by 32 m (509–541 m; ±42SD, p = 0.005), though not significantly different from controls, who also improved but to a lesser degree.

Conclusion: Resistance training improved muscle size and muscle strength in patients with liver cirrhosis compared to controls. Physical performance and mental component score (SF-36) improved within the exercise group. The results regarding resistance training are novel and readily applicable in the rehabilitation of patients with liver cirrhosis.

Clinical developments in metabolic and rare disease

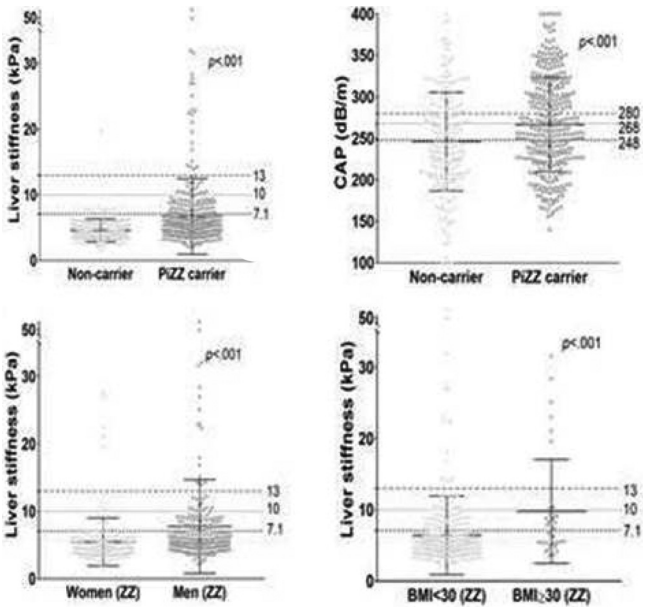
Email: vwoditsch@ukaachen.de

Background and Aims: Alpha1-antitrypsin deficiency (AATD) is among the most common genetic disorders but the liver phenotypes in adults remain poorly characterized. Therefore, we conducted a case-control study comparing adult carriers of the classical homozygous Z mutation ('PiZZ" genotype) with non-carriers.

Method: In cooperation with patient organizations and specialized respiratory physicians, we recruited 403 adults with the PiZZ genotype from Germany, Austria, Denmark, Portugal, Spain, Belgium, and the Netherlands (mean age 54 years, 45% female, mean BMI 24.8 kg/m^2) as well as 234 non-carriers without AAT mutation. Participants underwent a thorough clinical and laboratory workup to exclude hepatic comorbidity and to assess pulmonary symptoms. FibroScan determined liver fibrosis via liver stiffness measurement (LSM) and liver steatosis via controlled attenuation parameter (CAP). Data were adjusted for age, sex, BMI, diabetes mellitus and alcohol consumption.



Results: Serum liver enzymes (ALT, AST, GGT, and ALP) were mostly within the normal range, but significantly higher in PiZZ carriers compared to non-carriers. Significant liver fibrosis (LSM ≥ 7.1 kPa) was observed in 24% of PiZZ subjects (95/403), whereas advanced liver fibrosis (LSM ≥ 10.0 kPa) was present in 13.2% PiZZ carriers (53/403) and in 1.3% of non-carriers (OR = 18.9 [4.4–80.3]). Severe liver steatosis (CAP ≥ 280 dB/m) was detected in 39% of PiZZ patients (157/403) vs. 31% of non-carriers (OR = 2.1 [1.4–3.3]). Likewise, PiZ-overexpressing mice developed hepatic steatosis. Lower serum triglyceride, VLDL, and LDL cholesterol levels detected in PiZZ patients indicated impaired hepatic lipid secretion. The observed metabolic alterations and increased liver fibrosis/steatosis were also detected, when only patients without AAT augmentation therapy were considered. Moreover, the presence of liver fibrosis or steatosis was not associated with the severity of lung disease (COPD assessment test or need for long-term oxygen therapy). Several demographic and laboratory parameters discriminated between PiZZ carriers with and without significant liver fibrosis. Using a machine-learning algorithm, a score consisting of gender, BMI, GGT and platelet count predicted the presence of significant liver fibrosis with 85% accuracy (AUROC 0.77). As only 45% of PiZZ adults receive regular assessment of liver enzymes, this score might help to determine which patients deserve further hepatologic workup.

Conclusion: This study defines the liver phenotype of adult PiZZ carriers and uncovers associated metabolic alterations. Together with the identified predictors, these findings facilitate the hepatologic assessment and counseling of PiZZ patients.

Email: srock@alnylam.com

Background and Aims: Acute Hepatic Porphyrias are rare, often misdiagnosed genetic diseases caused by a mutation in aminolevulinic acid synthase 1 enzyme responsible for heme synthesis. This results in the accumulation of neurotoxic heme intermediates, aminolevulinic acid and porphobilinogen that can cause life-threatening attacks and chronic, debilitating symptoms due to injury to the nervous system. The most debilitating and frequent symptom during attacks is severe neurovisceral pain, most often in the abdomen, back, or limbs. Other common attack manifestations include nausea, fatigue, hypertension, tachycardia, motor weakness, and hyponatremia. Patients experiencing attacks often require urgent medical care. Chronic symptoms, most commonly pain, nausea, and fatigue, also occur in most patients and often contribute to a high disease burden and poor quality of life. We will be presenting updated ≥12-month data.
Method: EXPLORE is a prospective, international, observational study characterizing the natural history and clinical management of patients with hepatic porphyrias with recurrent attacks (≥3 attacks/year) or who receive prophylactic treatment to prevent attacks. Patient medical history, physical examination and porphyrin biomarkers, along with questionnaires on porphyria activity were collected.
Results: 112 patients enrolled from 13 countries and were followed for 12 months. Mean patient age is 39 years, with 89% female, and 93% with AIP, 4% variegate porphyria, and 3% hereditary coproporphyria. Patients reported 9.3 attacks in the 12 months prior to the study, with pain being the most common symptom, occurring in 99% of attacks. Mean attack duration was 7 days. Chronic symptoms were reported by 65% of patients, with pain being the most frequent symptom. On study annualized attack rate was 4.9 attacks/person, of which 77% required treatment at a healthcare visit or with hemin. For those patients on hemin prophylactically, attacks occurred with a mean attack rate per person-year of 4.0. Mean ALA and PBG levels at screening (during non-attack) were markedly increased to 8 times and 20 times the upper limit of normal, respectively.
Conclusion: EXPLORE, the first international natural history study in patients with hepatic porphyria and recurrent attacks, demonstrates that patients suffer from attacks and chronic symptoms. Given morbidity and mortality, there remains an unmet need for novel therapies to prevent attacks and treat chronic symptoms.

PS-144
Effect of sebelipase alfa on liver parameters over 96 weeks in a diverse population of children and adults with lysosomal acid lipase deficiency

B. Burton[1], A.C. Sanchez[2], M. Kostyleva[3], K. Allen[4], F. Abel[5]. *[1]Ann and Robert H. Email: bburton@luriechildrens.org

Background and Aims: Lysosomal acid lipase deficiency (LAL-D) is a rare, progressive disease characterized by accumulation of cholesteryl esters and triglycerides in the liver that leads to dyslipidemia, hepatomegaly, and liver cell damage. Sebelipase alfa (SA) is a recombinant human LAL indicated for the treatment of LAL-D.

Cirrhosis, n (%)*	8/30 (27)	4/17 (24)	
Liver volume, MN	1.4	1.2	−17.6
Liver fat content, %	8.1	6.5	−14.9
Spleen volume, MN	2.6	2.2	−16.5

n = 31, unless otherwise noted; results are medians. MN = multiples of normal. *Fibrosis = Ishak score of 1–4; cirrhosis = Ishak score of 5–6.

Method: In this multicenter, open-label study, eligible patients >8 months of age were given SA 1 mg/kg by IV infusion every other week for up to 96 weeks. Dose escalation to 3 mg/kg every other week and subsequently to 3 mg/kg weekly was allowed for patients who met protocol-defined criteria; dose reductions for tolerability were permitted to 0.35 mg/kg every other week. Reported here are effects on liver parameters at 96 weeks of SA exposure.
Results: A total of 31 patients were enrolled; median age was 12 y (range 3–55 y). Two patients (6%) had a prior liver transplant. No inferential statistical analyses were conducted as part of this study. Clinical characteristics at Baseline and Week 96 are provided in the table. Marked reductions in ALT and AST were observed. Liver fibrosis improved or did not progress in 7 of 13 patients (54%) with pairwise samples at Baseline and Week 96 and with Baseline Ishak stage of 0–5. Three patients had a ≥1-point reduction in Ishak stage, including 2 patients who had a ≥2-point reduction. One of 3 patients with Baseline stage of 6 and a pairwise sample at Week 96 improved to stage 2. SA was generally well tolerated. Most adverse events (AEs) were mild to moderate in severity. Three patients (10%) experienced infusion-associated reactions that were at most mild (n = 2) or moderate (n = 1) in severity. There were no discontinuations due to AEs. Two patients (6%) were positive for anti-drug antibodies on 1 occasion each; neither developed neutralizing antibodies.
Conclusion: Long-term treatment with SA was well tolerated and resulted in sustained improvements in markers of liver injury in this diverse population of patients with LAL-D.

PS-145
Autologous cell/gene therapy approach of hemophilia B using patient specific induced Pluripotent Stem Cells

Background and Aims: Hemophilia B (HB) is a genetic disorder due to an impaired activity of clotting factor IX (FIX), synthesized by hepatocytes. Current treatment based on regular intravenous injections of FIX is very restrictive, costly and only palliative. Gene therapy trials show promising results but their long-term efficacy is still unknown. It is therefore important to explore other therapeutic strategies. This project thus aims to bring a proof of concept for autologous cell/gene therapy of inherited liver diseases by transplanting hepatocytes differentiated from genetically corrected patient-specific induced pluripotent stem cells (iPSCs).

Method: We reprogrammed skin fibroblasts from a severe hemophilia B patient (FIX activity <1%) into iPSCs. Using the CRISPR/Cas9 technology, we then targeted the genomic insertion of a cassette including the hepatic specific apolipoprotein AII (*APOAII)* promoter driving the expression of a *F9* mini-gene. Non-corrected and corrected iPSCs were differentiated into hepatocytes in 2D cultures and in 3D spheroids to study the expression of *F9* mRNA.
Results: HB patient-specific fibroblasts were reprogrammed and one iPSC clone was deeply characterized for self-renewal and pluripotency. Karyotype of the iPSCs was normal and DNA sequencing confirmed the presence of the patient's mutation. CRISPR/Cas9 technology allowed accurate monoallelic correction at the targeted *AAVS1* safe harbor locus. The corrected or non-corrected iPSCs were differentiated into hepatocytes. Due to the promoter used, the *F9* mRNA expressed by the therapeutic cassette is detected earlier during differentiation compared to endogenous *F9* mRNA detected later in the non-corrected clone. Q-RT-PCR confirmed a higher expression of *F9* mRNA in the corrected clone in both 2D and 3D conditions.
Conclusion: We reprogrammed skin fibroblasts from a severe HB patient. HB-iPSCs were genetically corrected by targeted insertion of a therapeutic cassette using CRISPR/Cas9 technology. Corrected and non-corrected iPSCs were differentiated into hepatocytes in both 2D and 3D culture conditions. We detect the *F9* mRNA from the therapeutic cassette at early stages of differentiation compared to the endogenous one. Quantitative RT-PCR confirmed the higher level of FIX mRNA in corrected cells. The therapeutic efficacy, namely the FIX activity, of the correction approach is currently assessed *in vitro*, and *in vivo*, by transplanting corrected iPSC-derived HLCs into a HB mouse model.

PS-146
Low density lipoprotein receptor-deficient hepatocytes differentiated from induced pluripotent stem cells allow familial Hypercholesterolemia modelling, CRISPR/Cas-mediated genetic correction, and productive hepatitis C virus infection

Background and Aims: Familial Hypercholesterolemia type IIa (FH) is a liver genetic disorder caused by mutations in the Low Density Lipoprotein receptor (LDLR) and resulting in premature cardiovascular diseases. Hepatocytes are the only cells able to metabolize cholesterol into bile acids and are therefore the target for FH cell/gene therapy approaches but access to patient cells is restricted. Here, we investigated whether hepatocytes differentiated from induced pluripotent stem cells (iPSCs) from an FH-homozygous patient (FH-iHeps) could model the disease pathophysiology and be corrected by CRISPR/Cas9-mediated targeted recombination, and whether FH-iHeps and corrected iHeps (corr-FH-iHeps) were permissive to hepatitis C virus (HCV) infection.
Method: Using a non-integrative approach, we generated iPSCs from an LDLR-deficient (homozygous null mutation) FH-patient (FH-iPSCs). They were differentiated using a protocol recapitulating liver embryogenesis. For genetic correction, we constructed CRISPR/Cas9 and homologous recombination template plasmids targeting the *AAVS1* safe harbor genomic site and harbored the LDLR cDNA controlled by *apolipoprotein A2* promoter. Upon HCV inoculation, viral replication and production were quantified.
Results: FH-iHeps showed functional hallmarks of human hepatocytes and recapitulated the pathophysiology of FH characterized by an absence of LDLR expression and function. Genetically corrected FH-iPSCs showed monoallelic targeted integration, maintained pluripotency and a normal karyotype. Using the same protocol as for their uncorrected counterparts, we have differentiated them into functional iHeps (corr-FH-iHeps) where LDLR expression and function were restored and inducible by treatment with pravastatin, a lipid-lowering drug. Finally, we have inoculated both FH-iHeps and corr-FH-iHeps with cell-culture derived HCV particles and have demonstrated that they were as permissive to viral infection as primary human hepatocytes. Interestingly, virus production in FH-iHeps was significantly lower than in corr-FH-iHeps, indicating an indirect role of the LDLR in the viral morphogenesis steps rather than a direct one in the entry steps as previously suggested.
Conclusion: Our system provides a useful model for reassessing the controversial role of the LDLR in the HCV life cycle. It could also be used as a platform to screen drugs for treating dyslipidemia and it represents a novel approach to genetically correct metabolic diseases.

PS-147
ARO-AAT, a subcutaneous RNAi-based therapeutic for alpha-1 antitrypsin-related liver disease, demonstrates liver exposure-response and efficacy in preclinical studies

C. Wooddell[1], K. Blomenkamp[2], H. Chen[1], J. Griffin[1], R. Zhu[1], Q. Chu[1], H. Hamilton[1], J. Hegge[1], D. Christianson[3], Z. Li[1], J. Teckman[2], B. Given[3].

Email: cwooddell@arrowheadpharma.com

Background and Aims: Alpha-1 antitrypsin (AAT) deficiency is an autosomal co-dominant genetic disorder. AAT is an abundant serum protein primarily synthesized in liver. The PiZ mutation results in mis-folded protein (Z-AAT) that accumulates as polymers in hepatocytes and can lead to fibrosis, cirrhosis and HCC. Preventing, slowing or reversing liver accumulation of mutant protein could alter the course of AATD-related liver disease (AATDLD). Aside from liver transplant, there are no treatment options for aggressive AATDLD. We previously described an intravenous RNA interference (RNAi)-based therapeutic that demonstrated proof of concept efficacy in the PiZ mouse model expressing human Z-AAT and deep knockdown (KD) in healthy volunteers and patients (Wooddell et al, AASLD 2016, Turner *et al*, EASL 2016). Here we describe a subcutaneous RNAi therapeutic with liver selectivity, ARO-AAT, dose-dependent liver exposure and AAT KD that results in decreased Z-AAT protein in PiZ mouse liver. We hypothesize that the pharmacokinetics and selectivity of ARO-AAT will allow low doses to progress into the clinic with deep and durable target KD.
Methods: Pharmacokinetics were evaluated in rats and NHP. Biodistribution was evaluated in rats. Serum AAT reduction was evaluated in NHP and PiZ mice. ARO-AAT liver exposure and efficacy of AAT mRNA and protein reduction were evaluated in PiZ mice (1, 2, 4 and 8 mg/kg). Efficacy of ARO-AAT for reduction of Z-AAT protein production and accumulation was evaluated in PiZ mice.
Results: ARO-AAT in rats demonstrated high tissue distribution with highest exposure in liver through day 16. Peak levels were measured at day 4. Kidney contained the 2nd highest levels, which were 8.7-fold less than in liver. Liver AAT mRNA reduction was observed in PiZ mice across all doses tested (1, 2, 4, and 8 mg/kg) and days measured (days 8, 15, 22, 29 and 43). PiZ mice given 8 injections (4 mg/kg), dosed every other week, had undetectable monomeric Z-AAT protein and significantly reduced polymer accumulation in liver compared to

untreated mice. Mean serum AAT KD of 89–91% persisted at least 7 weeks following a second dose of 3 mg/kg in NHP.

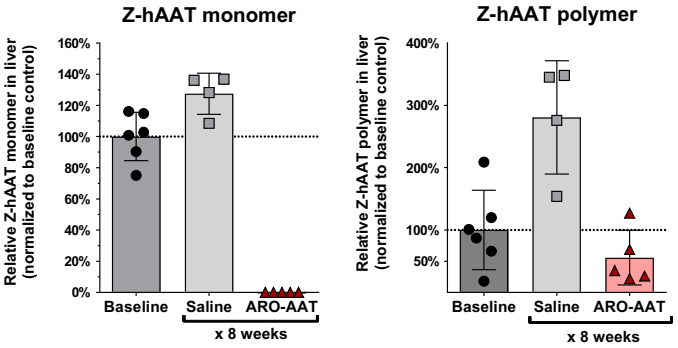

Figure: ARO-AAT reduces liver Z-AAT monomer and polymer content in PiZ mouse liver.

Conclusion: ARO-AAT, a new therapeutic candidate, selectivity targets the liver and reduces liver Z-AAT protein following multi-dose treatment. This subcutaneous RNAi therapeutic holds promise for treatment of patients with AATDLD.

Email: omurillo@unav.es

Background and Aims: Recently, we have demonstrated that an adeno-associated vector serotype 8 carrying the human ATP7B cDNA provides long-term correction of copper metabolism in Wilson's disease (WD) young male mice. However, the size of this vector genome (5.1 Kb) surpasses the optimal size of a packaged AAV genome representing a major drawback for its clinical application. Furthermore, the efficacy of this vector in female mice and in animals with advanced disease (12 weeks) is notably lower than in young male mice. In this work, our main objective was to develop an optimized version of the gene therapy vector for clinical use.
Method: To generate a smaller version of ATP7B, the first four metal binding sites (MBS) from the amino terminal region of the protein were deleted Δ57–486-ATP7B. An AAV vector expressing a mini ATP7B transporter under the control of a liver specific promoter was produced. Additionally, a recently developed synthetic AAV vector, AAV-Anc80, was used to limit the potential impact of preexisting immunity and to improve liver transduction. WD mice at different stages of the disease were treated and copper-related parameters, liver damage and additional parameters altered in WD disease were evaluated.
Results: The AAV vector expressing the mini-AP7B transporter showed a superior therapeutic efficacy in animals of both genders and in animals with advanced disease than the vector expressing the full-length protein. Moreover, we found that WD gene therapy, in addition to restore copper homeostasis and prevent liver damage, also significantly improved a number of additional parameters including cholestasis and haematological alterations observed in WD patients.
Conclusion: Our data demonstrate that gene therapy using an optimized gene therapy vector provides long-term correction of copper metabolism and additional pathological aspects associated with copper accumulation in WD animals independently of the gender and stage of the disease.

Clinical impact of HCV cure

Email: vincenza.calvaruso@unipa.it

Background and Aims: Large scale, real life data on the long term course of liver disease after HCV clearance obtained with DAAs are still scanty, and the separate effects on hepatic and non-hepatic causes of death still unclear.
Methods: We evaluated 4,147 patients (mean age 65.7 ± 11.5 years, 57.6% males) included in the prospective RESIST-HCV cohort who started DAAs treatment in 22 Centres between March 2015 and April 2017. All patients were follow after SVR to register liver-related and unrelated outcomes. The primary endpoint was the evaluation of survival since starting DAAs. Cox regression analysis was used to assess the predictors of liver-related and unrelated death.
Results: Patients were observed for a median of 50 weeks (range 1–199), 934 (22.5%) had diagnosis of chronic hepatitis (F3 in >90%), 2851 (68.7%) had Child A cirrhosis and 362 (8.7%) had Child B cirrhosis. Overall, 3,766 patients (90.8%) achieved SVR while 381 patients (9.2%) were HCV-RNA positive at the last control. Fifty-five patients (1.3%) died during the observation: 25 of them died for liver related causes and 30 for unrelated causes (16: cardiovascular disease, 6: sepsis, 8: other). The lack of SVR was associated with an increased incidence of overall mortality in comparison to patients with SVR, (hazard ratio [HR] 28.9; 95%confidence interval [CI], 16.5–50.8; $p < 0.001$) and death from liver-related and unrelated causes (HR: 18.5, 95%CI:8.2–41.3; $p < 0.001$ and HR, 45.5; 95%CI: 19.3–107.4; $p < 0.001$ respectively). By multivariate Cox regression analysis lack of SVR (HR: 14.9, 95%CI: 6.3–35.1; $p < 0.001$) and Child B cirrhosis (HR:29.4, 95% CI:3.8–223.9; $p < 0.001$) were independently related with liver

mortality. Independent predictors of liver-unrelated mortality were no SVR (HR: 41.77, 95%CI: 17.30–100.87; p < 0.001), Child B cirrhosis (HR: 3.00,95% CI:1.36–6.22; p = 0.006), BMI (HR:0.89, 95%CI:0.81–0.98, p = 0.023) and diabetes (HR: 2.38, 95%CI:1.13–5.00, p = 0.022)
Conclusions: In this real world setting using a variety of DAA regimens SVR reduced overall mortality and risk of liver-related and unrelated deaths at all stages of disease, nut mostly in Child A cirrhosis. The effect on cardiovascular deaths, which is evident also in the pre-cirrhotic stages deserves further follow up and investigation.

PS-150
Long-term impact of HCV eradication after all-oral therapy in patients with clinical significant portal hypertension

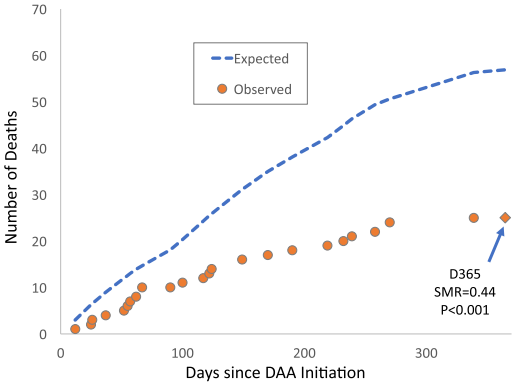
Email: slens@clinic.ub.es

Background and Aims: Previous data from our group showed that clinical significant portal hypertension (CSPH, HVPG > 10 mmHg) persists 24 weeks after sustained virological response (SVR) in up to 78% of patients with HCV-related cirrhosis treated with all-oral antivirals. These patients remain at risk of decompensation. However, long-term hemodynamic data is not available in this population.
Method: Multicenter prospective study of patients with HCV-related cirrhosis and CSPH achieving SVR after all-oral antiviral therapy. Patients with CSPH 24 weeks after therapy underwent a new hemodynamic assessment 96 weeks after end of treatment (SVR24 and SVR96, respectively).
Results: 226 cirrhotic patients with CSPH at baseline (BL) were included, 176 remained with CSPH at SVR24 (Lens et al. Gastroent 2017); 56 of them have SVR96 data. Most patients (77%) were CTP-A; 48 (86%) had esophageal varices (EV; 39% large) and 19 (34%) previous liver decompensation (LD). BL-HVPG was 17.3 ± 4.3 mmHg. Overall, HVPG decreased overtime –2 ± 3.2 mmHg at SVR24 and –4.3 ± 3.6 mmHg at SVR96 (both, p < 0.01). A clinically relevant decrease (>20%) was observed in 18 (32%) patients at SVR24 and in 35 (62%) at SVR96. Nevertheless, 43 (76%) patients at SVR96 still had CSPH. Cumulative CSPH persistence was 76% at SVR24 and 59% at SVR96. Interestingly, HVPG increased between SVR24-SVR96 in 10% of patients (any risk factor??). Among the 43 patients with LSM at all time points (BL-LSM 31–16 kPa), LSM decreased overtime –5.7–12 at SVR24 and –8.6–13 kPa at SVR96 (both p < 0.01). Importantly, six out of 10 patients with LSM <13.6 kPa at SVR96 still had CSPH. All previously LD patients remained compensated except 3 patients. De novo LD occurred in 2 patients. In addition, EV developed in 1 patient and increased in size in 4 patients, all patients had CSPH.
Conclusion: SVR to all-oral antiviral regimens is associated with a progressive reduction in portal pressure in patients with CSPH at baseline. However, CSPH may persist in up to 59% of patients even in the long-term, indicating persistent risk of decompensation and EV development/progression. In addition, currently available LSM cut-offs are not reliable to rule out CSPH after SVR.

PS-151
Survival benefits of direct-acting antiviral therapy in patients with decompensated hepatitis C cirrhosis
W.R. Kim[1], A. Osinusi[2], A. Mannalithara[1], R.A. Schall[2], D. Brainard[3]. *[1]Stanford University, Division of Gastroenterology and Hepatology, Stanford, United States; [2]Gilead Sciences, Foster City, [3]Gilead Sciences, Gilead Sciences, Foster City, United States*
Email: wrkim@stanford.edu

Background and Aims: Current direct-acting antiviral (DAA) therapy for hepatitis C virus (HCV) infection leads to sustained virological response (SVR) in the vast majority of patients, even in those with decompensated cirrhosis. SVR in patients with decompensated cirrhosis has been associated with improvement in liver function; however, the extent to which DAA impacts on mortality remains to be determined. We analyse mortality in patients who participated in clinical trials evaluating sofosbuvir-based regimens in patients with decompensated HCV cirrhosis (GS-US-334-0125, SOLAR and ASTRAL studies), in comparison with mortality predicted by a survival model derived in untreated HCV patients.
Method: Observed incidence of death was obtained from GS-US-334-0125 study, the pre-transplant cohorts of the SOLAR-1 and -2 studies, and the ASTRAL-4 study. In determining expected mortality without DAA therapy in the study participants, a previously validated prediction model was applied to estimate survival probability of each individual patient up to one year. The model, consisting of age, MELD-Na, sodium, albumin, and hepatic encephalopathy (HE), had been derived in patients with hepatic decompensation awaiting liver transplantation in the pre-DAA era. We computed the standardized mortality ratio (SMR), with which the observed and expected numbers of deaths were compared from the start of DAA therapy.
Results: There was a total of 492 patients, whose median age was 58 years, MELD 12, sodium 137 mEq/l and albumin 2.9 g/dl. Ascites and HE were common (79% and 63%, respectively). Altogether, 411/479 (86%) patients achieved SVR12. During the follow up, there were 25 deaths within one year of DAA therapy start, including 15 in the SOLAR and 10 in the ASTRAL data; no deaths occurred in GS-US-334-0125. The number of observed deaths in the clinical trials closely followed the expected/predicted numbers early in the treatment course (Figure). Starting at 100 days after initiation of DAA, however, the observed number of deaths was statistically significantly smaller than expected (SMR = 0.54, 95% confidence interval [CI] = 0.30–0.98). All subsequent deaths occurred at a lower frequency than expected. The last (25th) death during the study period occurred on day 339, when the SMR had decreased to 0.44 (95% CI = 0.30–0.65), which remained unchanged at the end of the analysis (day 365).



Conclusion: DAA therapy in patients with decompensated HCV cirrhosis leads to significantly decreased mortality, which may be apparent as early as 100 days after the initiation of therapy with the risk of mortality decreasing to 44% of the expected by the end of the first year.

PS-152

IFN-free DAA treatment of cirrhotic HCV patients with or without history of HCC: a multicenter prospective trial in Italy

Email: pietro.lampertico@unimi.it

Background and Aims: Whether sustained virologic response (SVR) to Interferon (IFN) free direct antiviral agents (DAAs) therapy is associated with an increased risk of developing HCC is a matter of debate. Aim of this study was to evaluate whether the incidence of de novo or recurrent HCC increases after starting DAA treatment and which variables are associated with HCC development.

Method: In a multicenter prospective cohort enrolled between Jun. 2014 and Sept 2017, 1,030 consecutive HCV cirrhotic patients with no history of HCC (Group 1): 603 (59%) males, median age 66 years (22–85), and 122 consecutive patients with radiological CR to HCC treatment (Group 2): 83 (68%) males, median age 73 years (48–86) were enrolled and treated with IFN-free DAA. SVR was obtained in 955 (97%) in group 1, pending SVR in 42 cases, and in 112 (95%) in group 2, pending 6 cases. Time from last imaging and last HCC treatment, age, gender, Child, AFP, HCV GT, presence of undefined/non-malignant liver nodules, duration of DAA therapy, were considered. Hazard rate analysis on time was performed to assess instant HCC incidence and recurrence, comparing values across the entire follow-up with flexible non-parametric smoothing techniques and parametric survival. Multivariable Cox regression analysis was performed to assess the association of variables with HCC development and recurrence.

Results: In SVR patients, during a median follow-up of 62 wks (range 1–174) de novo HCC occurred in group 1 in 36 patients (10/93 with undefined/non-malignant nodules), corresponding to an annual incidence of 3.8%, and during a median follow up of 48 wks (range 1–116) HCC recurred in 33 in group 2, corresponding to an annual incidence of 32.7%. Looking to smoothed estimation, an underlying non monotonic trend was observed in both groups with a peak of HCC instant incidence at 47 wks in group 1 and at 30 weeks in group 2. By multivariable Cox regression models, the presence of undefined/non-malignant hepatic nodules (HR = 3.5 CI 1.7–7.3, p = 0.001, with a time dependent relation, and Child-Pugh (HR = 1.6, 95%CI 1.2–2.1, p < 0.001) were associated with de novo HCC incidence in group 1, while overall no variables showed evidence of association with HCC recurrence.

Conclusion: IFN-free DAA treatment of HCV cirrhotic patients allows, in SVR population, a progressive decrease of de novo and recurrent HCC incidence after a non significant increased number of HCC observed at 30 weeks after stating DAA in patients with history of previous HCC and at 47 weeks after starting DAA in patients without history of HCC. Presence of undefined/non-malignant liver nodules and Child-Pugh class are independently associated with de-novo HCC development, being the presence of undefined/non-malignant hepatic nodules associated with the increased number of HCC at 47 weeks.

Email: martina.gambato@gmail.com

Background and Aims: Nowadays, using high effective and safe all-oral direct acting antivirals (DAAs), most cirrhotic patients can be cured. Unexpectedly, some studies reported high early hepatocellular carcinoma (HCC) recurrence rate after curative treatment (up to 30%), in HCC patients receiving antiviral therapy (AT). However, conflicting data still exists in this setting. We aimed to analyze HCC recurrence rate in a cohort of HCV-infected patients with prior HCC who underwent AT after achieving complete radiologic response.

Methods: HCV-infected patients with prior HCC who underwent AT between 01–2015 and 04–2017, included in the Navigatore web-based platform in Italy (>2000 participants), were considered for the study (n = 132). Clinical, virological and HCC-related features before starting AT and during the follow-up were registered. Patients treated with AT after LT (n = 23) or during the waiting list for LT (active HCC, n = 8) were excluded.

Results: One-hundred and one HCV-HCC patients who received AT after complete radiologic response were included (67% male, median age 68 years). Most of them (79%) were Child-Pugh (CTP) class A and median MELD was 9. They received different DAA regimens: 44% SOF/LDV, 22% SOF/RBV, 18% 3D, 11% SOF + DCV, 5% SOF + SMV, according to HCV genotype (65% G1) and clinical features. SVR12 was 91%. Baseline BCLC stage at HCC treatment was BCLC 0 in 37% and A in 63% with a median AFP of 11 ng/mL; 68% received resection/ablation and 32% TACE before starting AT. After a median follow-up of 22 months (IQR 15–27) since start DAA, the rate of HCC recurrence was

32.6% (33/101). The median time between the last radiological evaluation (no-active HCC) and AT was 2.5 months (IQR 1–5), with no difference between patients with HCC recurrence (H-R) compared to those without HCC recurrence (no H-R). Comparing the 2 groups (H-R vs no H-R) no difference was detected in term of CTP, MELD, APRI score, liver stiffness and BMI. The pattern of recurrence was: intrahepatic lesion (single nodule in 16/33, multifocal in 16/33) and extra-hepatic lesions in 1 patient who died. Nearly half of patients (16/33) received loco-regional treatment, 39% (13/33) resection, ablation or LT, 2/33 best supportive care and 2/33 are awaiting HCC treatment.

Conclusion: In this preliminary analysis, the rate of HCC recurrence in patients treated with DAAs was nearly 30%. Since the time between HCC eradication and DAAs starting was short, the real impact of DAAs on HCC natural course is still unclear. Full data analysis is still ongoing and will be presented at ILC2018.

PS-154

SVR is the strongest predictor of occurrence and recurrence of hepatocellular carcinoma in HCV cirrhotic patients after treatment with DAAs: a prospective multi-centric Italian study

Email: ana.lleo@humanitas.it

Background and Aims: Patients with hepatitis C virus (HCV) related cirrhosis have an expected high rate of progression to liver decompensation and hepatocellular carcinoma (HCC); dramatic improvement in viral eradication rates has been reached with direct antiviral agents (DAAs). Nevertheless, the real benefit of viral eradication after DAAs on disease progression, including HCC development, are still limited and controversial. We aim to prospectively assess the risk of HCC occurrence and early recurrence in a large prospective cohort of DAA-treated HCV-cirrhotic patients.

Methods: We analysed data prospectively collected from HCV-infected cirrhotic patients consecutively treated with DAA from January to December 2015 in 10 tertiary liver centers in Italy. Patients with either compensated or decompensated cirrhosis and/or previous HCC were enrolled.

Results: 1,927 patients were included; 161 patients had a previous history of HCC. Most patients were in Child Pugh class A (88% without history of HCC and 85% of patients with previously treated HCC), and the mean MELD score was 8 in both groups. 1,832 patients (95%) achieved SVR. No difference in SVR rates was observed regardless the history of HCC. Of the 161 patients with past HCC, 38 developed tumor recurrence during the follow-up (incidence person-year 24.8%). Patients with SVR had a significantly lower rate of HCC recurrence. Cox regression analysis highlighted SVR (HR 8.43; 95%CI: 2.85–24.9; p = 0.0001) and alfafetoprotein (HR 6.50; 95%CI: 1.91–22.1; p = 0.002) as independent predictors of HCC recurrence. Both SVR and alfafetoprotein were confirmed as solid predictors of recurrence at the multivariate analysis. 50/1,766 patients (2.8%) without a previous HCC history developed HCC during the follow-up (cumulative incidence p-year, 2.4%). Patients with SVR had a significantly lower rate of HCC recurrence at all time points. SVR was confirmed as the strongest predictor of HCC incidence from the univariate (HR 6.31; 95%CI: 3.07–13.0; p < 0.0001) and multivariate analysis (HR 5.02; 95%CI: 2.34–10.8; p < 0.0001).

Conclusions: This large real-life study highlights that SVR is associated with a significant decrease of recurrent or de novo HCC in cirrhotic patients treated with DAA. Longer follow up is underway to confirm these findings.

PS-155

Risk of total non-hepatic cancer following treatment for HCV infection with direct-acting antiviral agents

A. Chokkalingam[1], A. Singer[1], L. Telep[1], A. Osinusi[2], D. Brainard[3].

Email: anand.chokkalingam@gilead.com

Background and Aims: Hepatitis C virus (HCV) infection has been associated with extrahepatic co-morbidities. Prior to the introduction of direct-acting antiviral (DAA) agents, HCV therapy involved interferon (IFN), which has been reported to have anti-tumour effects, but has substantial side effects and has low sustained virologic response (SVR) rates. In contrast, DAAs are well-tolerated and have SVR rates >90%. To characterize the long-term effects of DAA-based therapy, we examined the risk of total non-hepatic cancer associated with DAA treatment, vs IFN treatment in the pre-DAA era.

Methods: Among 367,156 adults with chronic HCV infection enrolled between January 2006 and March 2017 in a U.S. administrative claims database, we identified 22,894 who were exposed to DAAs (follow-up through March 2017), and 10,989 who were exposed to IFN prior to May 2011 (introduction of boceprevir, follow-up through November 2013). All patients had ≥12 months of prior enrolment and no evidence of prior cancer at baseline. Absolute rates per 100 person-years (PY) of cancer events (identified by diagnostic claims, excluding liver cancer) were calculated, along with exact 95% Poisson confidence intervals (CIs). Hazard ratios (HRs) estimating cancer risk associated with DAA vs pre-DAA IFN were estimated using Cox proportional hazards methods, after adjustment for covariates and incorporation of weighting based on treatment propensity scores.

Results: Following DAA exposure and IFN exposure, median follow-up was 0.94 PY (Q1, Q3: 0.48 PY, 1.69 PY) and 2.59 PY (Q1, Q3: 1.12 PY, 4.15 PY), respectively. The absolute rate of total non-hepatic cancer following DAA exposure was slightly higher than that following IFN exposure: 6.07 per 100 PY (95%CI: 5.78–6.38) vs 5.52 per 100 PY (95% CI: 5.26–5.79). However, after adjustment for covariates including age, gender, and baseline comorbidities and medication use, as well as propensity score weighting, DAA exposure was associated with a significantly reduced risk relative to IFN exposure (HR: 0.86, 95%CI: 0.80–0.93). Further analyses, including analyses by major cancer site, are planned.

Conclusions: In this study, we found DAA exposure was associated with a lower risk of total non-hepatic cancer, relative to IFN. Given the well-described differences in SVR rates between DAA and IFN-based regimens, we hypothesize that the reduced risk of non-hepatic cancer associated with DAA therapy may reflect the long-term impact of successful HCV treatment at a population level.

Email: vithika.suri@gilead.com

Background and Aims: In Phase 3 studies in chronic hepatitis B (CHB) patients**,** tenofovir alafenamide (TAF), a new tenofovir (TFV) prodrug, has shown noninferior efficacy to tenofovir disoproxil fumarate (TDF) at Weeks 48 and 96, with superior bone and renal safety. TAF is a preferred treatment in the 2017 EASL HBV Guidelines, especially in patients with risk factors for TDF-associated renal and bone effects. We assessed the 1 year safety and efficacy in CHB patients with TDF risk factors (RF) who were switched from TDF to TAF.

Method: In 2 identically-designed studies, HBeAg-positive and -negative patients were randomized 2:1 to TAF 25 mg or TDF 300 mg QD and treated in a double-blind fashion for 96 weeks, after which patients received open-label (OL) TAF. Renal (serum creatinine [sCr], eGFR by Cockcroft-Gault [$eGFR_{CG}$] and urine biomarkers of tubular function) and bone (serial DXA scans at hip/spine and serum bone biomarkers) safety parameters, antiviral efficacy (HBV DNA < 29 IU/ml), and ALT normalization were assessed in the subset of switched patients having baseline RF for TDF: Age > 60 yr, osteoporosis of hip/spine, ≥Stage 2 chronic kidney disease (CKD), albuminurina (UACR > 30mg/g), hypophosphatemia (PO_4 <2.5 mg/dl), or comorbidities associated with CKD (e.g. HTN, DM, obesity).

Results: Of 1,298 patients randomized and treated, 540 switched to OL TAF at Week 96 (TAF→TAF in 360; TDF→TAF in 180), of whom 284 (53%) had ≥1 TDF RF; 123 (23%) patients had ≥2 RF. Baseline demographics were similar between groups. Renal and bone safety results at Week 144 are summarized in the table. At Week 144, TDF patients switched to TAF showed improvements in renal (sCr, $eGFR_{CG}$) parameters with a higher percentage of patients showing improvement vs worsening of CKD stage. Improvements in hip and spine BMD were seen at 1 year following switch. Patients continuing TAF showed similar small changes in renal/bone parameters. Antiviral efficacy was maintained in both groups and TDF patients switching to TAF at Week 96 had increased rates of ALT normalization at Week 144.

Table: Renal and bone safety results at Week 144 in CHB patients with TDF risk factors switched from TDF to TAF at Week 96

Change from Open-label (Week 96) baseline:	TDF→TAF (n = 101)	p value[a]
Renal parameters		
Serum creatinine, mean (SD) change (mg/dl)	−0.018 (0.064)	0.008
$eGFR_{CG}$, median (Q1, Q3) change (ml/min)	+3.0 (−1.8, 7.8)	<0.001
≥1 stage improvement in CKD stage from Week 96 (OL baseline) to Week 144, n/N (%)	9/51 (18)	ND[b]
≥1 stage worsening in CKD stage from Week 96 (OL baseline) to Week 144, n/N (%)	4/95 (4)	ND
Bone parameters		
Hip BMD, mean (SD) % change	+0.97 (2.88)	0.002
Spine BMD, mean (SD) % change	+2.18 (3.36)	<0.001

[a]p values from T test; [b]ND is testing not done.

Conclusion: CHB patients with risk factors for TDF toxicity who are switched from TDF to TAF have improved bone and renal safety and normalization of ALT levels whilst efficacy was maintained in this subgroup at one year.

Email: gihankhys@yuhs.ac

Background and Aims: Besifovir dipivoxil maleate (BSV) is an acyclic nucleotide phosphonate with a potent antiviral activity against hepatitis B virus (HBV). In the former phase 3 study, an antiviral efficacy of BSV for forty-eight week was shown to be comparable to

tenofovir disoproxil fumarate (TDF) in treatment-naïve chronic hepatitis B (CHB) patients. We evaluated long-term efficacy and safety of BSV in chronic hepatitis B patients who were positive or negative for hepatitis B e antigen (HBeAg+ or HBeAg-) in the extended follow up of a phase 3 study.

Method: After 48 weeks of double-blind comparison of BSV to TDF, eligible patients who had agreed with the extended study continued to participate in the open-label BSV study. The presented data were collected for 96 weeks. We evaluated virological, serological, and biochemical responses for efficacy analysis, and bone mineral density (BMD) and renal outcomes for safety analysis for both BSV group (BSV-BSV) and the group switched from TDF (TDF-BSV). The primary endpoint was the proportion with HBV DNA <400 copies/ml (response rate).

Results: Among 197 patients who received randomized treatments, 170 (87%) patients entered the open-label phase, and 161 (82%) completed 96 weeks of the study. The response rate of those who have taken BSV over 96 weeks is 87.21% while 85.71% of patients who switched the treatment from TDF were respondent. HBeAg seroconversion and ALT normalization were shown in 11.54% and 73.26% of patients in the BSV-BSV group, respectively. There were no drug resistant mutations to BSV and no adverse events related to bone mineral density or renal function. The safety profile was similar for the two groups.

Conclusion: BSV maintained efficacy in both suppression of HBV DNA and ALT normalization over 96 weeks without any evidence of resistance to BSV. Also, BSV is safe, well tolerated, and effective for those who have switched to BSV from TDF.

PS-158

Increased incidence of HBsAg seroclearance in HBeAg negative chronic hepatitis B patients discontinued Nuc therapy comparing to natural course–a propensity score matched study

W.-J. Jeng[1,3,5], H.-I. Yang[2,6], Y.-C. Chen[1,3,5], J. Liu[2,4], R.-N. Chien[1,3,5], I.-S. Sheen[1,5], C.-J. Chen[2], Y.-F. Liaw[3,5]. *[1]Department of Gastroenterology and Hepatology, Chang Gung Memorial Hospital, Linkou; [2]Genomic Research Center, Academia Sinica; [3]College of Medicine, Chang Gung University; [4]Stanford University School od Medicine and Lucile Packard Children's Hospital; [5]Liver research Unit, Chang Gung Memorial Hospital, Linkou; [6]Institute of Clinical Medicine, National Yang Ming University*

Email: liveryfl@gmail.com

Background and Aims: Hepatitis B s antigen (HBsAg) loss is a rare event during nucleos(t)ide analogue (Nuc) therapy but may increase in HBeAg negative chronic hepatitis B patients with sustained remission during off Nuc follow-up. It is unknown whether the incidence during and off Nuc is the effect of therapy or just an event of the natural course of chronic hepatitis B.

Aim: To test whether the incidence of HBsAg seroclearance in HBeAg negative CHB patients with finite Nuc therapy is higher than that of subjects in REVEAL natural history cohort.

Method: A total of 762 HBeAg negative CHB patients received finite Nuc therapy from Chang Gung Memorial Hospital were compared to 2,772 HBeAg negative REVEAL-CHB cohort patients whose baseline HBV DNA and HBsAg quantification data were available. Propensity score matching (PSM) on age, gender, cirrhosis, baseline ALT, HBV DNA and HBsAg (qHBsAg) levels were applied. The Incidence of HBsAg seroclearance was calculated. Cox regression model was used for investigating predictors of HBsAg seroclearance after adjustment for PSM-variables.

Results: Before adjustment, the Nuc-treated cohort showed older age, greater proportion of male, liver cirrhosis and genotype B, higher ALT, HBV DNA and qHBsAg levels and shorter follow-up duration. After 1:1 propensity score matching, there were 262 patients each in Nuc-treated and REVEAL cohort. The incidence rate of HBsAg seroclearance in Nuc-treated cohort was 105.637 x 10^4 person-year while it was 82.790 x 10^4 person-year in REVEAL cohort. Kaplan-Meier analysis showed higher cumulative HBsAg seroclearance rate in patients with finite Nuc-therapy (p = 0.001). The difference became more apparent after 6 years of follow-up since the entry of treatment (treatment duration: mean: 3.1 years). Multivariate Cox regression analysis showed that lower qHBsAg at entry (>=1000 vs. <1000, adjusted HR: 0.167(0.072–0.388), p < 0.0001) and patients with finite Nuc treatment (vs. REVEAL, adjusted HR: 3.41 (1.634–7.116), p = 0.0011) were two independent predictors for HBsAg seroclearance.

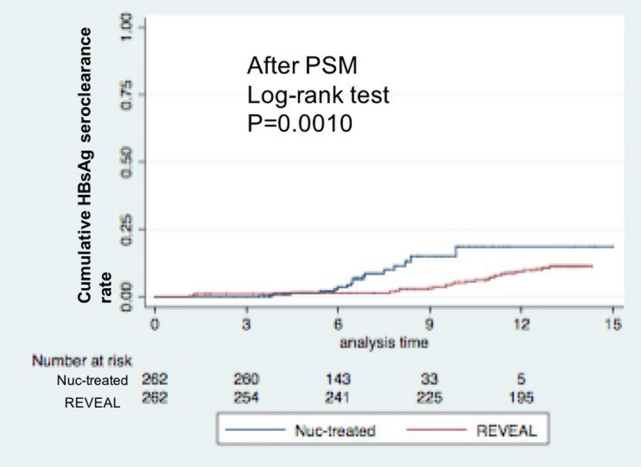

Figure: Cumulative HBsAg seroclearance rate of Nuc-treated cohort and REVEAL cohort after propensity score matching of age, gender, cirrhosis, baseline HBV DNA, qHBsAg and ALT.

Conclusion: The findings (1) patients with finite Nuc therapy had significantly higher incidence of HBsAg seroclearance than that during the natural course of CHB; (2) finite Nuc therapy was an independent factor for HBsAg seroclearance; indicate that HBsAg seroclearance in patients with finite Nuc therapy reflects the effect of therapy rather than just a natural event of HBeAg-negative CHB.

PS-159

Rates and predictors of HBsAg loss after discontinuation of effective long-term Entecavir or Tenofovir therapy in non-cirrhotic HBeAg-negative chronic hepatitis B patients: Results from the DARING-B prospective Greek study

M. Papatheodoridis[1], E. Rigopoulou[2], E. Hadziyannis[3], Z. Kalliopi[2], V. Xourafas[1], A. Lyberopoulou[2], N. Gatselis[2], I. Vlachogiannakos[1], S. Manolakopoulos[1], G. Dalekos[2], G. Papatheodoridis[1]. *[1]Medical School of National and Kapodistrian University of Athens, Laikon General Hospital, Department of Gastroenterology, Athens, Greece; [2]Thessaly University Medical School, Department of Medicine and Research Laboratory of Internal Medicine, Larissa, Greece; [3] Medical School of National and Kapodistrian University of Athens, Hippokrateion General Hospital, 2nd Department of Internal Medicine, Athens, Greece*

Email: gepapath@med.uoa.gr

Background and Aims: According to the recent European guidelines, cessation of nucleoside analogues (NAs) may be attempted in selected non-cirrhotic Chronic Hepatitis B patients (CHBe-) patients who have remained in long-term remission under NAs and will remain under close monitoring. Although virological relapses are common, they may be transient and lead to long-term remission and even HBsAg loss, the ideal endpoint of HBV therapy. This prospective study carefully assessed the rates and predictors of off-NAs HBsAg loss in non-cirrhotic CHBe- patients with long-term virological remission under entecavir (ETV) or tenofovir (TDF).

Method: 60 patients (M/F:39/21, age:59 ± 11 years) with CHBe- and no cirrhosis before therapy (Ishak-stage ≤ 4 and/or elastographic stiffness <10 kPa), who had received ETV/TDF for ≥4 years and had undetectable HBVDNA for ≥3 years consented to participate. None had coinfection, HCC or liver transplantation. All agreed to remain

under close follow-up (monthly for first 3 months and every 2/3 months thereafter in case of detectable/undetectable HBVDNA). Serum ALT, HBV DNA, HBsAg and interferon-inducible protein 10 (IP10) levels were determined at each visit after stopping ETV/TDF.
Results: Mean patient follow up has been 19 ± 9 months. No patient died or developed jaundice or decompensation. The cumulative rates of virological relapse defined as HBV DNA > 2000 IU/ml were 63%, 67% and 70% at 6, 12, and 18 months and of HBsAg loss were 5%, 10%, 20% and 30% at 0, 6, 12, and 18 months after NAs cessation. The probability of subsequent HBsAg loss was not affected by age, sex, liver fibrosis severity, pretreatment ALT or HBV DNA levels, but it was significantly higher in patients with lower HBsAg serum levels at NAs cessation [HR per 100IU/l: 1.35 (95%CI: 1.09–1.69), p = 0.008] or at month 1 [HR per 100IU/l:1.28 (1.05–1.56), p = 0.016], higher ALT at month 1 [HR per 10IU/l: 1.12 (1.01–1.26), p = 0.033] and higher IP10 at month 1 [HR per 10IU/l: 1.09 (1.01–1.19), p = 0.021].
Conclusion: Our prospective study shows that discontinuation of effective long-term (≥4-year) ETV/TDF therapy in non-cirrhotic CHBe- patients can lead to increasing HBsAg loss rates exceeding 20% after the first year of follow-up. Higher probability of subsequent HBsAg loss is associated with lower serum HBsAg levels at treatment cessation and at month 1 but also with higher ALT and IP10 levels at month 1 after ETV/TDF cessation suggesting that untreated early post-treatment flares may lead to immune control and functional cure.

PS-160
Effects of SB9200 (Inarigivir) therapy on immune responses in patients with chronic hepatitis B
R. Walsh[1], R. Hammond[1], K. Jackson[1], R. Edwards[1], C. Macfarlane[2], R. Iyer[2], M.-F. Yuen[3], H. Chan[4], N. Afdhal[2], S. Locarnini[1]. *[1]Victorian Infectious Diseases Reference Laboratory, Australia; [2]Spring Bank Pharmaceuticals, United States; [3]University of Hong Kong, Hong Kong; [4]The Chinese University of Hong Kong, Hong Kong*
Email: renae.walsh@mh.org.au

Background and Aims: Inarigivir (SB9200) is a small molecule dinucleotide orally active HBV antiviral with both direct acting and immune modulatory activity, stimulating the host innate antiviral response. It binds to the cytosolic pattern recognition receptor retinoic-acid-inducible gene (RIG-I) to enhance RIG-I binding to the 5'-epsilon region of the HBV pregenomic RNA. The ACHIEVE trial is a double-blind placebo (PL) controlled study of ascending doses of Inarigivir PO daily monotherapy or PL for 12 weeks, followed by a switch to 300 mg Tenofovir daily for a further 12 weeks. We report here the comparative effects of low dose Inarigivir monotherapy on the anti-HBs antibody (Ab) response (HBsAg epitope profile, and complexed Ab) on thirty-eight naive non-cirrhotic HBV patients randomised 4:1 to twelve weeks of 25 mg or 50 mg Inarigivir or placebo.
Method and Results: Inarigivir therapy resulted in significant decline in HBV DNA, HBV RNA and HBcrAg levels in the majority of treated patients with modest decline in HBsAg. Inarigivir therapy cohorts (25 mg and 50 mg doses) were further analysed for effects on immune responses, applying bioassays for developing Ab response markers predictive of HBsAg clearance including development of HBsAg clearance profile (CP) and complexed HBsAg/anti-HBs. A decline in HBV DNA together with the development of a HBsAg CP during the 12 weeks of Inarigivir therapy was observed in 1/16 (6%) subjects who received 25 mg of drug, and this response increased to 4/13 (31%) of subjects receiving 50mg of drug. This relationship was not observed in any PL subjects (n = 8) during the 12 weeks treatment period. The detection of anti-HBs Ab complexed with HBsAg, indicative of an underlying or emerging immune response, was enhanced from 2/16 (12%) in the 25 mg treatment cohort, to 6/13 (46%) in the 50mg Inarigivir therapy cohort during the 12 weeks of treatment. Furthermore, the development of complexed anti-HBs was enhanced in 6/13 (46%) of patients in the 50mg treatment cohort compared to the PL arm with only 1/4 (25%) subjects developing complexed anti-HBs.
Conclusion: Serum biomarkers indicative of Ab response were found to display a strong trend during 12 weeks of Inarigivir therapy compared to PL. Predictive markers of anti-HBs response were enhanced in the 50mg versus 25mg Inarigivir therapy cohorts, revealing a dose response relationship of nascent immune recovery due to low dose Inarigivir therapy, suggesting higher doses should be further studied.

PS-161
Subanalysis of the LOWR HDV-2 study reveals high response rates to Lonafarnib in patients with low viral loads
C. Yurdaydin[1,2], C. Kalkan[2], F. Karakaya[2], A. Caliskan[2], S. Karatayli[2], O. Keskin[2], R. Idilman[2], M. Bozdayı[2], C. Koh[3], T. Heller[3], J. Glenn[4]. *[1]Gastroenterology, Turkey; [2]Division of Gastroenterology, University of Ankara Medical School, Turkey; [3]Liver Diseases Branch, NIDDK; [4]Division of Gastroenterology and Hepatology and Department of Microbiology and Immunology, Stanford University School of Medicine*
Email: cihan.yurdaydin@medicine.ankara.edu.tr

Background and Aims: The LOWR HDV-2 study explored multiple combinations of LNF and RTV, with or without PEG-IFNα, for 12 to 48 weeks, in patients chronically infected with HDV. Antiviral responses were observed in all treatment groups. Here we sought to analyze response rates as a function of baseline viral loads (BVL) among patients completing 24 weeks of the various LNF-based regimens.
Method: 33 patients completed 24 weeks of the following LNF-based regimens:
Group 1 (n = 14): LNF 50 mg BID + RTV 100 mg BID. This included 2 re-treatment patients, who had previously been treated with a short oral course of LNF based therapy (LNF 200 mg BID or LNF 300 mg BID for 12 weeks), and achieved HDV RNA negativity for 6 months, followed by a return of HDV RNA to low BVL < 4 log; Group 2 (n = 6): LNF 25 mg BID + RTV 100 mg BID; Group 3 (n = 4): LNF 50 mg BID + RTV 100 mg BID + PEG-IFNα 180 micrograms QW; Group 4 (n = 5): LNF 25 mg BID + RTV 100 mg BID + PEG-IFNα 180 micrograms QW; Group 5 (n = 4): LNF 50 mg BID + RTV 100 mg BID + addition of PEG-IFNα 180micrograms QW for weeks 12–24. 12 of 33 (36%) patients had low BVL, defined as <4 logIU/ml and 21 of 33 (64%) patients had BVL > 4 logIU/ml. HDV RNA was measured by validated RoboGene® HDV RNA Quantification (LOQ: 14IU/ml; LOD 8IU/ml). Responders were defined as patients achieving >2 log drop in HDV RNA (or BLOQ for patients with BVL < 2 log) at the end of 24 weeks.
Results: 21 of 33 (64%) patients across all treatment groups were responders at 24 weeks. For patients with BVL > 4 log, response rate was 12 of 21 (57%). Response rate at 24 weeks for patients with low BVL < 4 log was higher, 9 of 12 (75%), described below:
7 of 7 (100%) patients treated with all oral LNF 50 mg BID + RTV 100 mg BID (Group 1) were BLOQ (n = 2) or PCR-negative (n = 5) at 24 weeks, including the 2 re-treatment patients. 1 of 1 patients from Group 4 and 1 of 1 patients from Group 5 became BLOQ at 24 weeks. 0 of 3 (0%) patients from Group 2 were BLOQ at 24 weeks. Group 3 had no patients with low BVL
Conclusion: 6-month LNF-based regimens achieved virologic responses in a majority of patients. All oral LNF 50 mg BID + RTV 100 mg BID appears to be particularly attractive for patients with low BVL, as 100% of patients were responders. These results also suggest that prolonged control of HDV may be achieved in appropriate patients by 6-month pulse therapy with all oral LNF 50 mg BID + RTV 100 mg BID, in both LNF naïve and experienced patients.

PS-162

Strong intrahepatic decline of hepatitis D virus RNA and antigen after 24 weeks of treatment with Myrcludex B in combinationwith Tenofovir in chronic HBV/HDV infected patients: Interim results from a multicenter, open-label phase 2b clinical trial

L. Allweiss[1], C. Dettmer[1], T. Volz[1], K. Giersch[1], A. Alexandrov[2], H. Wedemeyer[3,4], S. Urban[4,5], J.-H. Bockmann[1,4], M. Luetgehmann[4,6], M. Dandri[1,4]. *[1]University Medical Center Hamburg-Eppendorf, I. Department of Internal Medicine, Hamburg, Germany; [2]MYR GmbH, Bad Homburg, Germany; [3]Hannover Medical School, Department of Gastroenterology, Hepatology and Endocrinology, Hannover, Germany; [4]German Center for Infection Research (DZIF), Hannover, Heidelberg and Hamburg-Lübeck-Borstel Partner Sites; [5]University Hospital Heidelberg, Department of Infectious Diseases, Molecular Virology; [6]University Medical Center Hamburg-Eppendorf, Department of Medical Microbiology, Virology and Hygiene, Hamburg, Germany*
Email: lenaallweiss@hotmail.com

Background and Aims: Besides interferon alpha there is no approved treatment for patients chronically infected with hepatitis delta virus (HDV). Myrcludex B (MyrB) is a first-in-class entry inhibitor which blocks the HBV/HDV receptor sodium taurocholate co-transporter NTCP. Interim results of this phase 2b clinical trial on chronically HBV/HDV co-infected individuals receiving MyrB daily in combination with TDF demonstrated a dose-dependent HDV RNA decline in serum, which was accompanied by ALT reduction and normalization in some patients *(Wedemeyer et al., Hepatology 2017, DOI: 10.1002/hep.29500)*. Here we investigated the efficacy of MyrB treatment in reducing HDV intrahepatically using paired liver biopsies obtained at baseline (BL) and week 24.
Method: 120 HBeAg-negative patients with chronic Hepatitis D were randomized in 4 treatment arms. TDF treatment (245mg/day) started at least 12w prior to MyrB. MyrB was administered s.c. once daily at 2 (A), 5 (B) or 10 (C) mg for 24w. Patients in arm D received TDF alone. BL biopsies were available for 31 patients, paired liver biopsies for 22 patients. Virological parameters were assessed by qPCR and immunohistochemistry. Expression of inflammatory genes was determined by qPCR.
Results: At w24, intrahepatic HDV RNA declined in all MyrB arms with median reductions from BL by 0.78 log in A (n = 7), 1.07 log in B (n = 5) and by 1.34 log in C (n = 7). TDF treatment (D) showed modest HDV RNA reductions (0.30 logIU/ml, n = 3). Median HBV infection levels at BL (n = 31) were 0.23 HBV DNA copies/cell, 0.03 cccDNA copies/cell, 2.5 total HBV RNA/GAPDH; among paired biopsies, the strongest median reduction of HBV RNA (0.4 log) and total HBV DNA (0.6log) was determined in group C. Of note, immunohistochemistry revealed a substantial and dose-dependent decrease of HDAg+ cells. Accordingly, transcriptional levels of inflammatory chemokines decreased (e.g. CXCL10 median 0.45 Δlog 10) and such reduction was more pronounced in patients with intrahepatic HDV RNA decline of $\geq$1 log10.
Conclusion: Intrahepatic levels of HDV RNA and of HDAg+ cells strongly declined after 24 weeks of MyrB treatment in a dose-dependent manner. The concomitant ALT reduction and decrease of inflammatory cytokines suggests that the drop of HDV infection can diminish liver inflammation. Because of the strong decline of intrahepatic HDV infection levels induced by blocking HDV entry and turnover, HDV clearance might be achievable upon prolonged treatment durations.

Inflammation and fibrosis

PS-163

The I148M PNPLA3 impairs LXR signaling and cholesterol metabolism in human hepatic stellate cells

F. Bruschi[1], T. Claudel[1], M. Tardelli[1], A. Caligiuri[2], P. Starlinger[3], F. Marra[2], M. Trauner[1]. *[1]Medical University of Vienna, Division of Gastroenterology and Hepatology, Internal Medicine III, Vienna, Austria; [2]Medical University of Florence, Clinical Pathophysiology Department, Florence, Austria; [3]Medical University of Vienna, Department of Surgery, Vienna, Austria*
Email: francesca.bruschi@meduniwien.ac.at

Background and Aims: The I148M variant of the human PNPLA3 gene is strongly associated with hepatic steatosis and its progression toward severity of liver diseases, such as cirrhosis and cancer. Hepatic stellate cells (HSC) are key drivers of liver fibrosis and carriers of I148M PNPLA3 display higher pro-fibrogenic and pro-inflammatory profile compared to wild type (WT) PNPLA3 expressing HSC. Deranged cholesterol homeostasis and its accumulation promote liver fibrosis, but the impact of the I148M variant on cholesterol metabolism in HSCs has not yet been explored.
Method: Primary human HSC were isolated and sorted in two groups, according to the different PNPLA3 genotype (WT = wild type, I148M = variant). Moreover, we generated stably overexpressing WT and I148M PNPLA3 LX-2 cells. Total and free cholesterol were quantified by ELISA, expression and activity of cholesterol related genes was investigated via q-PCR, western blot and luciferase assays. LXR localization and tissue expression was evaluated using immunofluorescence staining in healthy and NASH liver specimen.
Results: Total (TC) and free cholesterol (FC) were significantly increased in HSC carrying the I148M PNPLA3, compared to WT carriers ($p < 0.01$). In line with increased cholesterol content, HSC expressing the PNPLA3 variant have lower expression of the cellular cholesterol sensor SREBP-2 and, subsequently, of its downstream key targets, such as LDL receptor (LDLr), for exogenous cholesterol uptake and HMG-CoA reductase, the limiting enzyme for cholesterol synthesis, at both protein and mRNA levels ($p < 0.01$). Liver staining showed that LXRα expression decreased in NASH patients, compared to healthy livers ($p < 0.05$), while LXRα was induced during primary human HSC activation, whereas the β isoform was high in quiescence state. LXR target genes, such as ABCA1, SREBP-1c, FAS and ACC1 were decreased in I148M HSC ($p < 0.01$), when conversely the synthetic LXR agonist T0901317 increased ABCA1 and reduced collagen1α1 expression. Moreover, luciferase assays using the LXR-RE and LXR constructs, showed that LXR activity was reduced in I148M HSC, but can be rescued by the T0901317.
Conclusion: We hereby report that HSC carrying the I148M PNPLA3 accumulate cholesterol, which does not derive from increased endogenous synthesis or uptake, but from diminished export via LXR activity. We propose that impaired LXR signaling is a consequence of reduced PPARγ activity, thus contributing to reinforce HSC activation and promoting fibrosis development.

PS-164

Induced pluripotent stem cell derived liver model for the study of PNPLA3-induced non-alcoholic fatty liver disease

S. Tilson[1,2,3], C.M. Morell[2], A.-S. Lenaerts[2], T.J. Liang[3], L. Vallier[1,2]. *[1]Wellcome Trust Sanger Insitute, Cellular Genetics, Hinxton, United Kingdom; [2]Wellcome Trust-Medical Research Council Stem Cell Institute, Surgery, Cambridge, United Kingdom; [3]National Institute of Diabetes and Digestive and Kidney Disease, Liver Disease Branch, Bethesda, United States*
Email: lv225@cam.ac.uk

Background and Aims: Non-alcoholic fatty liver disease (NAFLD) represents a growing public health burden. NAFLD is defined by

accumulation of fat within the liver which ranges in severity from simple steatosis through non-alcoholic steatohepatitis (NASH). Until recently, NAFLD has been considered a largely metabolic disease; however, recent studies have suggested that genetic factors could also majorly influence disease onset and evolution. Accordingly, genome wide association studies (GWAS) have identified the I148M variant in the gene coding for Patatin-like phospholipase domain-containing protein 3 (PNPLA3) which is strongly associated with NAFLD without underlying metabolic disease. However, very little is known about the mechanisms by which it influences disease development and progression. In order to elucidate these mechanisms, we have developed an *in vitro*, 3D co-culture liver model which takes advantage of the unique properties of human induced pluripotent stem cells (hiPSCs) and the CRISPR/CAS9 gene editing technology.
Method: We used CRISPR/CAS9 to generate hiPSC lines with either a complete knock-out of the PNPLA3 gene or with the I148M variant knocked-in. These genetically edited cells were then differentiated into hepatocytes and macrophages to model the metabolic and inflammatory aspects of the disease respectively. These cells were then cultured together in a three-dimensional matrix and treated with free fatty acids to model NAFLD *in vitro*.
Results: Both the knock-out and knock-in clones showed similar differentiation efficiency toward hepatocytes as wild-type cells thereby suggesting that the PNPLA3 mutations do not affect differentiation capacity of the hiPSC cells. Our results showed that several hepatic cell types can be grown together in the 3D system and establish significant cellular interactions. Furthermore, these cells showed enhanced maturity, functionality, and cell survival. Following treatment with free fatty acids, hepatocytes demonstrated significant lipid droplet accumulation and macrophages showed differential expression of inflammatory genes, in both wild type and genetically edited cells. Mutations in PNPLA3 altered the pattern of response to lipid induced stress indicating that PNPLA3 may affect lipid metabolism in our system.
Conclusion: Once fully established and characterized, these hiPSC lines will provide the first opportunity to fully analyse the role of PNPLA3 in the development and progression of NAFLD *in vitro*.

PS-165
Interfering with local fibrotic platelet activation significantly inhibits fibrosis in multiple animal models: suggestions of the importance of the platelet-wound healing axis for fibrosis

K. Stuart[1], H. Kabra[1], S. Jalgaonkar[1], T. Skurnac[1], A. Woolley[1], N. Snead[1], N. Bachtell[2], D. Leeming[3], M. Karsdal[3], J. Paderi[1]. *[1]Symic Bio, Research, Emeryville, United States; [2]Symic Bio, Medical, Emeryville, United States; [3]Nordic Bioscience, Biomarkers and Research, Herlev, Denmark*
Email: kstuart@symicbio.com

Background and Aims: Platelets are the largest source of TGF-beta and PDGF, both very pro-fibrogenic factors; consequently, the fibrosis-platelet activation axis has been suggested to play a key role in fibrosis progression. SBR-294 is a novel molecule designed to inhibit platelet activation on collagen within the fibrotic liver. It is composed of collagen-binding peptides grafted to a synthetic glycosaminoglycan (GAG). The peptides serve to disrupt collagen-mediated platelet activation while the GAG itself has potent anti-fibrotic properties. We tested the hypothesis that these dual mechanisms would demonstrate a reduction in fibrosis progression in two models of liver fibrosis.
Method: In vitro, SBR-294 was investigated for its ability to inhibit platelet-collagen activation as well as hepatic stellate cell activation and proliferation. In vivo, two separate models of liver fibrosis were investigated to establish the effects of SBR-294 with differing disease insults. In the carbon tetrachloride (CCl4) model, liver fibrosis was induced in mice by repeated intraperitoneal administration of CCl4 twice weekly over a 4-week period, with concurrent dosing of SBR-294. Liver fibrosis was assessed through liver biochemical and histological markers, as well as serum levels of pro-C3. In the STAM™ model, fibrosis was induced by a single subcutaneous injection of streptozotocin after birth and feeding of a high fat diet beginning at 4 weeks of age. SBR-294 was administered between weeks 5 and week 9, at which point livers were collected for histological and biochemical analysis.
Results: In vitro data demonstrates that SBR-294 dose dependently inhibited platelet binding to collagen surfaces with an IC50 of approximately 20 nM. In addition, SBR-294 inhibited hepatic stellate cell proliferation and activation in a dose-dependent manner. SBR-294 reduced the progression of liver fibrosis in two in vivo models of liver disease. In the CCL4 study, SBR-294 treatment significantly decreased collagen in the liver, as measured by hydroxyproline content and Sirius Red staining ($p < 0.01$). Additionally, mRNA levels of both types I and III collagen were significantly reduced ($p < 0.05$), and serum pro-C3 levels were decreased in mice treated with SBR-294. In the STAM model, SBR-294 reduced Sirius Red staining, as well as liver triglycerides ($p < 0.05$). In both studies SBR-294 had no deleterious effects to the liver, indicating a positive safety profile.
Conclusion: We have demonstrated the ability of SBR-294 blocks platelets binding and subsequent activation in vitro that resulted in reduced fibrosis in two distinct animal models in vivo. The results are important for the platelet-wound healing fibrosis axis.

PS-166
Anti-inflammatory and anti-fibrogenic effects of monoacylglycerol lipase inhibitors in the liver involve macrophage autophagy

D. Chokr[1,2], A. Habib[1,3], J. Wan[1], P. Hegde[1], P. Letteron[1], N. Pilard[1], A. Mansouri[1], A. Brouillet[4], E. Weiss[1], R. Moreau[1], M. Trauner[5], S. Lotersztajn[1]. *[1]INSERM-UMR1149, Centre de Recherche sur l'Inflammation, Paris, France; [2]Lebanese University, Laboratory of Cancer Biology and Molecular Immunology, Faculty of Sciences I, Hadath, Lebanon; [3]American University of Beirut, Biochemistry and Molecular Genetics, Beirut, Lebanon; [4]INSERM U 955, Eq 18, Hopital Henri Mondor, Creteil, France; [5]Medical University of Vienna, Division of Gastroenterology and Hepatology, Department of Medicine III, Vienna, Austria*
Email: ah31@aub.edu.lb

Background and Aims: Monoacylglycerol lipase (MAGL) is the rate-limiting enzyme in the degradation of monoacylglycerols. In addition to its role in lipid catabolism, MAGL is also a component of the endocannabinoid system as it degrades 2-arachidonoyl glycerol, an endogenous ligand for the cannabinoid receptors CB1 and CB2, into arachidonic acid. Recent studies have identified inhibition of MAGL as an interesting anti-inflammatory strategy in several experimental models of chronic inflammatory diseases. In the present study, we investigated the consequences of MAGL inhibition on inflammation and fibrosis during chronic liver injury, and the mechanisms involved.
Method: C57BL/6 mice and mice with global invalidation of MAGL ($MAGL^{-/-}$), or myeloid-specific deletion of either MAGL ($MAGL^{Mye-/-}$) or ATG5 ($Atg5^{Mye-/-}$), were used. Fibrosis was induced by repeated injections of carbon tetrachloride (CCl_4) or bile duct ligation. *In vitro* studies were performed on peritoneal or bone-marrow derived macrophages, and Kupffer cells.
Results: $MAGL^{-/-}$ or C57BL/6 mice exposed to the MAGL inhibitor MJN110 developed less fibrosis upon chronic administration of CCl_4 or following bile duct ligation, respectively, as reflected by decreased sirius red staining, reduced fibrogenic cell accumulation and low levels of fibrogenic genes, as well as decreased expresssion of inflammatory genes in the liver. Moreover, CCl_4-exposed $MAGL^{Mye-/-}$ mice showed a similar anti-inflammatory and anti-fibrogenic phenotype. In keeping, LPS-stimulated peritoneal, bone marrow-derived macrophages or Kupffer cells exposed to MJN110 or isolated from $MAGL^{Mye-/-}$ mice displayed reduced expression of inflammatory mediators. Since macrophage autophagy protects against inflammation and fibrosis in the liver (*Lodder et al, Autophagy, 2015; Denaes et al, Sci Rep., 2016*), we investigated

whether macrophage autophagy mediates the anti-inflammatory effects of MAGL inhibitors. MJN110 enhanced LC3 II lipidation and autophagic flux in isolated macrophages. Moreover, whereas the MAGL inhibitor MJN110 decreased the production of inflammatory mediators in LPS-stimulated macrophages from WT mice, this anti-inflammatory effect was lost in $Atg5^{Mye-/-}$ macrophages.
Conclusion: Overall, these data unravel MAGL as a novel immuno-metabolic target and demonstrate that MAGL inhibitors may be considered as interesting as anti-fibrogenic compounds.

PS-167
IL-33 regulates immune-mediated hepatitis by induction of Areg+ ILC2, M2 macrophages and ST2+ Tregs
A. Ochel, G. Tiegs, K. Neumann. *Experimental Immunology and Hepatology, Center for Experimental Medicine, Hamburg, Germany*
Email: a.ochel@uke.de

Background and Aims: Immune-mediated liver injury such as autoimmune hepatitis is characterized by T cell-mediated necroinflammation. The alarmin interleukin (IL) -33 is rapidly released from necrotic hepatocytes and induces activation of immune cells, such as type 2 innate lymphoid cells (ILC2) and regulatory T cells (Tregs), by binding to ST2. IL-33 dampens immune-mediated liver injury in a yet unknown mechanism. The epidermal growth factor like molecule amphiregulin (Areg) mediates tissue regeneration and enhances suppressive function of Tregs. Moreover, Areg is expressed by activated ILC2. This prompted us to investigate whether ILC2-derived Areg regulates immune-mediated hepatitis in an IL-33 dependent manner.
Method: Wildtype mice and $ST2^{-/-}$ mice were treated with IL-33 on 3 consecutive days. Subsequently, immune-mediated hepatitis was induced by Concanavalin A (ConA). Immune cells were analyzed 24 h later by flow cytometry. Transcriptional profiles were analyzed by quantitative RT-PCR.
Results: IL-33 pre-treatment protected wildtype mice from ConA-hepatitis as shown by significantly reduced serum ALT values. This correlated with increased frequencies of hepatic ILC2, eosinophiles, macrophages and Tregs, respectively. ILC2 from both IL-33/ConA- as well as IL-33-treated mice expressed the activation markers CD25, KLRG1 and Areg. Despite expression of CD25, ILC2 from ConA-treated mice failed to express KLRG1 and Areg. Eosinophils were un-activated in response to IL-33, demonstrated by downregulation of CD25, CD69, and CD62L. Macrophages were increased in response to either IL-33/ConA, IL-33 or ConA-treatment. Yet, macrophages were $Ly6c^{lo}$ $CD11c^{-}$ upon IL-33/ConA or IL-33-treatment and expressed the M2 markers *Arg-1*, *Ym-1* and *Areg*, suggesting an anti-inflammatory phenotype. In contrast, ConA-treatment alone induced pro-inflammatory $Ly6c^{hi}$ $CD11c^{+}$ macrophages. Wildtype Tregs showed increased ST2 expression in response to all treatment regimens. However, significantly increased frequencies of $ST2^{+}$ Tregs were only observed in the IL-33/ConA group. Interestingly, even higher frequencies of Tregs were found in $ST2^{-/-}$ mice, but these mice developed a more severe hepatitis than wildtype animals, suggesting that $ST2^{+}$ Tregs are crucial regulators of immune-mediated hepatitis.
Conclusion: IL-33 mediated protection from hepatitis might be due to activation of $Areg^{+}$ ILC2, polarization of M2 macrophages and activation of $ST2^{+}$ Tregs.

PS-168
TGR5-mediated signalling in the regulation of biliary epithlium permeability
K. Nicolas[1], M. Gregory[1], U.-B. Jose[1], S. Hayat[1], D. Isabelle[1], T. Zahra[1], G. Julien[1], C. Ullmer[2], E. Klaus[3], T. Tordjmann[1]. *[1]INSERM, U1174, Orsay, France; [2]Roche Innovation Center, Basel; [3]Muenster University, Institute of Medical Biochemistry, Muenster, Germany*
Email: thierry.tordjmann@u-psud.fr

Background and Aims: Bile acids (BA) are signaling molecules that bind to the nuclear receptor FXR (Farnesoid-X-Receptor) or to the membrane receptor TGR5 (Takeda G-protein coupled Receptor 5). When challenged with BA overload models (partial hepatectomy, Bile Duct Ligation (BDL)), TGR5-KO mice exhibit massive hepatic peribiliary necrosis as compared with WT mice, suggesting that an alteration of biliary epithelial permeability may occur in the absence of TGR5. In a separate study, we confirmed that TGR5, highly expressed in cholangiocytes, regulates paracellular permeability in the biliary epithelium through an impact on expression and phosphorylation of the tight junction protein JAM-A. However, TGR5-related signaling pathways involved in this context were completely unknown.
Method: A specific TGR5 agonist (RO5527239 (Roche)) and a specific EGF Receptor (EGFR) inhibitor (AG1478 *in vitro*, Erlotinib *in vivo*) were used in mice and in cultured cells (NRC, MDCK transfected or not with TGR5-GFP or JAM-A non phosphorylatable S285A mutant (Tet-Off = TO). PKC, c-Src kinase, MAPK pathway (Erk1 /2), JAM-A expression and phosphorylation were studied by western blot (WB) and immunofluorescence. Functional studies were performed on cells cultured on inserts for Trans Epithelial Resistance (TER) measurements. BDL were performed on JAM-A-KO mice treated or not with RO5527239, and liver injury was analyzed (plasma ALT and liver sections H&E staining).
Results: *In vivo* and *in vitro*, TGR5 agonist treatment induced an increase in JAM-A expression and phosphorylation and this effect was significantly dependent on EGFR transactivation. Importantly, EGFR inhibition also strongly reduced the TGR5-dependent increase in TER. Moreover, the impact of TGR5 on TER critically required JAM-A phosphorylation, as shown by the abolition of TGR5-induced TER increase in JAM-A S285A mutant MDCK-TO. This was in line with *in vivo* observations, as TGR5 agonist treatment significantly protected WT but not JAM-A-KO mice from BDL-induced liver injury. Our WB data suggest that TGR5-dependent JAM-A phosphorylation depends on PKCs, MAPK and c-Src.
Conclusion: Our *in vitro* and *in vivo* studies help to clarify the mechanisms by which the BA receptor TGR5 reinforces the sealing of biliary epithelium, by controlling expression and phosphorylation of the tight junction protein JAM-A, at least in part through EGFR-dependent processes.

Background and Aims: Ductular reaction (DR) expands in response to massive liver damage and loss of replicative capacity of hepatocytes in alcoholic liver diseases (ALD) and it is a key feature of alcoholic hepatitis (AH). DR consists of a heterogeneous population comprising liver progenitor cells (LPCs). Biological functions of DR and LPCs in chronic liver damage are not well understood. The secretory protein Slit2 and its receptor Robo1 are known to regulate cell growth, migration and vascularization. The aim of this study was to investigate the potential role of DR in regulating angiogenesis in chronic liver diseases and whether this repair process is mediated by slit2-Robo1 signaling.

Method: Gene expression of Slit2, Robo1 and progenitor markers was assessed by qPCR in liver biopsies of AH (n = 30) and healthy (n = 6) individuals. Correlation of markers of LPC and angiogenesis and SLIT2 and ROBO1 was assessed in transcriptomic data from patients with AH (n = 29) and chronic ALD (n = 12). Gene and protein expression of Slit2 was assessed in a mouse model of LPC expansion (DDC diet). Angiogenesis was examined in $Robo1^{+/-}Robo2^{+/-}$ mice fed with DDC by quantifying area occupied by $CD31^{+}$ cells and by analyzing von willebrand factor expression. LPCs- induced vasculogenesis was evaluated by incubating conditioned medium from LPC organoids generated from cirrhotic livers with human endothelial cells (HUVECs).
Results: Liver expression of SLIT2 and ROBO1 was significantly higher in patients with AH compared with healthy controls. The transcriptomic analysis of ALD progression revealed that markers of angiogenesis strongly correlated with DR expansion. In addition, LPC markers showed a strong positive correlation with the expression of SLIT2 and ROBO1. The association of DR with SLIT2 and Robo1 was confirmed by qPCR in patients with AH. Moreover, SLIT2 was found highly expressed at protein and gene expression level in DR cells isolated from DDC treated mice. $ROBO1/2^{-/+}$ mice treated with DDC diet displayed a reduced intrahepatic neovascular density at the periportal area whereas no impact on expansion of DR was observed. Conditioned medium of cirrhotic LPC organoids induced tube formation of endothelial cells.
Conclusion: DR is associated with angiogenesis markers and with SLIT2/ROBO1 expression in ALD progression. Moreover, SLIT2/ROBO1 pathway mediates angiogenesis in experimental model of chronic liver injury and DR induces vasculogenesis in vitro. These results suggest, that DR contribute to liver tissue repair by promoting angiogenesis through SLIT2/Robo1 signaling pathway.

Liver tumours: Experimental

PS-170
Therapeutic targeting of LGR5 tumor initiating cells in liver cancer

W. Cao, M. Li, J. Liu, B. Ma, W. Wang, M. Peppelenbosch, Q. Pan.
Erasmus University Medical Center, Gastroenterology and Hepatology
Email: q.pan@erasmusmc.nl

Background and Aims: Tumor initiating cells/cancer stem cells are thought to be responsible for the failure of treatment and tumor recurrence. Thus, the concept that therapeutic targeting these cells has attracted great interest. Leucine-rich repeat-containing G-protein coupled receptor 5 (Lgr5) is a recently identified stem cell marker. Here we investigate the role of LGR5-expressing cells in liver cancer, and the potential of therapeutic targeting.
Method: A LGR5-promotor driven diphtheria toxin (DT) receptor knock-in mouse model with a GFP reporter was used. Carbon tetrachloride (CCl_4) was used to induce chronic liver injury and diethylnitrosamine (DEN) was used to induce primary liver tumor in mice. Tumor organoids were cultured from primary liver tumors and DT was used to specifically ablate LGR5 expressing cells. Sorafenib and chemotherapeutic agent (5-FU) were combined with DT to treat liver tumors.
Results: In DEN-induced hepatic tumors, the percentage of LGR5 cells is significantly higher as compared to tumor adjacent tissue (n = 28, $p < 0.05$, 3-fold higher), and this even more apparent when compared to tissue of CCl_4-induced chronic injury (n = 28, $p < 0.001$, 52-fold higher). Tumor organoids generated by *ex vivo* culturing of primary mouse liver tumor contain a LGR5-expressing cell population. Subcutaneous transplantation of these tumor organoids into immunodeficient NOG mice results in solid tumors, which retain a LGR5 positive compartment. Isolation and transplantation of single $LGR5^{+}$ cells from mouse tumor into NOG mice formed tumor again. Thus, these cells have tumor initiating/cancer stem cell-like properties. Interestingly, the treatment of Sorafenib and 5-FU enriched the LGR5-expressing cells in liver tumor organoids. More importantly, the depletion of LGR5 tumor initiating cells by DT administration effectively delayed the tumor formation *in vivo* and the combination therapy of Sorafenib & DT or 5-FU & DT remarkably reduced the growth of tumor organoids.
Conclusion: LGR5 marks tumor initiating cells in liver cancer, which can be specifically targeted to inhibit tumor growth. Thus, innovative therapeutic approaches shall be further explored to effectively targeting these cells for combating liver cancer.

PS-171
Endoplasmic reticulum stress in hepatic stellate cells contributes to the progression of hepatocellular carcinoma

F. Heindryckx[1], N. Pavlovic[1], Pär Gerwins[1,2]. [1]*Uppsala University, Medical Cell Biology, Uppsala, Sweden;* [2]*Akademiska sjukhuset, Radiology, Uppsala, Sweden*
Email: fempie@gmail.com

Background and Aims: One of the key players in the progression of cirrhosis to hepatocellular carcinoma (HCC) is the hepatic stellate cell, which is activated during liver damage. Activated stellate cells create a favourable tumour environment and produce growth factors and cytokines that enhance tumour cell proliferation and migration. We have recently shown that inhibiting the endoplasmic reticulum (ER) stress-induced IRE1a signalling pathway blocks stellate cell activation *in vitro* and reduces liver fibrosis *in vivo*. We now wanted to identify the role of ER-stress in the cross-talk between stellate cells and cancer cells in HCC.
Method: HCC was induced in mice by weekly injections with diethylnitrosamine. Mice were treated with an IRE1a inhibitor 4u8C or control, samples were taken after 25 weeks. Tumour burden and collagen deposition was quantified on H&E and Sirius red staining, respectively. The HCC-cell lines (HepG2 and Huh7) and stellate cell line (LX2) were co-cultured using transwell assays and RNA was isolated after 48 hours. Tumour spheroids were formed by culturing HepG2 and LX2 cells on ultra-low-attachment plates on which viability was measured by resazurin. Non-directional and directional migration (chemotaxis) was assessed on fluorescently labelled cells using scratch wound assays and 2D CellDirectors, respectively. ER-stress was inhibited *in vitro* with 100 uM 4u8C.
Results: Treatment with 4u8C significantly decreased the number of tumours in vivo, compared to untreated controls. Sirius red staining showed a significant decrease in collagen deposition after treatment with 4u8C, compared to controls. Co-culturing experiments confirmed that tumour cells (HepG2 and Huh7) secrete factors that significantly increase mRNA expression of ER-stress markers (CHOP, spliced XBP1 and BiP) in LX2 cells. Co-culturing also led to significantly increased mRNA expression of stellate cell activation markers (aSMA and collagen) compared to mono-cultures. This was significantly decreased when 4u8C was added to the co-cultures. Tumour spheroid growth was significantly reduced in co-cultures after treatment with 4u8C. Co-culturing HepG2 and LX2 cells significantly increased migration on a scratch wound compared to mono-cultures. Treatment with 4u8C significantly decreased non-directional and directional migration towards a gradient of chemo-attractant in stellate cell - tumour cell co-cultures in 2D CellDirectors.
Conclusion: Our results suggest that ER-stress is an important mediator in the communication between stellate cells and cancer cells. Tumour cells secrete factors that induce ER-stress in stellate cells, which contributes to their activation. Blocking the IRE1a ER-stress pathway reduces stellate cell activation, tumour cell proliferation and migration. Components of the ER stress pathway may therefore be therapeutically relevant for HCC-patients.

PS-172

Genetic inactivation of Nrf2 prevents clonal expansion of carcinogen-initiated cells in a nutritional model of rat hepatocarcinogenesis

C. Orrú[1], M. Szydlowska[1], K. Taguchi[2], A. Perra[1], G.M. Ledda[1], M. Yamamoto[2], A. Columbano[1]. [1]*University of Cagliari, Biomedical Sciences, Cagliari, Italy;* [2]*Tohoku University, Medical Biochemistry, Sendai, Japan*
Email: claudiaorr16@gmail.com

Background and Aims: Dysregulation of the Keap1-Nrf2 pathway has been observed in experimental and human tumors, suggesting its possible role in cancer development. Here we assessed whether Nrf2 activation occurs at early steps of rat hepatocarcinogenesis, therefore being critical for the onset of hepatocellular carcinoma (HCC).
Method: Wild type (WT) and *Nrf2* knockout (KO) rats were treated with a single injection of diethylnitrosamine (DENA) followed by choline-devoid methionine-deficient (CMD) diet. This experimental model causes massive fatty liver and steatohepatitis with fibrosis, and allows to identify early stages of hepatocarcinogenesis. RNA was isolated from laser-microdissected preneoplastic nodules. qRT-PCR and Sanger analyses were performed to evaluate the expression of Nrf2-target genes and *Nrf2* mutations. Preneoplastic lesions were identified by immunohistochemistry for the placental form of glutathione S-transferase (GSTP), glucose-6-phosphate dehydrogenase (G6PD) and gamma-glutamyl-transpeptidase (GGT).
Results: We found that activation of Nrf2 takes place already in early preneoplastic lesions, revealed by the preneoplastic marker GSTP. *Nrf2* missense mutations, known to disrupt the Keap1-Nrf2 binding region, were present in 44% of GSTP-positive foci. To directly investigate whether Nrf2 is critical for initiation and/or clonal expansion of DENA-induced DNA-damaged hepatocytes, we used *Nrf2* KO rats. While *Nrf2* genetic inactivation did not alter DENA-induced initiation, it led to increased liver injury and chronic compensatory hepatocyte regeneration in rats given DENA and fed CMD diet. However, in spite of such a permissive environment, the liver of *Nrf2* KO rats did not display any preneoplastic lesion unlike that of WT animals.
Conclusion: These results demonstrate that, in a model of hepatocarcinogenesis resembling human non-alcoholic fatty liver disease (NAFLD): (i) Nrf2 is activated at early steps of the tumorigenic process; (ii) Nrf2 is mandatory for the clonal expansion of initiated cells and is therefore critical in HCC onset and progression.

PS-173

Primary liver cancers display divergent epimutator phenotypes in localized and metastatic disease

C.O. Rourke[1], S. Haefliger[2], J. Haegele[2], K. Burmeister[2], M. Matter[2], J. Andersen[1]. [1]*University of Copenhagen, Biotech Research & Innovation Centre, Copenhagen, Denmark;* [2]*University Hospital of Basel, Institute of Pathology, Basel, Switzerland*
Email: colm.rourke@bric.ku.dk

Background and Aims: Treatment with curative intent is compromised in a majority of primary liver cancer (PLC) patients due to advanced and metastatic disease at diagnosis. Genetic variants that drive progression remain elusive. Epigenetic alterations ("epimutations") comprise alternative genomic perturbation mechanisms which, given their dynamic nature, may facilitate rapid tumour diversification both in disease onset and progression. In this study, we deconstruct the epimutational landscapes of PLCs in primary and metastatic patient cohorts.
Method: We have integrated large-scale epigenomic data sets generated with Infinium Human Methylation 450 k BeadChips and stratified PLCs as intrahepatic cholangiocarcinoma (iCCA; n = 186), hepatocellular carcinoma (HCC; n = 366), combined hepatocellular cholangiocarcinoma (CHC; n = 13). Importantly, rapid autopsy samples for primary and metastatic iCCA (n = 24) and HCC (n = 38) underwent histopathological evaluation (histology, FISH) and 450 k methylation profiling. Differentially Methylated Regions (DMRs), Copy Number Alterations (CNAs) and network interaction hotspots were analysed.
Results: Extensive epigenome remodelling was detected in PLCs. Remarkably, HCC was uncovered as a disease predominantly hypomethylated ($p < 0.0001$) and iCCA a grossly hypermethylating disorder ($p < 0.0001$). Similar to histopathology, CHC displayed epigenomic features of both iCCA and HCC. Pan-cancer analysis of 6073 tumours (12 cancer types) confirmed iCCA and HCC as polarized extremes of epimutational processes in cancer. Divergent interactome hotspots of aberrant methylation were revealed, including *CASP8* promoter hypermethylation (iCCA), *CDKN1A* promoter hypermethylation (HCC) and *FGFR2* promoter hypomethylation in CHC. Progression of primary to metastatic PLC correlated with morphological changes (differentiation, grade, cytology) in 35% patients. Prominently, a disease stage-specific shift in epimutation modes was defined, with increasing proportions of hypermethylation in metastatic HCC and vice versa in metastatic iCCA. Intra-patient tracking of tumour evolution revealed that epimutations are highly clonal and display branched evolutionary patterns. Metastasis DMRs targeted cytoskeletal networks, such as *ELN* (HCC) and *MMP9* (iCCA).
Conclusion: PLCs are epimutationally polarized in primary and metastatic stages of disease, suggesting fundamental differences in their pathogenesis. Further studies will functionally trace genetic alterations and edit epimutations to assess their therapeutic potential.

PS-174

Upregulation of the imprinted DLK1/DIO3 locus in response to beta-catenin activation: a promising target for HCC treatment

Angélique Gougelet[1,2,3], D. Anais[1,2,3], G. Cécile[1,2,3], B. Terris[1,2,3], C. Perret[1,2,3], S. Colnot[1,2,3]. [1]*Institut Cochin-INSERM U1016, Paris, France;* [2]*CNRS UMR8104, Paris;* [3]*Université Paris-Descartes-Sorbonne Paris Cité, Paris, France*
Email: angelique.gougelet@inserm.fr

Background and Aims: We showed that miR-34a inhibition halves tumour progression, exclusively for HCC with β-catenin (β-cat) mutation, which concerns a third of HCC patients. We now attempt to determine if the targeting of a panel of miRNAs could be of therapeutic benefit.
Method: This project is realized on transgenic mice exhibiting an overactivation of β-cat signalling following the deletion of its inhibitor *Apc* (Apc^{KO}). This Cre-lox-based model is liver-specific and inducible by tamoxifen injection. Depending on the dose, mice either wholly exhibit hepatocytes with β-cat overactivation or develop tumours, with a genetic program similar to those of human HCC.
Results: In precancerous Apc^{KO} hepatocytes and, to a lesser extent, in tumors, β-cat activation upregulated the imprinted DLK1/DIO3 locus, including the 54 miRNAs, the long non-coding RNA MEG3, and the coding RNA DLK1, either expressed from the maternal or the paternal strand, meaning that parental imprinting is altered after β-cat activation. Using deep-sequencing approaches in Apc^{KO} hepatocytes, we showed that β-cat directly binds upstream of the locus and promotes its hypermethylation in intragenic regions, presuming a direct regulation by β-cat and DNA methylation. Kinetic sorting of Apc^{KO} hepatocytes from the tumoral model revealed that its hypermethylation and its overexpression are observable at day six after β-cat activation. Additionally, in coculture experiments, we observed that non-parenchymal cells also participate to the DLK1/DIO3 locus expression in hepatocytes, through mechanisms, which remain to be elucidated. Importantly, exposure of Apc^{KO} hepatocytes to demethylating agent reduced the locus expression and cell proliferation, similarly to β-cat or MEG3 silencing. In future, we will explore how genome editing of the β-cat binding site upstream of the

Figure: (abstract: PS-174)

locus affects the fate of Apc^{KO} hepatocytes and tumorigenesis. Preliminary experiments suggested that CRISPR/Cas9 editing of this site impaired the locus expression in Apc^{KO} hepatocytes, as expected. **Conclusion:** This project supports that the β-cat-dependent upregulation of the DLK1/DIO3 locus in early stages could be implicated in hepatocyte transformation towards a precancerous state. A control of the locus expression in hepatocytes should improve HCC treatment. Since miR-136, a miRNA produced from the locus, was also detectable in the serum in case of HCC, in mouse and human, its detection might also be useful for HCC diagnosis.

PS-175

Axin1 deficiency in human and mouse hepatocytes induces hepatocellular carcinoma in the absence of beta-catenin activation

A. Shirley[1], C. Coulouarn[2], R. Bruno[1], S. Mathilde[1], P. Bossard[1], S. Romain[1], J. Calderaro[3], J. Zucman-Rossi[3], J. Pierre-Alexandre[1], C. Perret[1], Hélène Gilgenkrantz[1,4]. Email: helene.gilgenkrantz@inserm.fr

Background and Aims: The Wnt/beta-catenin pathway is the most frequently deregulated pathway in hepatocellular carcinoma (HCC). Inactivating mutations of the gene encoding AXIN1, a known negative regulator of the Wnt/β-catenin signaling pathway, are observed in about 10% of HCCs. Whole-genome studies usually place HCC with *AXIN1* mutations and *CTNNB1* mutations in the group of tumors with Wnt/β-catenin activated program. However, it has been shown that HCCs with activating *CTNNB1* mutations form a group of HCCs, with a different histology, prognosis and genomic signature compared to those with inactivating biallelic *AXIN1* mutations. We aimed at understanding the relationship between *CTNNB1* mutations, *AXIN1* mutations and the activation level of the Wnt/β-catenin program.
Method: We evaluated two independent human HCC datasets for the expression of a 23-β-catenin target genes program. We modeled *Axin1* loss of function tumorigenesis in two engineered mouse models and performed gene expression profiling.
Results: Based on gene expression, we defined three levels of β-catenin program activation: strong, weak or no activation. While more than 80% *CTNNB1*-mutated tumors were found in the strong or in the weak activation program, most of the *AXIN1*-mutated tumors (>70%) were found in the subgroup with no activation. We validated this result by demonstrating that mice with a hepatocyte specific *Axin1* deletion developed HCC in the absence of β-catenin induction. We defined a 329-gene signature common in human and mouse *AXIN1* mutated HCC that is highly enriched in Notch and YAP oncogenic signatures.
Conclusion: *AXIN1*-mutated HCCs occur independently of the Wnt/β-catenin pathway and involve Notch and YAP pathways. These pathways constitute potential interesting targets for the treatment of HCC due to *AXIN1* mutations.

PS-176

Cytokine-induced killer cells recruit myeloid derived suppressor cells in HCC, which can be targeted by a PDE5 inhibitor

S.J. Yu[1,2], C. Ma[1], B. Heinrich[1], Z. Brown[1], M. Sandhu[1], Q. Zhang[1], Q. Fu[1], D. Agdashian[1], F. Korangy[1], T. Greten[1]. [1]*National Institutes of Health, Gastrointestinal Malignancy Section, Thoracic and Gastrointestinal Oncology Branch, Center for Cancer Research, National Cancer Institute, Bethesda, United States;* [2]*Seoul National University College of Medicine,*

Department of Internal Medicine and Liver Research Institute, Seoul, Korea, Rep. of South
Email: tim.greten@nih.gov

Background and Aims: Cytokine induced killer (CIK) cell-based immunotherapy has been shown to be effective as adjuvant single agent therapy in patients with early stage hepatocellular carcinoma (HCC). However, its efficacy is lacking in advanced HCC. Increased myeloid-derived suppressor cells (MDSCs), a tumor-promoting immune subset which correlates with tumor progression, have been found in HCC patients.
Method: LDH cytotoxicity assay was performed to explore whether MDSCs can suppress CIK cell lytic function against HCC cells *in vitro*. We used tadalafil, a FDA approved PDE5 inhibitor, to test whether it could suppress MDSCs. To test whether tadalafil enhance CIK antitumor effects *in vivo*, we established three different tumor models using two different HCC murine cell lines (RIL-175 and BNL), subcutaneous and orthotropic tumor models, using two different mouse strains (C57BL/6 and BALB/c).
Results: Here, we describe an accumulation of tumor infiltrating MDSCs upon CIK cell infusion *in vivo*. We show that MDSCs efficiently suppress the cytotoxicity of CIK cells against HCC tumor *cells in vitro*. CIK anti-tumor effects can be enhanced by tadalafil. Mechanistically, tadalafil suppressed MDSCs function by blocking both ARG1 and iNOS. *In vivo* studies confirmed that tadalafil augments the efficacy of CIK cell-based immunotherapy for HCC in subcutaneous and orthotropic murine HCC models. In three different tumor models using two different HCC murine cell lines, subcutaneous and orthotropic tumor models, using two different mouse strains, a consistent increase of MDSC levels after CIK cell single therapy was observed in tumor tissues. Tadalafil treatment prevented MDSC accumulation in the tumor microenvironment upon CIK cell therapy and increased its efficacy. Finally, tadalafil also suppressed the function of human $CD14^{+}HLA\text{-}DR^{-/low}$ MDSCs and enhanced human CIK function against HCC cell lines *in vitro*.
Conclusion: Our results suggest that targeting MDSCs is an efficient strategy to enhance the antitumor efficacy of CIK cells for the treatment of patients with HCC.

Background and Aims: Baveno VI and extended Baveno VI criteria, based on the combination of liver stiffness(LS) with platelet(PLT) values, have been proposed to avoid unnecessary oesophagogastroduodenoscopy(OGD) screening for large oesophageal varices(OV) needing treatment (OVNT). However, this approach has not been validated in patients with NASH cirrosis. In this study, we aimed to validate these criteria for OVNT in this group, also considering potential differences in LS values with the M and XL probes. We also investigated whether these criteria could be useful for avoiding OGD in patients at low risk of any grade EV.
Method: We evaluated in 10 centers 791 patients with NAFLD related compensated cirrhosis who had OGD within 6 month of reliable LSM. LSM was obtained by FibroScan machine by using M and/or XL probe. Baveno VI(LS <20 and PLT > 150,000) and extended Baveno VI(LSM <25 and PLT > 110,000) criteria were tested.
Results: Any grade OV were found in 31.2% of the population, while OVNT in 11.5%. Three-hundred thirty-eight patients had LSM by M probe only, 138 patients by XL probe only, and 314 by both M and XL probes. In the subgroup of 314 patients with both M and XL probes (training set) Baveno VI and Baveno VI extended criteria spared 33.3% and 58% of OGD, respectively, missing 0.9% and 3.8% of large OV, respectively (Table 1). In this subgroup we identified as the best thresholds for rule-out large OV, PLT > 110,000 and LSM < 30 KPa for M probe, and PLT > 110,000 and LSM < 25 KPa for XL probe. The use of these thresholds allowed sparing 68.5% and 65% of OGD, respectively, by missing 4.2% and 4.9% of large OV, respectively. These results were validated in the 338 patients with LSM by only M probe, and in the 138 with LSM by only XL probe. In the first group PLT > 110,000 and LSM < 30 KPa was confirmed better than Baveno and Baveno VI (61.8% VS. 33.4% vs 54.1% spared endoscopy, and 4.8% vs. 4.4% vs 4.4% of missed large OV). Similar good results were obtained in the second group –138 patients with LSM by only XL probe- for PLT > 110,000 and LSM < 25 KPa (46.4% of spared endoscopy, and 1.6% of missed large OV). When looking at any grade OV as the main outcome, the best identified thresholds in the training set of 314 patients with LSM by both M and X probes, were PLT > 180,000 and LSM < 25 KPa for M probe (33.4% spared OGD and 9.5% missed any grade OV in training set; 31.4% and 13.2%, respectively, in validation set), and PLT > 180,000 and LSM < 20 KPa for XL probe (33.4% spared OGD and 10.5% missed any grade OV in training set; 23.2% and 9.4%, respectively, in validation set). Sensitivity analysis considering separately all the centers overall confirmed the reported results.
Conclusion: The combination of PLT and LSM values – stratified according to FibroScan probe- could help to identify patients with

compensated NAFLD-related cirrhosis at low risk of any grade OV and of large OV, in whom OGD screening can be safely sparred.

Background: Fibrosis improvement (FI) is an important endpoint in clinical trials of therapies for NASH. Our aim was to identify predictors of FI using machine learning in patients with advanced fibrosis due to NASH who received the ineffective therapy simtuzumab (SIM).
Methods: A machine learning algorithm (GUIDE v26.4) was applied to data from two Phase 2b trials of SIM in adults with NASH and advanced fibrosis (NASH CRN F3-F4) to develop predictive models for ≥1-stage FI at Week 48 (W48). The trials were stopped due to lack of efficacy so treatment groups were combined for this analysis. We used clinical, histologic, and serum fibrosis marker data to construct models including only baseline (BL) data or BL plus longitudinal data through W48. A variable importance score (VIS) assessed the aggregated variable contribution across the intermediate nodes of a GUIDE tree. Variables with VIS ≥0.7 in ≥75% of 100 bootstrapped GUIDE trees were considered to be associated with FI. The predictive performance of the models (AUROCs and misclassification error rates) was calculated using 100 bootstrapped GUIDE trees with 10-fold cross validation.
Results: 410/477 randomized subjects (86%) with complete clinical and histologic data were included. 48 subjects (12%) had FI at W48 (F3, 18%; F4, 6.5%). Predictive models including only noninvasive BL data performed well and similarly to full models including histological data (AUROCs 0.79–0.82; Table). Addition of longitudinal data only slightly improved model performance. Variables associated with FI in the full BL model (in >90% of bootstrap trees) included lower NASH CRN and Ishak fibrosis stage and hepatic α-smooth muscle actin expression. Noninvasive variables identified in both models included lower BL AST, ELF, hyaluronic acid, APRI, FIB-4, FibroTest (≥95% of bootstrap trees), α2-macroglobulin, NAFLD fibrosis score, TIMP-1, PIII-NP, and serum LOXL2 (75–95% of trees). The optimal GUIDE tree categorized subjects according to BL AST ≤ vs. >30 U/l (AUROC 0.70; 95%CI 0.63–0.77) independent of fibrosis stage. FI was identified in 27% (30/110) of subjects with BL AST ≤ 30 U/l vs only 6% (18/300) of those with AST >30 U/l. Similar findings were observed with models restricted to subjects with bridging (F3) fibrosis.

Table: Model Performance for FI at W48

Model	Model Parameters	AUROC (95% CI)	Error Rate (95% CI)
Baseline	Full	0.79 (0.67, 0.86)	0.27 (0.15, 0.52)
	Noninvasive	0.79 (0.70, 0.85)	0.27 (0.17, 0.47)
Longitudinal	Full	0.82 (0.72, 0.89)	0.25 (0.16, 0.39)
	Noninvasive	0.81 (0.73, 0.89)	0.26 (0.14, 0.41)

Conclusion: Machine learning models suggest that spontaneous FI over 48 weeks in subjects with advanced fibrosis due to NASH is greatest in those with lower disease severity at BL. These data suggest that the placebo response in clinical trials can be minimized via refinement of patient selection using noninvasive markers.

PS-179

Hepamet Score: a new non-invasive method for NAFLD-related fibrosis screening in clinical practice

Email: javi.ampuero@gmail.com

Background and Aims: To develop a non-invasive tool to predict fibrosis stage in NAFLD patients.
Method: International study including biopsy-proven NAFLD patients from Spain (n = 768), USA (n = 281) and Italy (n = 288). Fibrosis was staged according to Kleiner score. Hepamet score was developed in the Spanish cohort and validated in the two external subsets. Hepamet score was compared with NAFLD fibrosis score (NFS) and FIB4 predicting ≥F2, ≥F3 and F4. Diagnostic accuracy was assessed according to AUROC, sensitivity, specificity, positive and negative predictive values, correct classification and grey zone.
Results: In the estimation cohort (adjusted by ALT, BMI and triglycerides), age [45–64 yo OR 2.71 (95%CI 1.06–6.91) & age ≥65 yo OR 5.62 (95%CI 2.07–15.27)], female [OR 2.28 (95%CI 1.26–4.13)], T2DM [OR 2.19 (95%CI 1.25–3.85)], HOMA ≥ 4 [OR 7.35 (95%CI 2.61–

20.69)], albumin ≤ 4g/dl [OR 2.56 (95%CI 1.18–5.55)], platelets ≤ 150.000 [OR 10.1 (95%CI 4.11–24.78)] and AST [35–69 UI/ml OR 2.40 (95%CI 1.34–4.28) & AST ≥ 70 UI/ml OR 7.68 (95%CI 3.33–17.71)] were related to advanced fibrosis. Diagnostic accuracy is shown in Table. Validation in USA and Italy subsets: (a) ≥F2: 0.80 (95%CI 0.74–0.86), 0.76 (95%CI 0.70–0.81); (b) ≥F3 0.86 (95%CI 0.80–0.91), 0.83 (95%CI 0.77–0.88); (c) cirrhosis 0.92 (95%CI 0.87–0.97), 0.82 (95%CI 0.75–0.89).

Conclusion: Hepamet Score is a non-invasive tool to determine fibrosis in NAFLD patients. Hepamet score is superior to available methods (FIB4 and NFS), improving diagnostic accuracy and correct classification, as well as narrowing grey zone. It could be useful as fibrosis screening method in patients at risk of suffering NAFLD-related fibrosis.

Email: p.n.newsome@bham.ac.uk

Background and Aims: The objective of this prospective study was to evaluate the diagnostic performance of CAP by FibroScan using either the M or XL probe, selected using the machine-embedded automated probe selection tool, in a cohort of patients with NAFLD versus steatosis at liver biopsy.

Method: According to the sample size calculation, 450 patients were enrolled to undergo FibroScan examination within 2 weeks of a clinically indicated liver biopsy (LB) for suspected NAFLD. Recruitment took place (Mar 2014–Jan 2017) at seven UK centres. LB were scored by two expert pathologists in a blinded manner with consensus using the NASH CRN system. NASH was diagnosed using the FLIP algorithm.

Diagnostic performance was assessed using area under the receiver operating curve (AUC). Cut-offs are computed for the Youden index and a sensitivity and a specificity of 90%.

Results: Among the 408 patients who completed the study, 381 had a valid FibroScan examination with CAP and a LB interpretable according to pathologist. 45% were female, with a median age 54 [IQR 18] years and BMI 33.8 [9.3] kg/m². Steatosis distribution was: S0: 12%, S1: 23%, S2: 28%, S3: 36%. 64% had NASH. The performance of CAP in distinguishing categories of steatosis is shown in the figure below.

	S ≥ S1	S ≥ S2	S = S3
CAP	AUC = **0.87** [0.82–0.92]	AUC = **0.77** [0.71–0.82]	AUC = **0.70** [0.65–0.75]
	$Cutoff_{Youden}$ = **302** dB/m	$Cutoff_{Youden}$ = **331** dB/m	$Cutoff_{Youden}$ = **337** dB/m
	Se = 0.80/Sp = 0.83	Se = 0.70/Sp = 0.76	Se = 0.72/Sp = 0.63
	PPV = 0.97/NPV = 0.37	PPV = 0.84/NPV = 0.58	PPV = 0.52/NPV = 0.80
	$Cutoff_{Se=0.90}$ = **274** dB/m	$Cutoff_{Se=0.90}$ = **292** dB/m	$Cutoff_{Se=0.90}$ = **302** dB/m
	Se = 0.90/Sp = 0.60	Se = 0.90/Sp = 0.45	Se = 0.90/Sp = 0.38
	PPV = 0.94/NPV = 0.47	PPV = 0.75/NPV = 0.71	PPV = 0.45/NPV = 0.87
	$Cutoff_{Sp=0.90}$ = **325** dB/m	$Cutoff_{Sp=0.90}$ = **370** dB/m	$Cutoff_{Sp=0.90}$ = **398** dB/m
	Se = 0.66/Sp = 0.89	Se = 0.34/Sp = 0.90	Se = 0.14/Sp = 0.90
	PPV = 0.98/NPV = 0.27	PPV = 0.86/NPV = 0.43	PPV = 0.45/NPV = 0.65

AUC: area under the receiver operating curve; Se: sensitivity; Sp: specificity; PPV: positive predictive value.
NPV: negative predictive value.

Conclusion: CAP had good performance to distinguish steatosis (S ≥ 1) but showed modest performance for the detection of higher grades of steatosis.

PS-181

Identification of serum protein biomarkers for non-invasive discrimination between NASH and simple steatosis using SOMAscan

M. Lai[1], H. Otu[2], L. Ngo[1], S. Dillon[1], X. Gu[1], N. Afdhal[1], T. Libermann[1].
[1]Beth Israel Deaconess Medical Center, Medicine, Boston, United States; [2]University of Nebraska – Lincoln, Lincoln, United States
Email: tliberma@bidmc.harvard.edu

Background and Aims: The gold standard for diagnosing NASH is liver biopsy. There is currently no high accuracy non-invasive test to discriminate between NASH and simple steatosis. We applied the SOMAscan proteomics platform that enables measurement of 1,310 proteins, including very low abundant proteins, to discover potential serum protein biomarkers for differentiating between NASH and simple steatosis and NASH with and without advanced fibrosis.

Method: Using SOMAscan (SomaLogic; Boulder, CO), quantitative serum protein profiles were generated from 20 subjects with simple steatosis, 20 subjects with NASH without advanced fibrosis (F0-2 fibrosis), and 20 subjects with NASH with advanced fibrosis (F3-4 fibrosis). To develop high accuracy predictors with the lowest number of proteins for discriminating NASH from simple steatosis and NASH with from NASH without advanced fibrosis discriminatory analysis was performed using 10,000 sub-sampled datasets. Each dataset contained a 4-fold split (i.e., 75%) of the original sample size. Counting the number of times a protein was identified with an adj. $p < 0.01$ in a "split" ranked these proteins according to their frequencies. Prediction accuracy, sensitivity and specificity of every combination of the top 10 proteins was determined to identify the highest accuracy predictors.

Results: A Leave-One-Out-Cross-Validation prediction accuracy of 91.7% was achieved for differentiating between NASH and simple steatosis using a 45-protein signature (adj. $p < 0.01$). A 43-protein predictor (adj. $p < 0.01$) that discriminated between NASH with advanced fibrosis and NASH without advanced fibrosis achieved 95%

prediction accuracy. Prediction analysis using combinations of the top 10 proteins identified a 5-protein signature (THBS2, BCL2A1, COLEC11, N6AMT1, GDF15) that distinguished between NASH and simple steatosis with an average 4-fold cross validation accuracy of 91.6% (93.9%sensitivity; 87% specificity) and AUROC of 0.9275. A 6-protein panel (SELE, IGFBP7, IGFBP5, NAGK, DCN, IL1R2) discriminated between NASH with advanced fibrosis and NASH without advanced fibrosis with an average 4-fold cross validation accuracy of 98.1% (96.2% sensitivity; 100% specificity) and AUROC of 1.

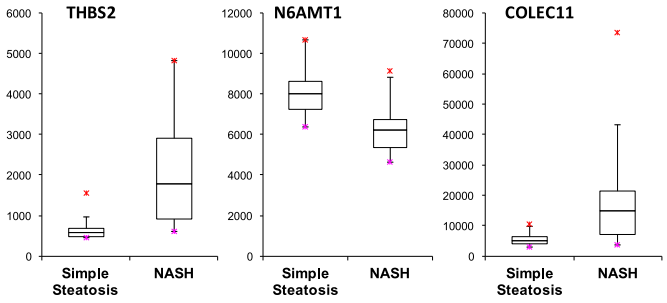

Figure: Box and Whisker Plots for 3 serum proteins that discriminate between NASH and simple steatosis.

Conclusion: This study demonstrates the feasibility of SOMAscan to discover high accuracy serum protein biomarkers linked to NASH and fibrosis. We aim to independently validate the diagnostic accuracy of these predictors in larger scale, prospective studies.

PS-182

The development of the diabetes liver fibrosis score: A new prediction model to detect advanced fibrosis in diabetics with nonalcoholic fatty liver disease

A. Singh[1], R. Lopez[1], A. Vigni[2], E. Lawitz[2], F. Poordad[2], A. Scott[2], T. Okubote[2], M. Scott[2], M. Mansouri[2], N. Alkhouri[3]. [1]*Cleveland Clinic, Gastroenterology and Hepatology, Cleveland, United States;* [2]*Texas Liver Institute, Gastroenterology and Hepatology, San Antonio, United States;* [3]*Texas Liver Institute, Texas Liver Institute, San Antonio, United States*
Email: singha4@ccf.org

Background and Aims: Patients with type 2 diabetes (T2DM) and nonalcoholic fatty liver disease (NAFLD) are at increased risk of having advanced fibrosis (AF). Recent data suggest that commonly used fibrosis scores such as the NAFLD fibrosis score (NFS) and FIB4 scores may have low sensitivity and negative predictive value when used specifically in a diabetic population. The aim of this study was to develop a simple noninvasive fibrosis score of AF in diabetics and compare its performance to other fibrosis scores.

Method: Using ICD-9 codes, patients with T2DM who had a liver biopsy for suspected NAFLD were identified. Patients with secondary causes of hepatic steatosis were excluded. Only patients with available clinical and laboratory data within 24-month period of liver biopsies were used for the analysis. Biopsies were assessed by a liver pathologist and the stage of fibrosis was determined (F0–F4) with AF being F3–4. A univariable analysis was performed to assess factors associated with advanced fibrosis. A predictive model was developed using logistic regression analysis. Discrimination and calibration for model performance were used for internal model validation. Receiver Operating Characteristics (ROC) analysis was performed to assess the value of the newly created score as well as known noninvasive fibrosis scores. Decision curve analysis (DCA) was performed to assess the net benefit of the predictive model.

Results: Out of 1,318 patients with T2DM and liver biopsies, 592 met inclusion criteria and 201 had AF. Mean age (years) at biopsy was 55.9 ± 11.2, 56% were females, 91% were overweight or obese. The new predictive model called the Diabetes Liver Fibrosis Score (DLFS) included the following variables: age, hypertension, chronic kidney disease, the use of statins, platelet count, and AST. The score has values ranging from 0 to 100. The AUROC for this model was 0.79 (95% CI: 0.75, 0.83) and internal validation of the model using bootstrap resampling showed an AUROC of 0.779. A score of 68.9 or higher maximizes specificity and PPV (98% and 86%, respectively). On the other hand, a score of 14.5 or lower maximizes sensitivity and NPV (95% and 92%, respectively). DLFS was significantly better than AST/ALT ($p < 0.001$), APRI ($p = 0.002$) and NFS ($p < 0.001$) at differentiating subjects with and without AF. There was no difference in AUCs when compared to FIB-4 score ($p = 0.13$) but decision curve analysis showed that our model provides more net benefit over a larger range of threshold probabilities (Figure).

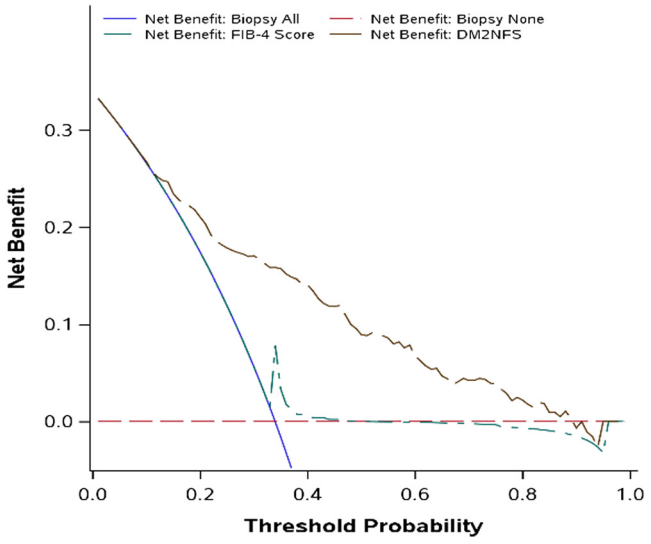

Figure: Decision curve analysis (DCA) showing the net benefit of DLSF in comparison to FIB4 score.

Conclusion: We developed a new diabetes-specific noninvasive fibrosis score that outperformed currently used fibrosis scores and may help in identifying diabetics at significant risk for liver-related morbidity.

PS-183

Long term prognostic value of the FibroTest in patients with non-alcoholic-fatty-liver disease (NAFLD), compared to chronic hepatitis C (CHC), B (CHB), and alcoholic liver disease (ALD)

M. Munteanu[1], J. Moussalli[2], M. Rudler[2], P. Lebray[2], H. Perazzo[2], J. Massard[2], R. Pais[2], F. Charlotte[2], V. Thibault[2], L. Olivier[2], L. Hannoun[2], M.A. Valantin[3], Y. Ngo[1], F. Drane[1], F.I. Bismut[3], O. Deckmyn[1], C. Housset[4], D. Thabut[4], V. Ratziu[5], T. Poynard[2]. Email: tpoynard@teaser.fr

Background and Aims: Although the FibroTest (FT) has been validated as a biomarker for the diagnosis of the stages of fibrosis in NAFLD with results similar to those in CHC, CHB and ALD, it has not yet been confirmed for the prediction of liver related death (Lrd), possibly due to the lower incidence of Lrd and the higher non-liver-related causes of mortality (APT 2014). The primary aim was to assess the long-term prognostic value of FT for Lrd in NAFLD.

Method: All patients (pts) in the prospective FibroFrance-NCT01927133 cohort who underwent a FT between 1997 and 2012 were pre-included. Mortality status was obtained from the physician, the hospital or the national register. The cause of death was classified as Lrd, "cardiovascular" (CVrd) and "other". Survival analyses (events defined as death or transplantation) were based on univariate (KaplanMeier, Logrank, AUROC) and multivariate (Cox-Risk-Ratio (CRR)) analyses, taking into account age, gender and response to antiviral treatment as covariates. The independent prognostic value of each FT component was assessed for each liver disease. The main endpoint was the performance of the FT (AUROC/CRR), for Lrd, compared to results observed in CHC, the most validated population.
Results: A total of 7,012 pts were included; 1,070, 3,420, 2,027 and 495 with NAFLD, CHC, CHB, and ALD, respectively. At baseline, NAFLD pts were older than those with CHC (median;95%CI), 57(56-58) vs 48 (47–49) years old; (p = 0.0001), similar for male prevalence 57% vs 59%;(p = 0.30), and had a lower severity of fibrosis presumed by FT (mean FT;95%CI and % cirrhosis (F4) (0.24;0.22–0.25;6.8% F4) vs (0.45;0.43–0.46; 21.7% F4); (p = 0.0001). Mean follow-up was 7 years. Survival at 15 years without Lrd (SwLrd) in patients with NAFLD was 94% (91–97; 38 Lrd) and 91% (89–92; 223 Lrd; p = 0.007) in CHC. The prognostic value (AUROC/CRR) of FT for SwLRD in patients with NAFLD was highly significant (p = 0.0001) .92(0.87–0.95)/1638(342–7839) and not different from CHC. 89(0.87–0.91)/2657(993–6586). Staging of NAFLD into 7 categories using FT predicted decreasing 5-year SwLrd in F4.3 vs F4.2 and F4.1 (Figure) as validated previously in CHC and CHB (J Hepatol 2014). The prognostic value of FT in NAFLD. 56(0.51–0.60)/3.9(2.4–6.4) for overall survival (OS) (n death = 249), was significant (p = 0.0001) but lower than that observed in CHC (n = 489)0.76(0.73–0.78)/32(22–46), as expected because of the lower incidence of Lrd in NAFLD vs CHC. FT was also significant (p = 0.0001) for the prediction of CVrd .62(0.53–0.70)/vs. 58(0.51–0.65) in CHC, driven by a decrease in Apo1 and older age. Using CHB/ALD instead of CHC reported the same results.

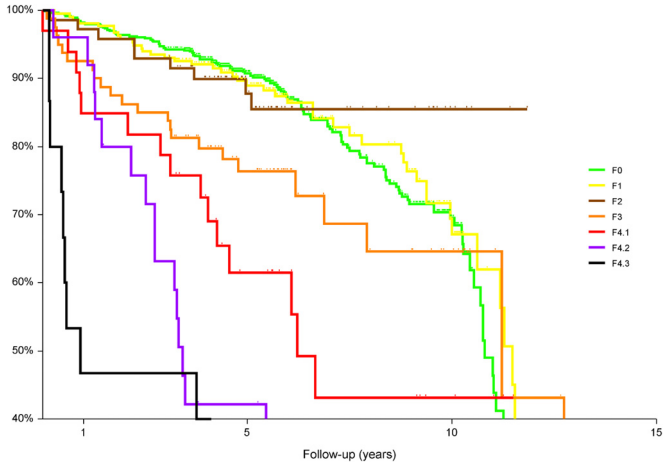

Figure: Survival according to 7 stages of fibrosis presumed by the FibroTest in 1,070 NAFLD patients.

Conclusion: The FibroTest has a high predictive value for survival without liver disease or transplantation in patients with NAFLD, similar to that observed in patients with CHC, CHB, and ALD.

Late breaker: Orals

LBO-001

A multicenter, randomized, double-blind, PLB-controlled trial of Galectin-3 inhibitor (GR-MD-02) in patients with NASH cirrhosis and portal hypertension

N. Chalasani[1], G. Garcia-Tsao[2], Z. Goodman[3], E. Lawitz[4], M. Abdelmalek[5], M. Rinella[6], M. Ryan[7], M. Noureddin[8], C. Jue[9], M. Pyko[1], A. Allgood[10], H. Shlevin[10], R. Horton[10], E. Zomer[10], P. Traber[10], R. Loomba[11], B. Tetri[12], A. Sanyal[13], S. Harrison[14]. *[1]Indiana University School of Medicine; [2]Yale University School of Medicine; [3]Inova Fairfax Hospital; [4]The Texas Liver Institute; [5]Duke University Medical Center; [6]Northwestern University – Feinberg School of Medicine; [7]Digestive and Liver Disease Specialists; [8]Cedars Sinai Medical Center; [9]Digestive Health Specialists; [10]Galectin Therapeutics; [11]University of California San Diego Medical Center; [12]Saint Louis University; [13]Virginia Commonwealth University; [14]Pinnacle Clinical Research*
Email: nchalasa@iu.edu

Background and Aims: Galectin-3 protein is implicated in the pathogenesis of NASH and toxin-induced fibrosis in animal models, both of which were improved by GR-MD-02, a novel gal-3 inhibitor. To test the safety and efficacy of GR-MD-02 in patients with NASH cirrhosis and PH.
Method: Phase 2B study randomized adults with NASH cirrhosis and portal hypertension (PH) to receive either placebo (PLB), or GR-MD-02 at 2 mg/kg (GR2), or GR-MD-02 at 8 mg/kg (GR8) in 26 biweekly intravenous infusions over 52 weeks. Eligibility criteria were HVPG ≥ 6 mmHg, no or small varices, NASH cirrhosis by biopsy, and no complications from cirrhosis. Primary endpoint was change in HVPG (Δ HVPG) at the end of treatment (EOT), compared to baseline (BL); secondary endpoints were changes in liver histology and the development of complications. Subgroup analyses were conducted in (a) no esophageal varices at BL and (b) mild PH (HVPG between ≥6 and <10 mmHg) at BL.
Results: 162 patients were randomized to receive PLB (n = 54), GR2 (n = 54), or GR8 (n-54). BL demographic, clinical, and laboratory characteristics were similar among the 3 groups. Baseline HVPG (mmHg) was 11.6 ± 4 in PLB, 12.3 ± 4.3 in GR2, and 12.7 ± 4.2 GR8 groups. 81 patients had no esophageal varices at BL (33 PLB, 25 GR2, and 23 in GR8) and 53 had mild PH (20 PLB, 17 GR2, and 16 in GR8). The total patient population had no statistically significant difference in Δ HVPG between PLB and GR (Δ PLB = 0.3 mmHg, Δ GR2 = −0.37 mmHg, Δ GR8 = −0.42 mmHg). There was no effect on fibrosis or NAFLD Activity Score, but there was a statistically significant improvement in hepatocyte ballooning with GR2 (p = 0.03) and a trend with GR8 (p = 0.09) versus PLB.
In patients without varices, there was a significant difference in ΔHVPG between PLB and GR2 (PLB = 0.8 mmHg, GR-2 = −1.08 mmHG, p < 0.01 vs PLB) but not with GR8 (−0.42 mmHg), p = 0.36 vs PLB). Also, significantly fewer patients receiving active treatment developed new varices at E0T (PLB 6, GR2 = 0 (p = 0.02) and GR8 = 1 (p = 0.12) and for combined treatment groups versus PLB (p = 0.01). In mild PH, there was a significant difference in ΔHVPG between PLB and both treated groups (PLB = 1.7 mmHg, GR2 = −0.2, p = 0.055 vs PLB, GR8 = −0.2, p = 0.036 vs PLB). Responder analysis, defined as the percent who had both ↓HVPG ≥ 2 mmHg and ≥ 20% ↓HVPG was significantly higher in GR2 (13% PLB vs. 43% in GR-2, p = 0.01) but not GR8 (18%, p = ns). GR2 and GR8 were well tolerated with similar proportion of AEs and SAEs; more patients discontinued GR8 with AE (n = 5), 0 in PLB or GR2.
Conclusion: GR-MD-02 did not improve HVPG or liver fibrosis in the entire study population, but significantly improved hepatocyte ballooning. Significant and clinically relevant beneficial effects of GR2 were evident in NASH cirrhosis without varices, or those with

mild PH. Significantly fewer GR2 patients developed new varices at EOT. These data warrant further investigating GR-MD-02 in patients with NASH cirrhosis without varices.

LBO-002

NGM282, an engineered analogue of FGF19, significantly improves markers of bile acid synthesis, hepatic injury and fibrosis in PSC patients: Results of a phase 2, multicenter, randomized, double-blind, placebo-controlled trial

G. Hirschfield[1], O. Chazouillères[2], J. Ph Drenth[3], D. Thorburn[4], S. Harrison[5], C. Landis[6], M.J. Mayo[7], A. Muir[8], J.F. Trotter[9], M. Karsdal[10], M. Jaros[11], L. Ling[12], K.H. Kim[12], S. Rossi[12], R.M. Somaratne[12], A. Depaoli[12], U. Beuers[13]. *[1]University of Birmingham, Birmingham, United Kingdom; [2]Assistance Publique Hopitaux de Paris, Hepatology and Gastroenterology, Paris, France; [3]Radboud University, Nijmegen, Netherlands; [4]Royal Free Hospital, London, United Kingdom; [5]Pinnacle Clinical Research, Live Oak, United States; [6]University of Washington, Medicine, Seattle, United States; [7]University Texas Southwestern Medical Center, Medicine, Dallas, United States; [8]Duke University Medical Center, Medicine, Durham, United States; [9]Texas Digestive Disease Consultants, Clinical Research, Southlake, United States; [10]Nordic Biosciences, Herlev, Denmark; [11]Summit Analytical, Chicago, United States; [12]NGM Bio, Clinical Development, S. San Francisco, United States; [13]AMC, University of Amsterdam, Amsterdam, Netherlands*
Email: srossi@ngmbio.com

Background and Aims: PSC is an inflammatory, cholestatic and progressively fibrotic liver disease devoid of effective medical interventions. NGM282, an engineered, non-tumorigenic FGF19 analogue, is an experimental agent in development for chronic liver diseases that potently regulates CYP7A1-mediated bile acid (BA) homeostasis. We evaluated the biologic activity and safety of NGM282 in patients with PSC.

Method: Sixty-two patients, with diagnosed PSC by EASL criteria and an elevated ALP >1.5 x ULN at Baseline (BL), were randomized to NGM282 1mg, 3mg or placebo as a daily SC injection for 12W. Treatment was stratified by current UDCA treatment at BL. Enrollment criteria allowed for PSC patients with stable dominant strictures, small duct disease, features of autoimmune hepatitis and compensated cirrhosis. The primary endpoint was change in ALP from BL to W12, with secondary endpoints of safety as well as surrogate biomarkers of BA synthesis, hepatic injury and liver fibrosis.

Results: Potent target engagement was seen in NGM282-treated subjects *vs.* placebo, with significant reductions in C4 and serum BA (Table 1). At W12, ALP was not significantly reduced from BL in either UDCA-treated or -untreated subjects. However, ALT and AST significantly improved with both doses as early as W1 and sustained through W12 with the 3mg dose. Moreover, total Enhanced Liver Fibrosis [ELF] Score, PIIINP and TIMP-1 also decreased, with the greatest effect in those stratified to higher risk disease (ELF >9.8 at BL, n = 26). Decreases in PRO-C3 were significant across both treatment arms. There was no difference in PSC-related clinical events between NGM282 *vs.* placebo study arms. No drug-induced pruritus was observed in either NGM282 study arm. There was no evidence of neutralizing anti-drug antibodies detected during or after NGM282 treatment. The most common adverse events in NGM282-treated subjects were diarrhea, frequent stools and injection site reactions, the majority of which were mild and resolved while on treatment.

Conclusion: NGM282 potently inhibited BA synthesis, decreased markers of hepatic inflammation and significantly improved markers of fibroblastic response and matrix formation in PSC patients, consistent with effects seen in NASH patients. The significant improvements in PRO-C3, ELF and serum transaminases support longer trials of NGM282 in PSC, with a focus on liver fibrosis as a meaningful surrogate endpoint of efficacy.

Table 1: Mean Change from BL to W12 of Key Biomarkers

	Placebo (n = 20)	NGM282 1 mg (n = 21)	NGM282 3 mg (n = 21)
C4 (ng/ml)	0.4	−7.9#	−14.7*
Total Serum BA minus UDCA (umol/l)	−4.03	−12.6#	−16.8#
ALP (U/l)	5	26	−3

LBO-003

RO7049389, a core protein allosteric modulator, demonstrates robust anti-HBV activity in chronic hepatitis B patients and is safe and well tolerated

E. Gane[1], A. Liu[2], M-F. Yuen[3], C. Schwabe[1], Q. Bo[2], S. Das[4], L. Gao[2], X. Zhou[2], Y. Wang[2], E. Coakley[5], Y. Jin[2]. *[1]Auckland Clinical Studies, Auckland, New Zealand; [2]Roche Innovation Center Shanghai, Shanghai, China; [3]Unversity of Hong Kong, Medicine, Hong Kong, China; [4]Roche Products Limited, Shire Park, United Kingdom; [5]Roche Innovation Centre New York, New York, United States*
Email: sudip.das@roche.com

Background and Aims: RO7049389 is a small molecule, Class I HBV core protein allosteric modulator (CpAM). It induces formation of abnormal hepatitis B virus (HBV) core aggregates resulting in defective capsid assembly thereby suppressing HBV replication. In the AAV-HBV mouse model, robust HBV DNA declines (≈3.0 $\log_{10}$ copies/ml) were observed over 56 days of dosing.

Method: The ongoing Phase I study investigates the safety, tolerability, pharmacokinetics (PK), and anti-HBV activity of RO7049389. Study Part 1 evaluates the safety and PK of single ascending doses (SAD) of RO7049389/placebo (5 dosing cohorts from 150–2000 mg) and multiple ascending doses (MAD) (5 dosing cohorts from 200–800 mg BID x 14 days) in healthy volunteers (HVs). Study Part 2 also interrogates the anti-HBV effects of RO7049389 in untreated chronic HBV (CHB) patients (4 planned cohorts BID x 28 days).

Results: 75 HVs have been dosed in this study. Across the dosing range, RO7049389 was rapidly absorbed and eliminated from plasma. A trend of greater than dose-proportional increases in exposure from 150 to 1000 mg, and approximately dose-proportional increases from 1000 to 2000 mg were observed in SAD cohorts. Accumulation of RO7049389 in MAD cohorts was minimal or none.

A blinded safety evaluation demonstrated that RO7049389/placebo in HVs was well tolerated in the SAD and MAD cohorts. In Part 1, a total of 55 adverse events (AEs) were reported in 36/75 HVs. In Part 2, a total of 14 AEs were reported in 3/7 patients. All AEs were reported as being mild in intensity with only five being considered as related to RO7049389, these were: nausea, abdominal discomfort, rash and 2 cases of headache. No serious AEs or AEs leading to drug discontinuation were reported and no clinically significant changes in ECG parameters, vital signs, or laboratory safety test results were observed.

Six CHB patients completed 28 days dosing period of RO7049389 at a dose of 200mg BID. Robust and continued HBV DNA declines from pre-dosing levels were observed, with median (maximal) decline being 2.7 (3.4) $\log_{10}$ IU/ml and below the limits of detection in 3/6 patients. No on-treatment virologic rebound was observed.

Conclusion: The RO7049389 appears to be safe, generally well tolerated and demonstrates robust anti-HBV activity over 28 days of dosing in patients with CHB.

Email: fabien.zoulim@inserm.fr

Background and Aims: JNJ-6379 is a potent and selective HBV replication inhibitor with a dual mode of action, inhibiting both early and late steps of the viral life cycle. This study aims to evaluate safety, pharmacokinetics and antiviral activity of multiple ascending doses of JNJ-6379 in CHB patients.

Method: Treatment-naïve, HBeAg-positive or -negative CHB patients, with plasma HBV DNA >2000 IU/mL, METAVIR <F3 and ALT/AST <2.5 the upper limit of normal, were enrolled into this ongoing, randomized, double-blind, placebo-controlled Phase 1b study. Patients were randomized in a 3:1 ratio to receive JNJ-6379 or placebo for 28 days with 8 weeks follow-up. To date, 3 groups have been evaluated (25 mg QD [after 100 mg loading dose], 75 mg QD and 150 mg QD). Evaluation of a fourth group (250 mg QD) is ongoing.

Results: Across all groups (n = 36), median age was 42.5 years (range: 21–58), 83% males, 78% Caucasian, 11% Asian, 6% Black/African American, 6% other/not reported. 25% of patients were HBeAg-positive.

At Day 29, substantial reductions from baseline in HBV DNA (Table) and HBV RNA were observed in all 3 treatment groups. No notable changes in HBsAg were observed.

Adverse events (AEs) or laboratory abnormalities ≥Grade 3 were infrequent (≤3 patients/dose); 64% (23/36) experienced ≥1 AE on treatment (25 mg, n = 9/12; 75 mg, n = 6/12; 150 mg, n = 8/12). There was one serious AE (right frontal lobe mass, unrelated to study drug), one discontinuation due to AEs (isolated ALT/AST flare with no bilirubin elevation, likely related to study drug), and no dose-limiting toxicities. After repeated administration, drug exposure increased in a dose-dependent manner. Apparent drug clearance was low, and similar across groups and ethnicities.

Conclusion: JNJ-6379 administered for 28 days was generally well tolerated and resulted in potent antiviral activity at all doses evaluated, and the data from this study warrants additional evaluation of the compound in phase 2a.

Email: jens.ricke@med.uni-muenchen.de

Background and Aims: SORAMIC is an RCT comprising diagnostic, local ablation and palliative studies. Based on the result of the diagnostic study patients were assigned to either the local ablation or palliative cohort. The palliative treatment cohort (reported here) was designed to determine the efficacy and safety of combining SIRT (Selective Internal Radiation Therapy) with sorafenib in patients with advanced HCC.

Method: In the palliative treatment cohort, patients not eligible for TACE were randomised 11:10 to either SIRT with Y-90 resin microspheres plus sorafenib (target dose 400 mg bid) or sorafenib alone. The primary endpoint was overall survival (OS; Kaplan-Meier analysis) in the intention-to-treat population.

Results: In the ITT palliative treatment cohort, 214 patients were randomised to SIRT + sorafenib and 205 to sorafenib alone. Median OS was 12.1 months (95% confidence interval [CI], 10.4–14.6) in the SIRT + sorafenib arm, and 11.5 months (95% CI, 9.9–13.9) in the sorafenib arm (hazard ratio [HR], 1.018; 95% CI, 0.821–1.262; p = 0.8726). In the per-protocol group, median OS was 12.6 months (95% CI, 11.6–16.0) in the SIRT + sorafenib arm (n = 134), and 11.5 months (95% CI, 9.8–13.9) in the sorafenib arm (n = 200; HR, 0.919; 95% CI, 0.722–1.170; p = 0.4914). Subgroup analyses of the per-protocol population revealed a survival benefit of SIRT+ sorafenib for: patients ≤65y (HR 0.820); without PVT (HR 0.745); Child Pugh A vs B (HR 0.356); BCLC A & B vs C (HR 0.800). When stratified by PVT, a survival benefit was seen in: patients ≤65y (HR 0.736); without cirrhosis (HR 0.746); Child Pugh A vs B (HR 0.356); without metastases (HR 0.804). Adverse events (AEs) of Common Terminology Criteria for AE Grade ≥3 were reported in 128/176 (72.7%) patients in the SIRT + sorafenib arm and 126/193 (65.3%) patients in the sorafenib arm, respectively.

Conclusion: The addition of SIRT to sorafenib did not result in a significant improvement in Overall Survival compared to sorafenib alone. Subgroup analyses led to hypothesis generating results for patient groups with potential clinical benefit.

LBO-006

JKB-121 in patients with nonalcoholic steatohepatitis: A phase 2 double blind randomized placebo control study

A.M. Diehl[1], S. Harrison[2], S. Caldwell[3], M. Rinella[4], A. Paredes[5], C. Moylan[6], C. Guy[7], M. Bashir[8], Y. Wang, PhD[6], Dr. L. Miller[9], A. Chang, PhD[9], E. Sc Wu, PhD[9], M. Abdelmalek[9]. *[1]Duke University, Division of Gastroenterology, Durham, United States; [2]Pinnacle Research, San Antonio, United States; [3]University of Virgina Health System, Charlottesville, United States; [4]Northwestern Univrsity, Division of Gastroenterology, Chicago, United States; [5]Brooke Army Hospital, Division of Gastroenterology, San Antonio, United States; [6]Duke University, Division of Gastroenterology, Durham; [7]Duke University, Department of Pathology, Durham, United States; [8]Duke University, Center of Advanced Magnetic Resonance Development, Durham, United States; [9]TaiwanJ Pharmaceuticals Co, Ltd, Zhubei City, Taiwan*
Email: manal.abdelmalek@duke.edu

Background and Aims: NASH is a rapidly growing cause of chronic liver disease worldwide with significant medical need for effective treatments. TLR-4 is a key mediator of obesity-associated inflammation, insulin resistance and hepatic inflammation and fibrosis. JKB-121 is a weak antagonist of the TLR-4 receptor demonstrated to prevent NASH in a methionine/choline deficient diet fed rat model of NAFLD, decrease NASH and fibrosis in STAM model and inhibit hepatic stellate cell activation and collagen expression in vitro. The aim of this study was to assess the safety/tolerability and biologic activity of JKB-121 in patients with biopsy-proven NASH.
Methods: This is a multicenter, randomized (1:1:1), double-blind, placebo-controlled study in adults with biopsy-proven NASH with a NAS ≥ 4 (1 point in each component), stage 1–3 fibrosis, ≥6% liver fat content (LFC) by MRI-PDFF, and elevated liver aminotransferases (ALT > 40 U/l for women and > 60 U/l for men). Randomization was stratified by diabetes status. Patients received JKB-121 5 mg, 10 mg, or placebo twice daily for 24 weeks. The primary endpoint was reduction in LFC by MRI-PDFF and/or serum ALT at 24 weeks. Exploratory endpoints included serum biomarkers (FIB4, Fibro Test).
Results: 65 patients were randomized (median age, 51.0 years; woman, 68%; type 2 diabetes 66%; median BMI 35.2; median LFC 17.3%; median ALT 69 ± 36 U/l). Baseline characteristics, including histologic grade and stage, LFC, and biochemical parameters were comparable among groups. At week 24, median relative and absolute LFC improved in all groups with no difference in JKB-121 treatment groups compared to placebo (p > 0.05). At week 24, in JKB-121 5 mg, 10 mg vs placebo, change in ALT was -5.4 U/l, -3.8 U/l, and -15.2 U/l, p > 0.05) with biochemical remission (ALT < 40 U/l on two consecutive measures) in 28.5%, 18.2%, and 31.8%, respectively, (p > 0.05). JKB-121 did not improve BMI, glycosylated hemoglobin, HOMA-IR, total-, LDL-, HDL-cholesterol or triglycerides compared to placebo. Fib4 improved in the placebo group (p < 0.05). The most frequent drug-related adverse events (AEs) in JKB-121-treated patients were nausea (26.4% vs 22.7% in placebo), dizziness (36% vs 0%), constipation (9.1% vs 4.5%), vomiting (14.3% vs 4.5%), fatigue (9.1% vs 4.5%), and most AEs were mild. Serious AEs occurred in two patients; neither were considered drug-related. There were no deaths. Drug-related AEs leading to withdrawal in 10 mg, 5 mg vs placebo occurred in 27.3%, 9.5% vs 0%, respectively.
Conclusions: A notable improvement in LFC, ALT and FIB4 was observed in the placebo group in this 24 week NASH study. JKB-121 did not further improve the response rate in patients with NASH (F1-F3) compared to placebo. Given the multiple relevant biologic pathways of TLR-4 in pathogenesis NASH, further investigation of TLR-4 inhibition, as well as factors contributing to higher placebo response rates, is warranted.

Table 1

	Placebo (n=22)	JKB-121 5 mg (n=21)	JKB-121 10 mg (n=22)

Early assessment of safety and efficacy of tropifexor, a potent non bile-acid FXR agonist, in patients with primary biliary cholangitis: An interim analysis of an ongoing phase 2 study

C. Schramm[1], G. Hirschfield[2], A.L. Mason[3], H. Wedemeyer[4], L. Klickstein[5], S. Neelakantham[5], P. Koo[5], J. Sanni[5], M. Badman[5], D. Jones[6]. *[1]University Medical Centre Hamburg-Eppendorf, Department of Medicine and Martin Zeitz Centre for Rare Diseases, Hamburg, Germany; [2]University of Birmingham, National Institute of Health Research (NIHR) Biomedical Research Unit (BRU) and Centre for Liver Research, Birmingham, United Kingdom; [3]University of Alberta, Division of Gastroenterology and Hepatology, Edmonton, Canada; [4]Universitätsklinikum Essen, Klinik für Gastroenterologie und Hepatologie, Essen, Germany; [5]Novartis Institutes for BioMedical Research, Translational Medicine, Cambridge, United States; [6]Newcastle University, Institute of Cellular Medicine, Newcastle-upon-Tyne, United Kingdom*
Email: michael.badman@gmail.com

Background and Aims: In patients with primary biliary cholangitis (PBC), incomplete response to first-line therapy with ursodiol (UDCA) is associated with increased risk of cirrhosis and death. The bile acid FXR agonist obeticholic acid is approved as second-line therapy for PBC. Tropifexor (LJN452) is a selective and highly potent, non-bile acid FXR agonist that reduces cholestasis and hepatocellular damage in rodent models. This trial was designed to test the safety, tolerability and preliminary efficacy of tropifexor in PBC patients.
Method: This ongoing multi-part, international, double blind, placebo controlled, ascending dose Phase 2 study enrolled PBC patients with an inadequate response to UDCA (ALP ≥ 1.67xULN or Bilirubin > ULN), who were taking UDCA. Patients were randomized in cohorts (approx. 10 active to 5 placebo) to receive 30 µg, 60 µg or 90 µg of tropifexor once daily, or matching placebo, for 4 weeks. A planned interim analysis was conducted on completion of Cohort 3 (90 µg tropifexor). The pre-specified primary efficacy outcome was change in GGT from baseline to avoid the confounding effect of FXR mediated induction of ALP. Safety analyses included number of subjects to discontinue, evaluation of adverse events and laboratory markers.
Results: There were no deaths, non-fatal serious adverse events or discontinuations due to adverse events or itch. Baseline demographic and biochemical parameters were similar across groups (ALP 358, 317, 281 and 323 iU for pooled placebo, 30, 60 and 90 µg tropifexor arms). There was a brisk decrease in GGT, ALP, ALT and AST (tabulated below) with 72% reduction in GGT at 90 µg tropifexor at day 28. Biochemical markers had not yet reached their maximum changes at completion of dosing. Reductions in HDL of 33% and 26% occurred at doses of 60 µg and 90 µg tropifexor respectively and returned to baseline by end of study. There was no increase in total or LDL cholesterol at any dose of tropifexor tested.
Conclusion: Tropifexor was generally safe and well tolerated at the doses tested. The dose dependent activity on markers of cholestasis (GGT) and hepatocellular damage (ALT) indicates the potential benefit of FXR agonism by tropifexor in PBC. The absence of

discernible increase in itch raises the possibility that tropifexor may have a tolerability advantage over obeticholic acid. Tropifexor shows promise as a potential future therapy for PBC and longer term studies are warranted.

Table: Summary of mean change (%) from baseline at day 28 and repeated measures analysis for LFT parameters

%change	Placebo (n = 16)	Tropifexor 30 µg (n = 10)	Tropifexor 60 µg (n = 9)	Tropifexor 90 µg (n = 12)

Email: joy.peter@medicine.ufl.edu

Background and Aims: The fixed dose combination of once daily 300 mg glecaprevir, an HCV NS3/4A protease inhibitor (PI), and 120mg pibrentasvir (GP), an NS5A inhibitor (NS5Ai), was FDA approved for the treatment of chronic HCV infection; including genotype 1 (GT1) patients who failed a prior NS5Ai-containing regimen without prior exposure to a PI. The aimes of this study are: (1) to add further evidence in GT1 NS5Ai/SOF ±RBV failures utilizing the FDA label-consistent GP regimen given for 16 weeks and (2) to explore a shorter 12-week duration of GP in non-cirrhotic subjects and compensated cirrhotics (RBV added).

Total Started	Arm A GP 12 wks (n = 71)	Arm B GP 16 wks (n = 41)	Arm C GP + RBV 12 wks (n = 22)	Arm D GP 16 wks (n = 20)
	Non-Cirrhosis		Cirrhosis	
GT 1/1A	56(79%)	31(78%)	18(82%)	17(85%)
White	42(59%)	18(45%)	13(59%)	14(70%)
Black	27(38%)	21(53%)	8(36%)	6(30%)
Male	59(83%)	32(80%)	16(72%)	17(85%)
SAE	1(1%)	0(0%)	1(1%)	0(1%)
Response*	(n = 49)	(n = 16)	(n = 17)	(n = 11)
SVR 4	**96%**	**100%**	**82%**	**100%**
Relapse	1(2.4%)	0(0%)	0(0%)	0(0%)
Breakthrough	1(2.4%)	0(0%)	3(18%)	0(0%)

*Among those reaching time point.

Method: NS5Ai plus SOF±RBV-experienced, chronic HCV GT1 participants were randomized as follows: up to 150 non-cirrhotics (NC) in 2:1 ratio to *Arm A- GP for 12 weeks (NC-12)* and *Arm B- GP for 16 weeks* (*NC-16*) and up to 100 with compensated cirrhosis (CC) in a 1:1 ratio to *Arms C-GP + weight-based RBV BID for 12 weeks (CC-12 + R)* and *Arm D-GP for 16 weeks (CC-16).* Randomization is stratified by GT1 subtype (1b or non-1b). All baseline samples and any virologic failure samples are subject to deep sequencing for NS3 and NS5A resistance-associated substitutions. Primary endpoint is sustained virologic response 12 weeks post treatment (SVR12).
Results: To date, 196/154 subjects have been screened/dosed. The primary reason for screen failures was decompensated cirrhosis. The enrolled population is mostly male (81%), 40% Black, and majority are GT1a (83%). Of the dosed 112 NCs, 69% have reached SVR4 or 12 (SVR 4/12). In NC-12, 47/49 (96%) and in NC-16 16/16 (100%) achieved SVR4/12. Among 42 dosed CCs, 14/17 (82%) in CC-12 + R and 11/11 (100%) in CC-16 achieved SVR4/12 to date (TABLE 1). 5 treatment failures were observed: 2 in NC-12 (1 relapse, 1 breakthrough) and 3 in CC-12 + R, which were all breakthroughs, leading to suspension of the CC-12 + R arm. There have been no early treatment discontinuations to date. The most frequent adverse events (AEs) are fatigue (10%) and headache (15%). Two serious AEs, a small bowel obstruction (Arm A) and sepsis (Arm C)- have been observed.
Conclusion: Patients who failed direct acting antiviral HCV therapy represent a challenging population with few retreatment options. To date, treatment failure has occurred in 3% of NCs and 11% of CCs, all confined to the experimental 12 week regimens. Complete outcome and resistance data of this large ongoing study of GP for prior GT1 NS5Ai + SOF ±RBV failures will be presented.

Background and Aims: WTX101 (bis-choline tetrathiomolybdate) is a copper-protein-binding agent that reduces plasma non-ceruloplasmin bound copper (NCC) by forming tripartite complexes with albumin and increases biliary copper excretion. In a Phase 2 study in Wilson disease (WD), oral once-daily WTX101 rapidly reduced $NCC_{corrected}$ (corrected for copper in tripartite complexes), improved disability and neurological status, and stabilized liver function over 24 weeks. We present preliminary 72-week efficacy and safety data from an ongoing Phase 2 study extension, the first prospective report on long-term disease control with WTX101 in WD.
Method: All 22 patients completing the 24-week open-label, single-arm Phase 2 study opted to continue once-daily response-guided treatment with WTX101 in the extension. Key parameters reviewed to 72 weeks included hepatic status, $NCC_{corrected}$, neurological status, safety and tolerability.
Results: Mean ALT, international normalized ratio, albumin, and Model for End-Stage Liver Disease score improved or remained stable between week 24 and 72. Reversible ALT elevations requiring dose adjustments, observed in 39% of patients (at > = 30 mg/day) to week 24, were not observed in the extension. Elevated mean (SD) $NCC_{corrected}$ at baseline (3.6 [2.1] μM) was reduced and controlled at week 24 (0.9 [1.0] μM) and remained controlled at week 72 (0.5 [0.7] μM) with accompanying continuous improvements in disability and neurological status in most patients. Low platelet (56%) and neutrophil (32%) counts were common at baseline, with similar reporting throughout follow-up; low hemoglobin was infrequent. Most cytopenias were not accompanied by low NCC levels and unlikely to reflect copper deficiency. Two subjects had evidence of neutropenia accompanied by mild anemia and low NCC potentially consistent with copper deficiency at week 36 and 72, respectively; both responded rapidly to dose reduction. Overall, the number of reported adverse events (AEs) and serious AEs (SAEs) decreased by more than 50% from weeks 1–24 (175 AEs and 11 SAEs) to weeks 25–72 (71 AEs and 4 SAEs). Between week 24 and 72, 89% of AEs were mild or moderate, with 89% considered unrelated or unlikely related to therapy.
Conclusion: Once-daily treatment of WD patients with WTX101 up to 72 weeks provided long-term disease control as shown by sustained improvements in NCC, disability and neurological status and stable hepatic function, with a favorable tolerability profile.

LBP-002

Treatment efficacy and safety of seladelpar, a selective peroxisome proliferator-activated receptor delta agonist, in primary biliary cholangitis patients: 12- and 26-week analysis from an ongoing international, randomized, dose raging phase 2 study

Background and Aims: Seladelpar is a potent and selective PPAR-delta agonist with potential as a new therapeutic approach for patients with inflammatory liver diseases. From an ongoing open-label phase 2 study in patients with primary biliary cholangitis (PBC), we report biochemical, disease symptom, and safety data with up to 26 weeks of treatment across three doses (2 mg, 5 mg and 10 mg) of seladelpar.
Methods: Randomized, open-label study (EudraCT**:** 2016-002996-91) of patients with PBC that were either inadequately responding to ursodeoxycholic acid (UDCA, alkaline phosphatase -AP- ≥1.67x upper limit of normal) or intolerant of UDCA. Data up to 12 weeks evaluated seladelpar doses of 2, 5 and 10 mg/day. Data up to 26 weeks evaluated

ELSEVIER

doses of 5 and 10 mg/day. After 12 weeks, patients on 5 mg could escalate to 10 mg if their AP treatment goal was not achieved. The primary efficacy outcome is the AP % change from baseline. Secondary outcomes include AP responder analyses, and changes in other liver, metabolic, and inflammatory markers. Pruritus was evaluated with a visual analogue scale (VAS, 0–100) and specific questionnaires. Safety analysis includes evaluation of adverse events (AE) and laboratory markers.

Results: As of January 2018, 71 patients were exposed to at least one dose of seladelpar, of whom 53 received 12 weeks of treatment and 42 received 26 weeks of treatment. At baseline, mean AP were 358, 333, and 262 UI/l in the 2, 5, and 10 mg groups, respectively. At 12 weeks, changes in AP were -21%, -33%, and -45% in the 2 (n = 6), 5 (n = 25), and 10 (n = 22) mg groups, respectively. At 26 weeks, 69%, 67%, and 79% of patients had an AP < 1.67 x ULN in the 5 (n = 13), 5 to 10 (n = 6), and 10 mg (n = 19) groups, respectively, and falls in AP were equal across regimens: -45%, -43%, and -43%, respectively. Overall, 29% had a normal AP at 26 weeks. At 12 weeks, median ALT changes were -9%, -28%, and -35% in the 2, 5, and 10 mg groups, respectively and decreases were maintained at 26 weeks in the 5 and 10 mg groups (≥-40%).

Seladelpar did not increase pruritus. Baseline median pruritus VAS was 10 and 36 in the 5 and 10 mg group, respectively, and patients in the 10 mg group experienced consistent decreases during follow up (-24% at week 26) suggesting anti-pruritic activity. Seladelpar was generally safe and well tolerated, with no transaminase elevation safety signal. There were 6 serious AEs and none were deemed related to seladelpar.

Conclusion: In patients with PBC, Seladelpar demonstrates potent and sustained anti-cholestatic and anti-inflammatory efficacy over 26 weeks of administration (10mg daily, or 5 mg titrated to 10 mg). Treatment efficacy is not associated with pruritus, and future studies will evaluate long term efficacy, safety as well as potential anti-pruritic properties.

LBP-003

Scheduled endoscopic dilatation of dominant strictures improves survival in patients with primary sclerosing cholangitis

C. Rupp[1,2], T. Hippchen[1], D. Gotthardt[1], A. Stiehl[1], P. Sauer[1]. [1]*Medical University Hospital (New Krehl Clinic), Internal Medicine IV, Heidelberg, Germany;* [2]*Medical University Hospital (New Krehl Clinic), Interdisciplinary Endoscopy Unit, Heidelberg, Germany*
Email: christian_rupp@med.uni-heidelberg.de

Background and Aims: Endoscopic treatment of dominant strictures in patients with Primary sclerosing Cholangitis (PSC) is recommended in those patients present with symptoms. Benefits following dilatation or stenting included improvement of clinical symptoms and of liver biochemical test results, as well as a longer transplantation-free survival compared to that predicted in survival models. The impact on actual long term survival of a scheduled endoscopic treatment independent of symptoms up to a resolution of dominant strictures has not been evaluated so far.

In this prospective trial, we compared clinical outcome and long-term survival in PSC patients with adherence to a provided scheduled endoscopic surveillance and treatment program to that in PSC patients receiving endoscopic diagnostic and therapy only on clinical demand.

Method: PSC patients that were treated at our tertiary center between 1987 and 2016 were included into the study. All patients were offered to participate in an endoscopic surveillance and treatment program with scheduled endoscopic interventions (scheduled group). Diagnostic ERC was performed annually and endoscopic treatment of identified DS was carried out in defined intervals up to a complete resolution of the stricture. Patients who refused to participate received surveillance with clinical evaluation, liver function tests and imaging methods, including liver ultrasound and magnetic resonance imaging in frequent intervals. Endoscopic intervention was performed in case of deterioration of cholestasis or signs of acute cholangitis (on demand group).

Results: The final study cohort comprises 286 PSC patients. 133 (46.5%) patients received ERC according to our proposed scheduled program. In the 153 (53.5%) remaining cases ERC was conducted on demand. Clinical and laboratory baseline characteristics did not differ between both groups. After a follow-up period of thirty years the transplantation-free survival in patients with scheduled endoscopic therapy was significantly higher compared to patients with on demand therapy (median: 17.9 vs. 15.2 years; log-rank: p = 0.008). In subgroup analysis benefit of scheduled ERC was achieved in patients with dominant stricture (17.8 vs. 11.1 years; log-rank: p < 0.001), but not in patients without dominant stricture (21.0 vs. 18.7 years; log-rank: p = 0.8). Multivariate analysis confirmed presence of inflammatory bowel disease IBD (p = 0.03), presence of DS (0.006), Mayo risk score MRS (p = 0.02) and adherence to scheduled endoscopy (p = 0.005) independently associated with transplantation-free survival.

Conclusion: Scheduled endoscopic surveillance and therapy improves transplantation-free survival in PSC patients with dominant strictures.

LBP-004

Long term outcomes of treatment with Trientine in Wilson disease: Final results from a multicentre study in patients withdrawn from d-Penicillamine therapy

K.H. Weiss[1], N. Manolaki[2], M.G. Zuin[3], C. Kruse[4], A. Dhawan[5]. [1]*University Hospital Heidelberg, Internal Medicine IV, Heidelberg, Germany;* [2]*"Aghia Sophia" Children's Hospital, 2nd Department of Pediatrics, Athens, Greece;* [3]*University of Milan, Department of Health Sciences, Milan, Italy;* [4]*Univar B.V., Medical Affairs, Rotterdam, Netherlands;* [5]*King's College Hospital London, Paediatric Liver GI Nutrition Centre, London, United Kingdom*
Email: KarlHeinz.Weiss@med.uni-heidelberg.de

Background and Aims: Trientine dihydrochloride (Trientine; UNIVAR B.V.) is a common treatment for Wilson Disease. This study aimed to assess efficacy, safety, and tolerability outcomes of Trientine chelator-based treatment after withdrawal of d-Penicillamine. ClinicalTrials.gov Identifier: NCT02426905.

Method: In a multicenter, retrospective cohort study assessments were performed for 6, 12, 24, 36 and 48 month time points and at the latest available follow-up after Trientine initiation. A total of 81 patients were enrolled into the study, with 77 (95.1%) patients included in the intention to treat (ITT) population. Primary endpoint was investigator rated outcome of hepatic and neurologic symptoms, additional efficacy analysis included copper parameter, LFTs. Safety reporting included SAE and discontinuation rate.

Results: Of the 77 patients included in the ITT population, 16 (20.8%) patients were under the age of 18 years. Reasons for discontinuation of D-Penicilamine were adverse events (58 [75.3%] patients) or lack of clinical improvement (12 [15.6%] patients).

On average, patients were treated with trientine for 73.3 (±74.76) months. The mean total dose per day during treatment was 1005.7 (±425.32) mg. Treatment with trientine improved hepatic symptoms in 49.4% of patients, with 35.1% asymptomatic, 10.4% unchanged and 5.2% worsened, whereas neurological symptoms remained unchanged in 36.4% of patients, with 46.8% asymptomatic, 14.3% improved and 2.6% worsened. Overall, the median NCC concentration showed a decrease from baseline to latest follow up (n = 35 [–0.613 ± 1.7318]).

A total of 17 (22.1%) patients experienced a serious TEAE. The majority of these TEAEs were resolved, resolved with sequelae or improved. Only two serious TEAEs were considered related to trientine and both resolved. Treatment with trientine was permanently discontinued due to a TEAE in 1 (1.3%) patient (anemia). Two (2.6%) patients discontinued trientine treatment due to inadequate hepatic response.

Figure 1; Hepatic and Neurological Outcome Over Time (ITT)

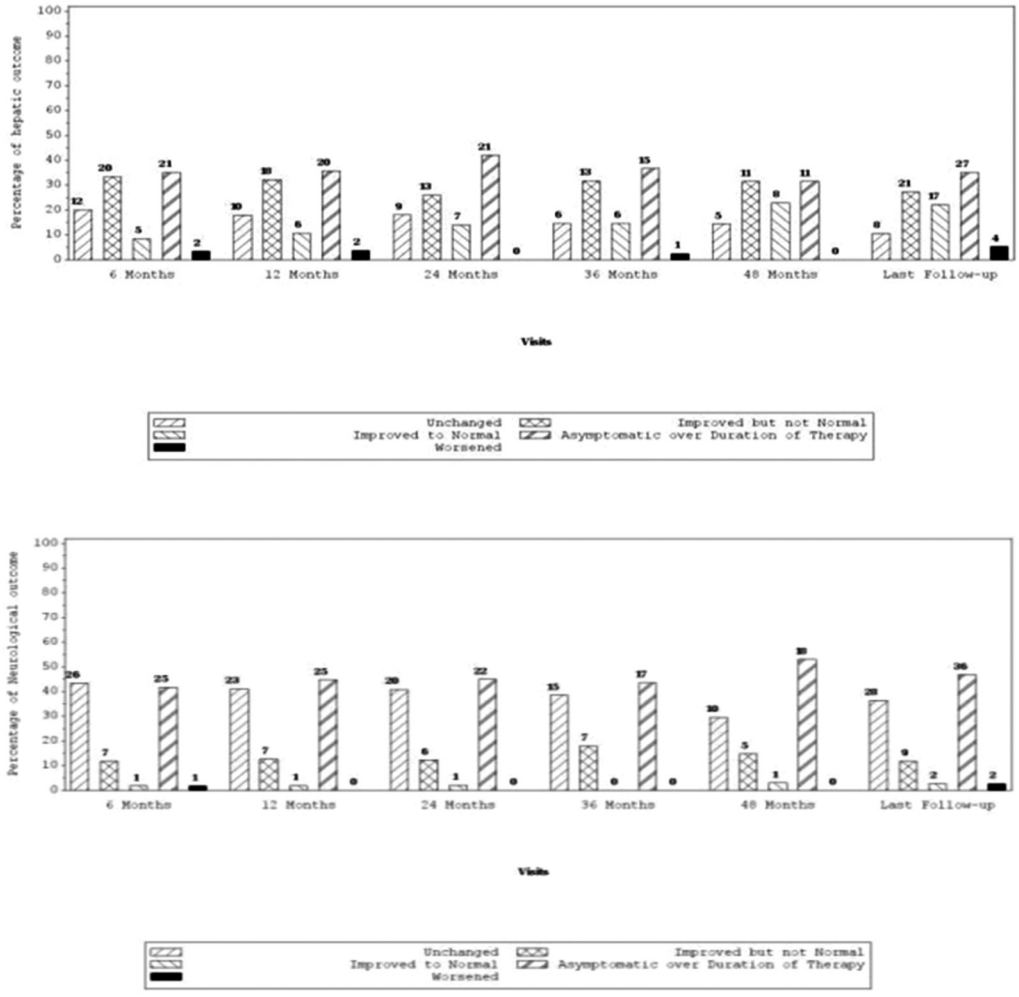

Figure: (abstract: LBP-004)

Conclusion: Anti-copper therapy with trientine was effective following withdrawal of treatment with d-Penicillamine. Trientine well tolerated and the rates of symptomatic deterioration were lower than reported in previous series. These findings supports Trientine's prominent role in Wilson Disease management.

LBP-005

Results of a placebo-controlled double blind randomised trial to investigate the efficacy of rifaximin-alpha versus placebo in improving systemic inflammation in patients with cirrhosis and chronic hepatic encephalopathy (RIFSYS Trial)

V. Patel[1], M.J.W. Mcphail[1], A. Zamalloa[1], S. Støy[1,2], G.M. Vijay[1], X. Huang[1], G. Rogers[3], J. Choo[3], L. Edwards[1], E. Gray[1], C. Woodhouse[1], S. Gencer[4], M. Coen[4], J. Wendon[1], K. Bruce[5], D. Shawcross[1]. *[1]King's College London, Liver Sciences, 1st Floor James Black Centre, School of Immunology & Microbial Sciences, Faculty of Life Sciences and Medicine, London, United Kingdom; [2]Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark; [3]South Australian Health and Medical Research Institute, Microbiome Research, Adelaide, Australia; [4]Imperial College London, Biomolecular Medicine, Division of Computational and Systems Medicine, Department of Surgery and Cancer, London, United Kingdom; [5]King's College London, Institute of Pharmaceutical Science, 5th Floor Franklin-Wilkins Building, London, United Kingdom*

Email: debbie.shawcross@kcl.ac.uk

Background and Aims: Rifaximin-α is efficacious in the prevention of the recurrence of overt hepatic encephalopathy (HE) but its mechanism of action remains unclear. We postulated that rifaximin reduces gut microbiota-derived endotoxaemia and systemic inflammation which is a known driver of HE and contributes to cirrhosis associated immune dysfunction and susceptibility to developing infection.

Methods: A randomised placebo-controlled double blind study of rifaximin-α versus placebo was performed in 38 patients with cirrhosis and chronic persistent overt HE or with ≥2 episodes of overt HE in the previous 6 months; 19 in each arm. Rifaximin-α 550mg (TARGAXAN) twice daily or placebo was administered for 90-days. The primary outcome was a 50% reduction in spontaneous neutrophil oxidative burst (OB) after 30-days. Secondary outcomes included Psychometric Hepatic Encephalopathy Scale (PHES) testing, 16S rRNA faecal microbiota profiling, plasma, urine and faecal ^{1H}NMR metabolic profiling, whole blood bacterial DNA quantification, neutrophil TLR4 expression and plasma cytokine analyses. Assessments were undertaken at baseline and at 30 and 90-days.

Results: Patients were well matched with no significant difference in their median MELD [11(8–15) rifaximin vs 10(8–12) placebo], ammonia or HE grade. Participants on rifaximin but not placebo normalised their HE grade by day-30 [grade 1 to 0; p = 0.014]. Trail's A (PHES) improved significantly on rifaximin compared to placebo over 90-days; p = 0.012 and line tracing after 30-days; p = 0.023. OB did not

change. While a non-significant reduction (p = 0.09) in neutrophil TLR4 expression (surrogate marker of circulating endotoxin) after 30-days of rifaximin was observed, significant (p < 0.001) reductions in plasma TNFα occurred to day-90. Despite this there were no global changes in gut microbiota composition as assessed by alpha and beta diversity. Minor changes in circulating whole blood microbiota profiles were observed with rifaximin but no change in endogonenous metabonomic profile.

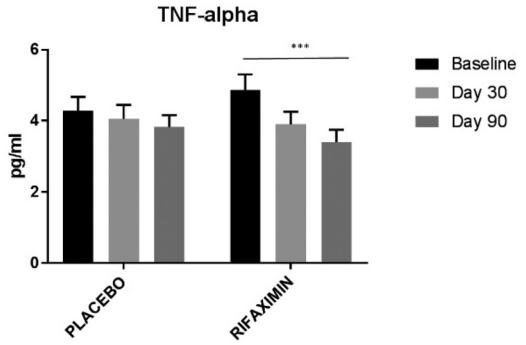

Figure: Plasma TNFα concentrations over 90 days demonstrating significant (***, p < 0.001) reductions in the group receiving rifaximin.

Conclusions: In addition to providing significant benefit in cognitive function, rifaximin led to a reduction in systemic inflammation in the absence of any change in gut microbiota composition. Quantitative metagenomic profiling of paired saliva and faecal samples is now being undertaken to interrogate this further.

LBP-006

PBI-4050, a potential anti-fibrotic drug, improves liver fibrosis in Alström Syndrome, an ultra-rare disease

S. Baig[1], T. Geberhiwot[1], L. Gagnon[2], B. Grouix[2], P. Laurin[2], L. Foulkes[3], C. Dorion[2], F. Cesari[2], O. Vaughan[3], J. Moran[2]. [1]*Queen Elizabeth Hospital, Centre for Rare Disease, Birmingham, United Kingdom;* [2]*Prometic Biosciences Inc., Laval, Canada;* [3]*Prometic Biosciences Ltd., United Kingdom*
Email: l.gagnon@prometic.com

Background and Aims: Fatty liver in Alström syndrome (AS) is observed in early childhood and is rapidly progressive compared to the common metabolic syndrome-related NASH: 50% of patients manifest severe fibrosis/cirrhosis (F3/F4) by early adulthood. PBI-4050 is an orally active drug candidate in phase 3 clinical trials for Idiopathic Pulmonary Fibrosis; it has demonstrated strong anti-fibrotic activity in numerous animal models of fibrosis in the liver, kidney, lung, heart or pancreas. PBI-4050 has been shown to significantly reduce liver fibrosis in CCl4-induced liver fibrosis, in bile duct ligation, in obese and in diabetic (*ob/ob* and *db/db*) mouse models. The aim of this study was to determine if PBI-4050 can improve liver fibrosis in AS patients.
Method: A phase 2, single-centre, single-arm, open-label study was undertaken in adult subjects with AS. The primary objective was to evaluate the safety and tolerability of 800 mg PBI-4050 administered orally once daily for up to 84 weeks, with secondary/exploratory objectives including evaluation of liver fibrosis (enzyme levels, quantitative MRI and FibroScan® analysis). An interim analysis was performed to compare the baseline and last available measurement for each patient.
Results: Twelve adult subjects (8 males, 4 females) with AS were enrolled. There were no drug-related serious adverse events, and PBI-4050 was well tolerated. The interim analysis suggests that treatment with PBI-4050 reduced liver fibrosis as measured by quantitative MRI [T1-corrected score] (p = 0.02, 95% CI -92.3, -9.8), and also correlated with the lowering of mean FibroScan® values from 10.2 to 8.6 kPa (p = 0.05, 95% -2.9, -0.3). Furthermore, the results of insulin clamp studies showed that PBI-4050 reduced mean endogenous glucose production (EGP) (1.88 to 0.89, ↓47%, p = 0.03); EGP is an indicator of hepatic insulin resistance.
Conclusion: These results demonstrate the potential of PBI-4050 to improve liver fibrosis, and support its further development as a treatment for liver fibrosis in AS.

LBP-007

Phase 1/2a trial of a bioartificial liver support system for acute liver failure patients

S. Lee[1], J.-H. Lee[2], D.-H. Lee[3], H. Park[2], Y. Kim[2], M. Park[2], E.M. Jang[3], J.G. Jung[3], J.K. Noh[3], Y. Hee-Hun[3], S.-K. Lee[4]. [1]*Samsung Medical Center, Department of Surgery, Seoul, Korea, Rep. of South;* [2]*Samsung Medical Center;* [3]*Lifeliver, Co.Ltd;* [4]*Samsung Medical Center, Department of Surgery*
Email: sukkoo.lee@samsung.com

Background and Aims: Bioartificial liver (BAL) support offers a potential means of improving survival of acute liver failure (ALF) patients by providing partial liver function until a suitable donor liver is found or the native liver undergoes regeneration. Previous studies have suggested that ALF patients treated using BAL maintain a more stable medical condition, which may positively influence outcome after liver transplant (LT). This clinical trial was conducted to evaluate the safety and efficacy of the LifeLiver BAL system in ALF patients.
Method: Patients with evidence of acute liver failure exhibiting hepatic encephalopathy grade 2 or worse who were listed for deceased donor liver transplant were eligible for enrollment. Hepatocytes were harvested from 3~4 weeks old male pigs weighing 4 to 10 kg, raised in a sterile environment. The isolate hepatocytes were cultured to form spheroids and were then mixed with 1.5% alginate solution and placed in a high content/speed immobilization apparatus and dropped into 100mM calcium solution. The Ca-alginate-immobilized hepatocyte spheroid beads were packed within the bioreactor of the BAL system. BAL treatment was continued for up to 12 hours.
Results: Six patients were given BAL treatment and were included in the safety analysis. Adverse events related to BAL treatment included coagulopathy (increased INR), pneumonia, sepsis and disease progression. One patient developed upper gastrointestinal tract bleeding and sepsis following BAL treatment and eventually died while waiting for transplant. No evidence of porcine endogenous retrovirus (PERV) were seen.
Five patients completed the study per protocol and were included in the efficacy analysis. Four patients showed apparent decrease in serum ammonia levels and MELD scores during BAL treatment. Hepatic encephalopathy either decreased or remained stable throughout the BAL treatment period in 4 patients.
Conclusion: The LifeLiver BAL support system showed safety and efficacy in ALF patients with hepatic encephalopathy. Two patients were successfully bridged to liver transplantation.

Email: martin.sprinzl@unimedizin-mainz.de

Background and Aims: Patients with chronic hepatitis B (cHB) regularly require long-term nucleos(t)ide analogue (NUC) treatment, because HBsAg loss is rarely achieved. Therefore we studied the addition of pegylated interferon alfa-2a (Peg-IFN) to an ongoing NUC therapy in patients with HBeAg-negative cHB, aiming to reduce serum HBs-antigen concentrations.
Patients and Methods: HBeAg-negative cHB patients (HBsAg >100 IU/ml) under effective NUC treatment for ≥1 year were randomized to receive additional Peg-IFN (180µg/week) for 48 weeks (Peg-IFN group, n = 112) or continuing NUC monotherapy (control group, n = 58) in a prospective open-label phase IIb study (EudraCT-Nr: 2011-002812-10). The modified intention-to-treat (mITT) population (n = 165), covering ≥1 post-baseline HBsAg assessment is reported. Primary response after 48 weeks of treatment was defined by reduction of ≥1log10 in serum HBsAg concentration compared to baseline. Secondary endpoints were HBsAg seroconversion and overall HBsAg concentrations. Adverse events (AEs) were assessed. Fisher's Exact test[#], T test[$], chi[2] test[§].
Results: The mITT population was predominantly male (74.6%) and Caucasian (75.2%). Liver elastrography assessment resulted in an average of 6.5 kPa and 6.9 kPa in the interferon- and control- group, respectively. HBV genotyping was available in 20.6% (n = 34/131), showing HBV genotype D (81.8%) and genotype A (9.1%) most frequently. The mean HBsAg concentration in the interferon group (6,548 ± 10,326 IU/ml) at baseline was lower than in the control group (8,427 ± 12,660 IU/ml) but differences were not statistically significant ($p > 0.05^{\$}$).
Primary response (HBsAg log drop) was achieved in 24.5% (n = 26/110) of the Peg-IFN group compared to 1.9% (n = 1/55) in the control group ($p < 0.0001^{\#}$). Six patients (5.5%) in the Peg-IFN group had a HBsAg seroconversion, whereas none occurred in the control group ($p > 0.05^{\#}$). In the Peg-IFN group HBsAg loss was observed in 15.8% (n = 16/110), whereas the control group failed HBsAg clearance ($p < 0.05^{\S}$). Most patients (94.6% in the Peg-IFN- and 58.6% in the control-group) experienced at least one AE. Only 27 (3.2%) AEs were graded as severe. No death was reported.
Conclusions: The addition of Peg-IFN to an ongoing NUC regimen accelerates HBsAg reduction in comparison to standard NUC therapy of HBeAg negative cHB patients. Further exploratory analyses to identify predictive factors in order to optimize the balance between benefit and adverse events are ongoing.

LBP-009

Long term real life follow-up of patients with chronic hepatitis C virus and decompensated cirrhosis after direct acting antivirals – what is the clinical benefit of antiviral treatment?

M. Cheung[1], D. Mutimer[2], K. Agarwal[3], A. Brown[4], M. Aldersley[5], G. Foster[6], W. Irving[7]. *[1]Blizard Institute, Barts & The London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom; [2]Queen Elizabeth Hospital, Centre for Liver Research and NIHR biomedical Research Unit, Birmingham, United Kingdom; [3]Institute of Liver Studies, King's College Hospital, London, United Kingdom; [4]St. Mary's Hospital, Imperial College Healthcare NHS Trust, London, United Kingdom; [5]St. James's University Hospital, Leeds, United Kingdom; [6]Blizard Institute, Barts & The London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom; [7]NIHR Nottingham Digestive Diseases Biomedical Research Unit, Nottingham, United Kingdom*
Email: michelle.cheung@qmul.ac.uk

Background and Aims: Efficacy of direct acting antivirals (DAA) in treating chronic hepatitis C virus (HCV) is well established, however the long term clinical benefits of achieving sustained virological response (SVR) in patients with advanced liver disease is unclear. We describe the ongoing follow up of patients with decompensated cirrhosis treated with sofosbuvir + ledipasvir or daclatasvir +/- ribavirin on the Expanded Access Programme (EAP) in England.
Method: Out of 843 patients treated on the EAP, we included patients started between April-November 2014 who achieved SVR12, and all patients with virological failure. Only patients with a history of decompensation and/or Child B7 liver disease at treatment baseline were analysed. Patients who died or were lost to follow-up before 12 weeks post treatment end were excluded. Data was prospectively collected from treatment sites through a national biobank HCV Research UK, which included death, hepatocellular carcinoma (HCC), liver transplant, wait list status, latest available MELD scores.
Results: There were 330 SVR and 124 treatment failures, of whom 53 achieved viral clearance with retreatment. Five patients were lost to follow up prior to retreatment outcomes. Median follow up was 136 weeks (range 24–174) from treatment start. Baseline characteristics (74% male, median age 54 and MELD 12) were similar in the 383 HCV

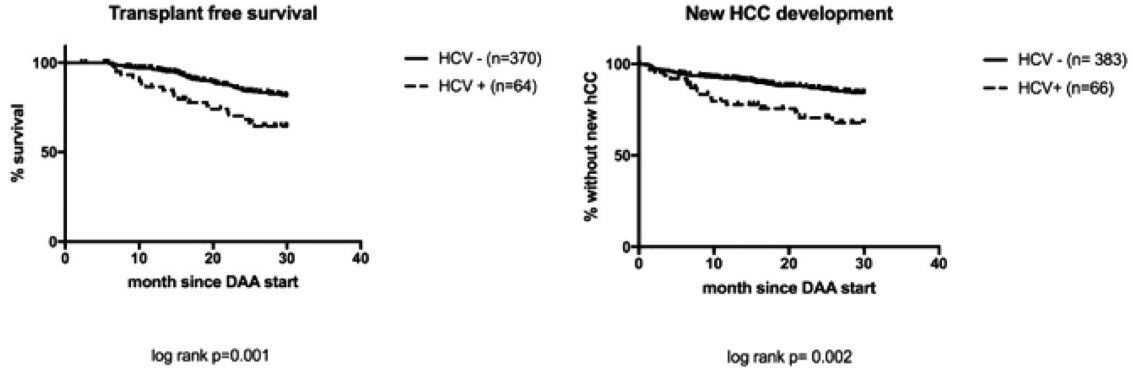

Figure: (abstract: LBP-009)

cleared patients and 66 patients who remained viraemic, apart from proportion of genotype 3 infections (43 vs 62%).
At 30 months, hazard ratios for death and new HCCs were 0.44 (95% CI 0.23–0.84) and 0.43 (0.21–0.88) respectively, between HCV clear and viraemic patients. Among 42 patients with baseline HCC only 1 recurred after DAA.
Conclusion: This large real life cohort shows sustained benefit in survival and HCC development in patients with decompensated cirrhosis following viral clearance.

LBP-010
High efficacy and safety of grazoprevir and elbasvir for 8 weeks in treatment-naive, non-severe fibrosis HCV GT1b-infected patients: Interim Results of the STREAGER Study
A. Abergel[1], C. Hezode[2], T. Asselah[3], D. Larrey[4], J. Gournay[5], V. Loustaud-Ratti[6], V.D. Martino[7], I.F. Hubert[8], D. Samuel[9], B. Chanteranne[1], M. Dodel[1], F. Faure[1], B. Pereira[1], G. Lamblin[1], C. Campos[1], L. Muti[1], M. Reymond[1], C. Teilhet[1]. *[1]Chu Estaing, Clermont-Ferrand, France; [2]Henri Mondor Hospital (AP-HP), Créteil, France; [3]Beaujon Hospital (AP-HP), Clichy, France; [4]Hospital Gui De Chauliac, Montpellier, France; [5]Nantes University Hospital Hotel-Dieu, Nantes, France; [6]Hospital Center University De Limoges Dupuytren, Limoges, France; [7]Regional University Hospital of Besançon Jean Minjoz, Besançon, France; [8]C.H.U. d'Angers, Angers, France; [9]Paul-Brousse Hospital (AP-HP), Villejuif, France*
Email: aabergel@chu-clermontferrand.fr

Background and Aims: Genotype 1b is the most common HCV genotype globally, accounting for the largest proportion of infections in Europe, Latin America, Russia, Turkey, and East Asia. Reducing treatment duration can improve adherence and reduce drug exposure. Accordingly, we evaluate the efficacy of 8 weeks of the protease inhibitor grazoprevir 100 mg/d (GZR) and NS5A inhibitor elbasvir 50 mg/d (EBR) among treatment-naïve patients, with non-severe fibrosis. Recommend adding combined as a fixed dose combination single tablet.
Method: Pooled analysis included the 82 first treatment-naïve (TN), with non-severe fibrosis (Fibroscan®<9.5 kPa and Fibrotest®<0.59), HCV GT1b-mono-infected patients without advanced kidney disease enrolled in STREAGER trial, a study which aims to include 120 patients. The primary end point was the proportion of patients with HCV RNA below the lower limit of quantification (LLOQ) 12 weeks after treatment (SVR12).

Table: Relapsers characteristics

Genotype	Age	Sex	Viral Load at screen (IU/ml)	Fibrosis (Fibroscan®)	RAS at relapse
1b	52	M	14.000.000	6.4 kPa	Y93H
1e	57	M	453.899	9.1 kPa	L28M R30Q A92T Y93H
1b	60	F	16.437.573	5.1kPa	L31M Y93H

Results: Mean age was 54 ± 13 years, 37% were male, viral load higher than 800.000 IU/ml: 51/82 (62%); ALT higher than the upper limit of normal: 35/82 (43%). Using Fibrotest® (FT), 48 had a F0-F1 fibrosis score (FT < 0.32); by Fibroscan® (FS) 73 had F0-1 fibrosis score (FS < 7.1 kPa). By end of treatment (EOT), 95% (78/82) of patients had HCV RNA < LLOQ. No adverse event grade III or IV was observed. Relapse occurred in 3 patients, including one patient with genotype 1b by Innolipa and one patient with genotype 1e by sequencing (wrongly included) (Table). After excluding the patient with genotype 1e, SVR12 was 79/81 (98%). In addition, it's important to note that another patient relapsed 24 weeks after EOT (SVR24) despite reaching SVR 12. Additional efficacy data will be available at the EASL meeting.

Conclusion: High SVR12 (79/81, 98%) was achieved in a TN non severe fibrosis GT1b-infected population in patients treated for 8 weeks by the combination grazoprevir and elbasvir.

LBP-011
A pilot study of empagliflozin for the treatment of non-alcoholic steatohepatitis in patients with type 2 diabetes mellitus
L.L. Lai[1], S. Vethakkan[1], N.R.N. Mustapha[2], S. Mahadeva[1], W.-K. Chan[1]. *[1]University of Malaya, Department of Medicine, Kuala Lumpur, Malaysia; [2]Hospital Sultanah Bahiyah, Department of Pathology, Alor Setar, Malaysia*
Email: wahkheong2003@hotmail.com

Background and Aims: Sodium-glucose cotransporter-2 inhibitors (SGLT2i) are a novel class of drugs that lower glucose by inducing renal glycosuria. SGLT2i confers multiple metabolic benefits and improves cardiovascular outcomes in patients with type 2 diabetes mellitus (T2DM). There is limited human data on SGLT2i for the treatment of non-alcoholic steatohepatitis (NASH).
Method: In this investigator-initiated, single-arm, open-label, pilot study, empagliflozin 25mg daily was added to usual therapy of T2DM for 24 weeks in nine consecutive biopsy-proven non-cirrhotic NASH patients who had no prior exposure to SGLT2i therapy. A repeat liver biopsy was performed at the end of treatment. Histopathological examination was reported according to Non-alcoholic Steatohepatitis Clinical Research Network scoring system. The histological outcomes were compared with the placebo group of a 48-week clinical trial previously conducted at the same centre. Hepatic steatosis at baseline and follow-up were also evaluated by measurement of volumetric liver fat fraction (VLFF) using HepaFat-Scan.
Results: Median age was 55 (47–60) years old and 44% were male. All patients were obese with median body mass index of 30 (28–35) kg per m^2. The distribution of fibrosis stage at baseline was F0, 11%; F1, 67%; F3, 22%. There was significant reduction in BMI (median change, Δ = –0.7 kg per m^2, p = 0.011), waist circumference (Δ = –3 cm, p = 0.033), systolic blood pressure (Δ = –9 mmHg, p = 0.024), diastolic blood pressure (Δ = –6 mmHg, p = 0.033), fasting blood glucose (Δ = –1.7 mmol/l, p = 0.008), total cholesterol (Δ = –0.5 mmol/l, p = 0.011), gamma glutamyl transpeptidase (Δ = –19U/l, p = 0.013), VLLF (Δ = –7.8%, p = 0.017) and histological steatosis grade (Δ = –1, p = 0.014). All histological components either remained unchanged or improved, except in one patient who had worsening hepatocyte ballooning. The histological outcomes of patients who received empagliflozin, and when compared with historical placebo, are shown in Figure 1. Empagliflozin resulted in significantly greater steatosis improvement (78% vs. 26%, p = 0.025) and fibrosis improvement (33% vs. 6%, p = 0.040) compared with historical placebo.

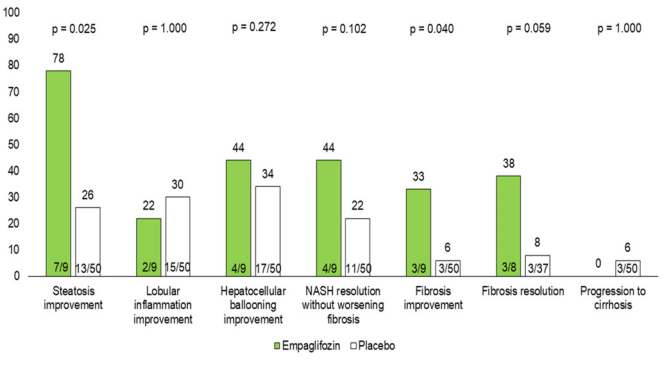

Figure 1: The histological outcomes of patients who received empagliflozin compared with placebo. Note: The placebo group is from a separate 48-week clinical trial previously conducted at the same centre.

Conclusion: This pilot study provides primary histological evidence that brief therapy with empagliflozin may be useful for the treatment of NASH. These promising preliminary findings justify the need for a

larger randomized, double-blind, placebo-controlled trial of empagliflozin in NASH for a longer duration.

LBP-012

Interim safety, tolerability pharmacokinetics, and antiviral activity of ABI-H0731, a novel core protein allosteric modulator, in healthy volunteers and non-cirrhotic viremic subjects with chronic hepatitis B

M.-F. Yuen[1,2], K. Agarwal[3], E. Gane[4,5], C. Schwabe[4], W. Cheng[6,7], W. Sievert[8], D.J. Kim[9], S.H. Ahn[10], Y.-S. Lim[11], K. Visvanathan[12], E. Ruby[13], S. Liaw[13], R. Colonno[13], U. Lopatin[13]. *[1]Queen Mary Hospital, Hong Kong; [2]The University of Hong Kong, Hong Kong; [3]King's College Hospital, London, United Kingdom; [4]Auckland Clinical Studies, Auckland, New Zealand; [5]New Zealand Liver Transplant Unit, Auckland City Hospital, Auckland, New Zealand; [6]Linear Clinical Research, Nedlands, Australia; [7]Royal Perth Hospital, Department of Gastroenterology & Hepatology, Perth, Australia; [8]Monash Health, Melbourne, Australia; [9]Hallym university, Korea, Rep. of South; [10]Severance Hospital, Korea, Rep. of South; [11]Asan Medical Center, University of Ulsan College of Medicine, Department of Gastroenterology, Seoul, Korea, Rep. of South; [12]St Vincents Hospital, University of Melbourne, East Melbourne, Australia; [13]Assembly Biosciences, San Francisco, United States*
Email: uri@assemblybio.com

Background and Aims: Core Protein Allosteric Modifiers (CpAMs) target the HBV core protein, a pleotropic protein involved in multiple steps of the HBV life cycle. ABI-H0731 is a potent and selective CpAM being developed to improve functional cure rates for chronic HBV (CHB) infection. Here we report the interim results on safety, tolerability, pharmacokinetic (PK) and antiviral efficacy in two ongoing studies: ABI-H0731-102 in healthy volunteers and ABI-H0731-101(B) in non-cirrhotic, viremic CHB patients.
Method: Up to 12 healthy volunteers or viremic CHB patients per cohort were randomized (10:2) and treated with 100–400 mg ABI-H0731 or placebo once daily for up to 14 days (Study 102) or up to 28 days (Study 101(B)) in double-blinded, placebo-controlled fashion. Patients were stratified by HBeAg status (7 pos:5 neg). Safety, PK and pharmacodynamic responses were monitored.
Results: Forty-nine subjects have been dosed to date in studies 102 (n = 24) and 101(B) (n = 25). Median (range) age was 38 (24–61) and 40 (26–55) years, respectively. In both studies, the majority were male (≥90%), with 13% and 76% Asian in studies 102 and 101(B), respectively. Mean baseline HBV DNA levels were 8.0 ± 1.1 $\log_{10}$ in HBeAg pos and 3.8 ± 1.5 $\log_{10}$ IU/ml in HBeAg neg patients. No serious adverse events (AEs) and no dose limiting laboratory toxicities have occurred in either study. A single G3 treatment-emergent AE leading to drug discontinuation was seen at 400 mg, otherwise all TEAEs were mild (G1) and/or unrelated to study drug. Treatment emergent laboratory abnormalities were infrequent, mild and/or deemed unrelated to study drug. Exposures increased in a dose proportional manner and were similar between CHB patients and healthy subjects. Steady state was readily achieved (<5 days) with approximately 2-fold accumulation seen in both patients and volunteers. HBV declines of 1.3 ± 0.3 and 2.2 ± 1.0 $\log_{10}$ IU/ml were seen in HBeAg pos/neg subjects (respectively) at 100 mg/day, the lowest dose tested, with greater declines observed at higher doses. HBV RNA reductions were generally proportional to reductions of plasma HBV DNA.
Conclusion: Preliminary data indicate that ABI-H0731 is generally safe and well tolerated, has a dose-proportional PK profile in patients similar to that in healthy volunteers, and once daily dosing results in potent antiviral activity. ABI-H0731 is progressing to Phase 2a proof of concept studies in 2018.

LBP-013

Comparisons the durability of 6 months and 12 months prolonged treatment duration after cessation chemotherapy in chronic hepatitis B patients with prophylaxis antiviral therapy: A open level randomized clinical trial

T.-H. Hu[1], P.-L. Tseng[1,2], M.C. Tsai[1,2], K.-C. Chang[1], Y.-H. Yen[1].
[1]Kaohsiung Chang Gung Memorial Hospital and Chang Gung University College of Medicine, Kaohsiung, Taiwan, Division of Hepato-Gastroenterology, Department of Internal Medicine, Taiwan; [2]Graduate Institute of Clinical Medical Sciences, Taiwan
Email: dr.hu@msa.hinet.net

Background and Aims: Prophylaxis antiviral therapy is the current recommendation for chronic hepatitis B patient receiving chemotherapy. According the American Association for the Study of Liver Diseases guideline in 2009, the treatment duration is guided by baseline HBV-DNA. However, there is no report to compare the ideal consolidation antiviral therapy duration after cessation chemotherapy. The aim of our study was to compare the relapse rate of finite 6-month and 12-month consolidation antiviral therapy in patients with HBV-DNA < 2000 IU/ml or HBV-DNA ≥ 2000 IU/ml after cessation chemotherapy.
Method: The enrolled patients were randomized into 4 groups. Patients received Tenofovir 300 mg or Entecavir 0.5 mg once daily orally one week before chemotherapy. In patients with baseline HBV DNA < 2000 IU/ml, consolidation therapy for 6 months after cessation of chemotherapy was assigned as group A and consolidation therapy for 12 months was assigned as group B. In patients with baseline HBV DNA ≥ 2000 IU/ml, consolidation therapy for 6 months was assigned as group C and consolidation therapy for 12 months was assigned as group D. Virological relapse was defined as the elevation of serum HBV DNA level > 1 log10 (IU/ml) with 3-month interval after cessation TDF or ETV treatment. Clinical relapse was defined as serum HBV DNA ≥ 2000 IU/ml and ALT > 80 IU/l after cessation antiviral therapy.
Results: A total of 61 patients were enrolled from 2013 to 2016. Fifty-six (91.8%) patients were HBeAg negative and 28 patients (45.9%) were breast cancer. Overall 1-year virological and clinical relapse was 52.1% and 23.2% respectively. There was no difference of virological and clinical relapse rate between the group A, B, C and D. Virological relapsers had higher end-treatment HBsAg levels than non-relapsers. Clinical relapsers had higher pretreatment ALT and HBV DNA than non-relapsers. In univariate analysis, end-treatment HBsAg level ≥ 500 IU/ml and pre-treatment HBV DNA ≥ 2000 IU/ml were predictors of virological relapse. Pre-treatment HBV DNA ≥ 2000 IU/ml and ALT ≥ 40 IU/ml were predictors of clinical relapse. In multi-variate analysis, end-treatment HBsAg level ≥ 500 IU/ml was the significant predictor in predicting virological relapse (adjust hazard ratio (HR): 2.77 p = 0.02). Pre-treatment ALT ≥ 40 IU/ml was the significant predictor in predicting clinical relapse (HR: 11.20; p = 0.003).
Conclusion: There is no difference in relapse rate between 6 months or 12 months prolonged antiviral therapy in patients with HBV DNA < or ≥2000 IU/ml after cessation chemotherapy. Patient with ALT ≥ 40 IU/ml and/or end-treatment HBsAg level ≥ 500 IU/ml should be close monitored after cessation NA therapy in area with limited resource or should keep antiviral therapy to the end point of HBV treatment.

LBP-014

Long-Term Obeticholic Acid (OCA) treatment associated with reversal or stabilization of fibrosis/cirrhosis in patients with Primary Biliary Cholangitis (PBC)

C. Bowlus[1], P. Pockros[2], A.E Kremer[3], A. Pares[4], L. Forman[5], J.P. Drenth[6], S. Ryder[7], E.S. Malecha[8], R. Pencek[8], U. Iloeje[8], L. Macconell[8], D. Shapiro[8], B. Pierre[9]. *[1]University of California-Davis, Sacramento, United States; [2]Scripps Clinic, La Jolla, United States; [3]Friedrich-Alexander-University Erlangen-Nürnberg, Department of Medicine 1, Erlangen, Germany; [4]University of Barcelona, IDIBAPS, CIBERehd, Hospital Clinic, Barcelona, Spain; [5]University of Colorado, Denver, School*

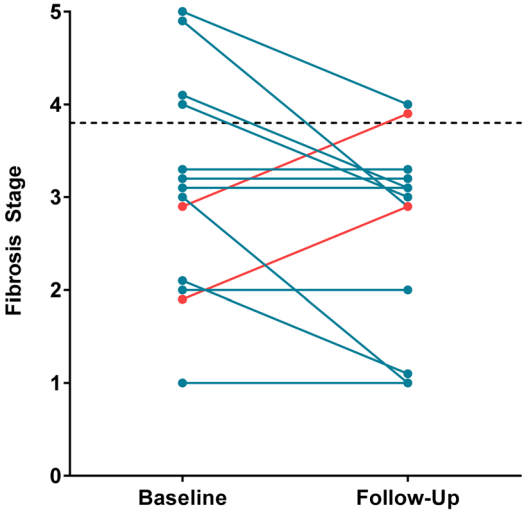
Email: christopher.bowlus@ucdmc.ucdavis.edu

Background and Aims: OCA, a selective and potent FXR agonist is licensed for PBC treatment in combination with UDCA (UDCA inadequate response), or as monotherapy (UDCA intolerance). POISE, a 12-month double-blind (DB), placebo-controlled Phase 3 study with an open-label extension, demonstrated the efficacy (biochemical response) and safety of OCA in PBC patients unresponsive/intolerant to UDCA. Liver histology is optional for diagnosing PBC and is infrequently used, but remains the gold standard for assessing liver fibrosis. PBC is progressive, with UDCA non-response associated with significant fibrosis progression. In preclinical models and non-PBC clinical studies, FXR agonism with OCA has shown anti-fibrotic properties. The aim of this POISE substudy was to evaluate the effect of 3-years of OCA therapy on fibrosis progression using paired liver biopsies.
Method: Patients enrolled into POISE had the option to participate in a biopsy substudy. These patients had biopsies prior to (≤1 year from DB baseline) and after 3 years (range: 2.9–3.0 y) of OCA treatment. Biopsies were centrally read and assessed with a 6-tier staging system (F0 = no fibrosis, F1 = periportal fibrosis, F2 = bridging fibrosis with rare septa, F3 = bridging fibrosis with many septa, F4 = incomplete cirrhosis, F5 = cirrhosis).
Results: 13 patients (58 years, 12 female, 11 Caucasian, 13 on UDCA, baseline median ALP: 322 U/l and direct bilirubin: 1.5 uM) had paired biopsies adequate for analysis. At baseline, 9 patients presented with precirrhotic fibrosis [F1 (n = 1), F2 (n = 3), F3 (n = 5)]) and 4 with cirrhosis [F4 (n = 2), F5 (n = 2)]. At the last visit prior to biopsy, ALP was reduced and direct bilirubin was comparable to baseline (median changes: -99 U/l and 0.0 uM, respectively). After 3 years of OCA, the majority of patients improved (n = 6, 46%) or maintained (n = 5, 38%) histological stage, while 2 patients (15%) worsened (figure). Of the 4 patients with baseline cirrhosis, 3 (75%) improved to fibrosis without cirrhosis.



Scoring system: 0=no fibrosis, 1=periportal fibrosis, 2=bridging fibrosis with rare septa, 3=bridging fibrosis with many septa, 4=incomplete cirrhosis, 5= cirrhosis. Dashed line separates fibrotic and cirrhotic stages.

Figure: Fibrosis stage at baseline and follow-up.

Conclusion: The vast majority (85%) of these patients with incomplete response to UDCA achieved stabilization or regression of fibrosis/cirrhosis after 3 years of OCA. These data are consistent with the observed anti-fibrotic properties of FXR agonism and suggest that OCA can slow or reverse histological progression in PBC patients who have had an incomplete response to UDCA. The effect of OCA on clinical outcomes is under evaluation in the Phase 4 COBALT study (EudraCT:2014-005012-42).

LBP-015
Safety, tolerability, and pharmacokinetics of BMS-986263/ND-L02-s0201, a novel targeted lipid nanoparticle delivering HSP47 siRNA, in healthy participants: A randomised, placebo-controlled, double-blind, phase 1 study

B. Soule, G. Tirucherai, U. Kavita, S. Kundu, R. Christian. *Bristol-Myers Squibb, Bristol-Myers Squibb, Princeton, United States*
Email: benjamin.soule@bms.com

Background and Aims: BMS-986263/ND-L02-s0201 is an intravenously (IV) administered lipid nanoparticle containing a small interfering ribonucleic acid (siRNA) that inhibits production of heat shock protein 47 (HSP47, a collagen-specific chaperone). This novel formulation uses Vitamin A-moieties conjugated to the nanoparticle surface to maximize drug delivery to hepatic stellate cells. Preclinical and previous phase 1b/2 data suggest that disrupting collagen synthesis via HSP47 inhibition may reverse fibrosis and may represent a new treatment (tx) strategy for advanced liver fibrosis. This phase 1 study evaluated safety, tolerability, and pharmacokinetics (PK) of fixed dose BMS-986263 in healthy participants (ppts).
Method: IM025-001 was a three part, randomised, placebo-(PBO) controlled, double-blind, parallel-group study in healthy non-Japanese (Part A) and Japanese (JPN; Part B) adults aged 18–55 years weighing 60–90 kg; Part C is ongoing. Ppts were pretreated with antihistamines as a precaution to prevent infusion reactions, which occurred in 21% of BMS-986263–treated ppts in a phase 1a study, and received either BMS-986263 90 mg IV or PBO once weekly (QW) for 3 weeks. The primary objective was safety and tolerability of BMS-986263.
Results: Of 25 ppts, 20 received BMS-986263 (Part A, n = 12; Part B, n = 8) and 5 received PBO (Part A, n= 2; Part B, n = 3). Most ppts were men (92%), median age was 35.5 years, and 57% of Part A ppts were white. The study was completed by 22 (88%) ppts. Two non-JPN ppts (1 BMS-986263; 1 PBO) refused pre-tx antihistamines, and 1 JPN ppt (BMS-986263) withdrew consent. No deaths, discontinuations due to adverse events (AEs), or serious AEs were reported (table). PK samples for BMS-986263 plasma concentrations collected on Days 1 and 15 showed that geometric mean peak concentration, overall exposure, and total clearance of HSP47 siRNA were comparable between non-JPN and JPN ppts, with no apparent relationship between body weight and BMS-986263 exposure.

AEs, n (%)	BMS-986263 n = 20	Placebo n = 5
Ppts with		
≥1 AE	17 (85)	3 (60)
≥1 mild AE	16 (80)	3 (60)
Infusion reaction	1 (5)	0
Most common (≥15%)		
Phlebitis	7 (35)	0
Burning sensation	4 (20)	1 (20)
Headache	3 (15)	0

Conclusion: BMS-986263 90 mg IV QW for 3 weeks was generally well tolerated with no clinically meaningful differences in tolerability or PK profiles for healthy non-JPN vs JPN ppts. These results support further study of BMS-986263 in patients with advanced liver fibrosis.

Email: hanying@fmmu.edu.cn

Background and Aims: Stem cell treatment may improve liver function in cirrhosis. However, the long-term effects of stem cell treatment on survival and risk of hepatocellular carcinoma (HCC) has not been established.
Method: We took advantage of a large cohort of decompensated cirrhotic patients treated with autologous peripheral blood stem cell (PBSC) transplantation (n = 282), compared with standard medical treatment (SMT, n = 286) over a 10 year period and analyzed the survival and incidence of HCC Conventional Cox proportional hazard regression was used to determine the hazard ratio (HR) for treatment modality and other prognostic factors. Propensity score (PS) matching was used to corroborate the findings.
Results: The long term survival rate was significantly higher in the PBSC group than SMT (p = 0.007 by Log Rank test). The benefit of PBSC on survival was observed in both CTP class B (p = 0.015) and class C patients (p = 0.027) and was confirmed in PS matched patients (p = 0.001). The overall incidence of HCC was comparable between the PBSC and SMT group (18.1% vs. 19.2% for the entire study population and 21.1% vs. 20.4% for matched patients, p = 0.255). PBSC was an independent prognostic factor for survival for both the entire and PS matched cohorts. Other prognostic factors include age, Child-Turcotte-Pugh (CTP) class and hyponatremia.
Conclusion: In conclusion, our data support the long term benefits and safety of PBSC transplantation.

Email: abderrahim.oussalah@univ-lorraine.fr

Background and Aims: Patients with cirrhosis are at a high risk of hepatocellular carcinoma (HCC). The *SEPT9* gene is a key regulator of cell division and tumor suppressor whose hypermethylation is associated with liver carcinogenesis. The primary aim of this study was to evaluate the diagnostic accuracy of a PCR-based assay for the analysis of *SEPT9* promoter methylation in circulating cell-free DNA (m*SEPT9*) for diagnosing HCC among cirrhotic patients.
Method: We report two phase II biomarker studies that included cirrhotic patients with or without HCC from France (initial study) and Germany (replication study). All patients received clinical and biological evaluations, and liver imaging according to current recommendations. The primary outcome was defined as the presence of HCC according to guidelines from the American Association for the Study of Liver Diseases. The adjudicating physicians were blinded to patient results associated with the m*SEPT9* test.
Results: We included 289 patients with cirrhosis (initial: 186; replication: 103), among whom 98 had HCC (initial: 51; replication: 47). The m*SEPT9* test exhibited high diagnostic accuracy for HCC diagnosis, with an area under the receiver operating characteristic curve (AUROC) of 0.944 (0.900–0.970, p < 0.0001) in the initial study (replication: 0.930 [0.862–0.971, p < 0.0001]; meta-analysis: AUROC = 0.940 [0.910–0.970, p < 0.0001]). In multivariate logistic regression analysis, the number of positive m*SEPT9* triplicates was the only independent variable significantly associated with HCC diagnosis (initial: OR = 6.30, for each m*SEPT9* positive triplicate [2.92–13.61, p < 0.0001]; replication: OR = 6.07 [3.25–11.35, p < 0.0001]; meta-analysis: OR = 6.15 [2.93–9.38, p < 0.0001]). AUROC associated with the discrimination of the logistic regression models in initial and validation studies were 0.969 (0.930–0.989) and 0.942 (0.878–0.978), respectively, with a pooled AUROC of 0.962 ([0.937–0.987, p < 0.0001]).

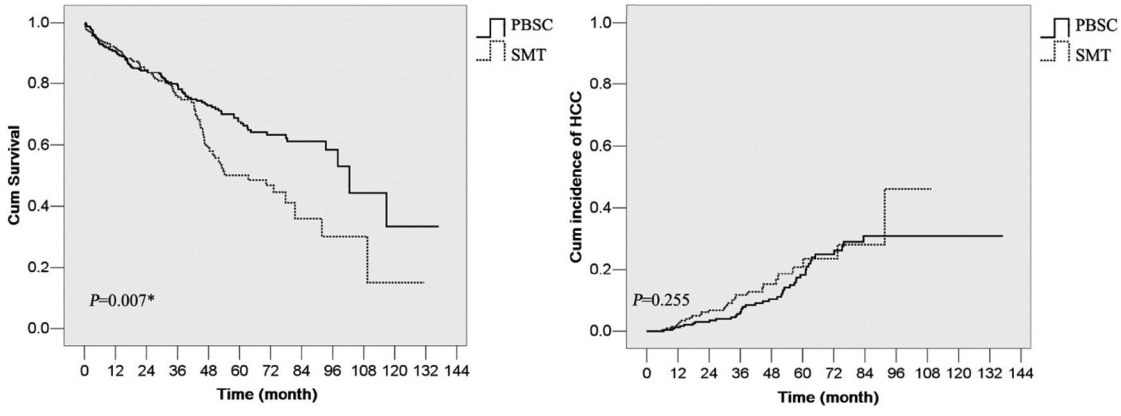

Figure 1: (abstract LBP-016)

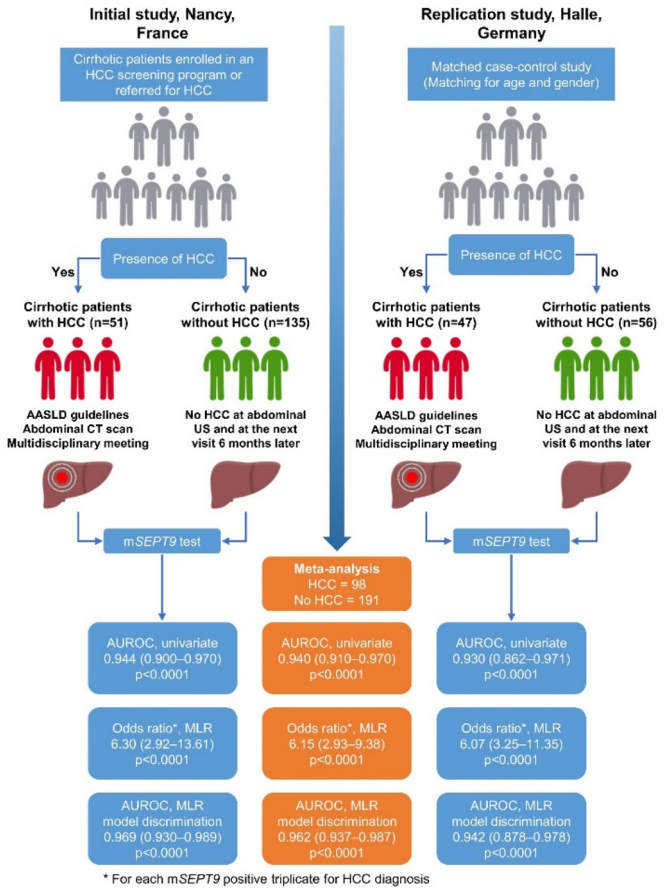

Figure 1: Study design and diagnostic accuracy measures obtained in the initial (Nancy, France) and replication (Halle, Germany) studies, and their meta-analysis for the assessment of the m*SEPT9* test to diagnose hepatocellular carcinoma.

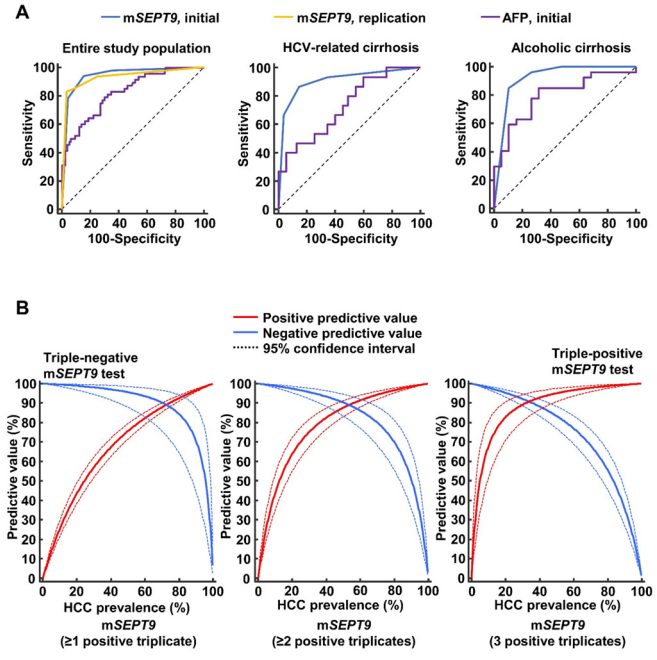

Figure 2: (A) Diagnostic accuracy of the m*SEPT9* test for hepatocellular carcinoma diagnosis in the initial and replication studies. (B) Bayesian estimation of the positive and negative predictive values of the three m*SEPT9* test thresholds for HCC diagnosis.

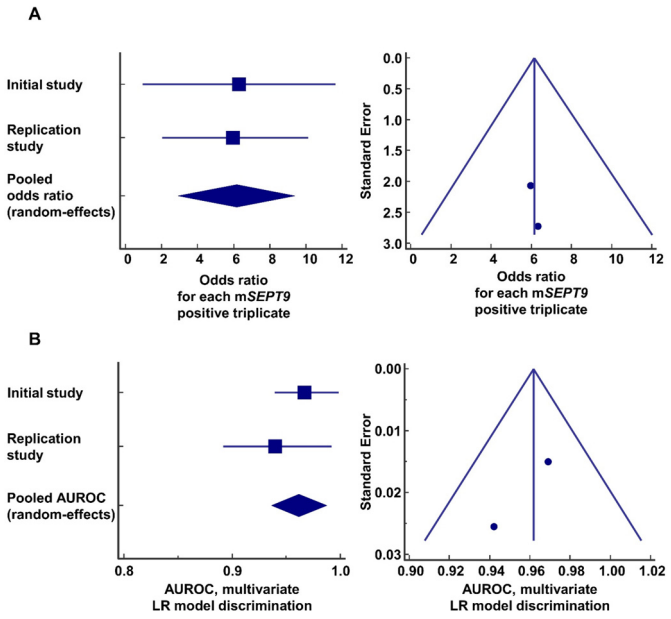

Figure 3: Meta-analysis of the ORs and AUROCs from initial and replication studies for the association between a positive m*SEPT9* triplicate and the diagnosis of hepatocellular carcinoma.

Conclusion: Among patients with cirrhosis, the m*SEPT9* test constitutes a promising circulating epigenetic biomarker for HCC diagnosis at the individual patient level.

LBP-018

A human in vitro three-dimensional bioprinted tissue system can be used to model nutritional damage and protective effects of MSDC-0602K, a novel modulator of the mitochondrial pyruvate carrier

J. Colca[1], D. Carter[2], A. Rothmeier[2], T. Murphy[2], A. Chen[2]. [1]*Cirius Therapeutics, Kalamazoo, United States;* [2]*Organovo, San Diego, United States*
Email: jcolca@ciriustx.com

Background and Aims: A major trigger for the development of NASH is overnutrition. The growing global incidence of NASH mirrors the availability of nutrients. Over-nutrition also results in insulin resistance and type-2 diabetes, which are often co-morbidities associated with NASH and which are known to drive more adverse outcomes. MSDC-0602K, a modulator of the mitochondrial pyruvate carrier (MPC), is in clinical trials as a potential treatment for NASH. Preclinical studies have shown that the mitochondrial pyruvate carrier is increased in expression in animals fed a high fat diet. Moreover, selective knockouts of each of the mitochondrial proteins that make up the carrier have shown that the MPC is a key driver of both NASH pathology and pharmacology of MSDC-0602K. Here we have evaluated whether a bioprinted human organoid system can be used to model the effects of MSDC-0602K in human tissues. Such a system might be used to strengthen the understanding of the pharmacology and provide evidence for non-invasive biomarkers that might predict clinical response.
Method: For each study, ExVive™ Human Liver Tissue (Organovo, San Diego) was fabricated by bioprinting primary human hepatocytes, hepatic stellate cells, Kupffer cells, and endothelial cells into a 3D tissue architecture. Tissues matured in vitro for 3 days and then were challenged with various concentrations of fructose and fatty acids. In some cases, the insults included pulse concentrations of lipopolysaccharide (LPS). MSDC-0602 (Cmax clinical levels) was added with the treatments after the initiation of the nutrient changes. Tissues were stained for α-smooth muscle actin for stellate cell activation

and Masson's Trichrome for content of collagen. Medium was collected for potential markers of tissue damage.
Results: The combination of fructose and fatty acids produced an increase in smooth muscle actin and collagen. Nutrient stimuli alone produced NASH-type liver pathology including steatosis, inflammation, ballooning, and fibrosis. Further damage could also be produced by adding a pulse challenge with LPS. The histological damage could be reduced by adding MSDC-0602 either in parallel with or up to one week after the challenge. Analysis of media demonstrated that the nutrient damage response included the release to the medium of mitochondrial DNA.
Conclusion: These data show that the human in vitro 3D bioprinted liver model can be adapted for demonstrating NASH-type liver pathology and the pharmacology of the novel MPC modulator can be modeled in this system. Three exposures of MSDC-0602K are currently being evaluated in a large Phase 2b clinical trial in subjects with biopsy-confirmed NASH. Samples collected for biomarkers in this trial will be evaluated for changes in parameters that are being identified by this human organoid system including evidence of protection of mitochondria.

13C-methacetin breath test is a highly accurate non-invasive point of care test for detecting CSPH in patients with NASH
J. Bosch[1], C. Bureau[2], N. Chalasani[3], E. Lawitz[4], M. Abdelmalek[5], M. Rinella[6], S. Harrison[7], A. Berzigotti[8], A. Sanyal[9], M. Noureddin[10], D. Rockey[11], T.I. Ber[12], Y. Ilan[13], G. Garcia-Tsao[14]. *[1]Hospital Clinic, Spain; [2]Hopital Purpan, France; [3]Indiana University School of Medicine, United States; [4]The Texas Liver Institute, United States; [5]Duke University, United States; [6]Northwestern, United States; [7]San Antonio Military Medical Center, United States; [8]Inselspital Bern, Switzerland; [9]Virginia Commonwealth University, United States; [10]Cedars Sinai Medical Center, United States; [11]Medical University of South Carolina, United States; [12]Exalenz Bioscience, Israel; [13]Hadassah, Israel; [14]Veteran Affairs Hospital, West Haven, United States*
Email: jbosch@clinic.cat

Background and Aims: Hepatic Venous Pressure Gradient (HVPG), a measurement of portal pressure, correlates with chronic liver disease severity. Clinically significant portal hypertension (CSPH), defined as HVPG ≥ 10 mmHg is associated with an increased risk of decompensation in patients with compensated cirrhosis. Esophageal varices (EV) indicate the presence of CSPH and are also predictive of decompensation. The ^{13}C-Methacetin Breath Test (MBT) using the Exalenz BreathID® System, is a non-invasive, real-time molecular correlation spectroscopy assay that quantitates hepatic cytochrome p450 1A2 metabolism of ingested non-radioactive ^{13}C-labeled methacetin by measuring the abundance of $^{13}CO_2$ in expired breath. The MBT measures a relevant liver metabolic function that has been shown to reflect the degree of overall liver impairment. Here we aimed to determine the accuracy of the MBT in the detection of CSPH.
Method: MBT was performed on 257 patients with NASH- compensated cirrhosis (i.e. no prior variceal hemorrhage, ascites or encephalopathy), pooled from two prospective studies, all of whom had HVPG measured and upper endoscopy performed in a period near the MBT.
Results: Of the 257 NASH-cirrhosis patients, 158 were female (61.5%), median age was 58.7 years, median BMI was 34.6 g/m^2, and median HVPG was 10.6 mmHg (range 1.5–27.5 mmHg). Of the total, 122 (47.5%) had CSPH and/or EV; 61 had CSPH and EV, 47 had CSPH but no EV and 14 had EV without CSPH. MBT values, adjusted by percentage dose recovered (PDR) and noise, allowed to establish a cut-off to accurately rule–in the presence of CSPH/EV. Only 15/257 (5.8%) of patients were wrongly classified as having CSPH. The MBT-based rule-in model had a sensitivity of 76.3%, specificity of 84.5%, PPV was 89.1% (82.6%-93.7%) and NPV was 68.3% with a CI 95% of 0.837–0.925 ($p < 0.0001$) and AUROC of 0.881.

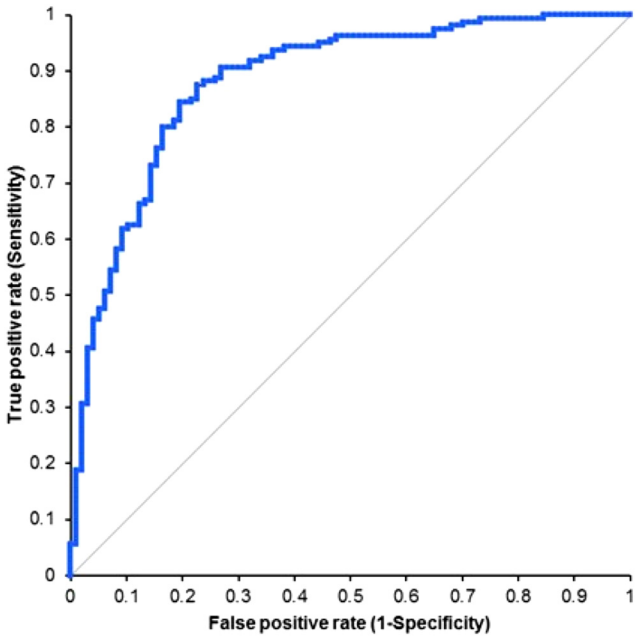

Figure 1: Shows a ROC curve for the detection of CSPH.

Conclusion: The MBT is highly accurate at detecting CSPH in patients with NASH- compensated cirrhosis. MBT provides a valid point-of-care tool for identifying patients at increased risk for hepatic decompensation in a non-invasive and non-operator dependent fashion.

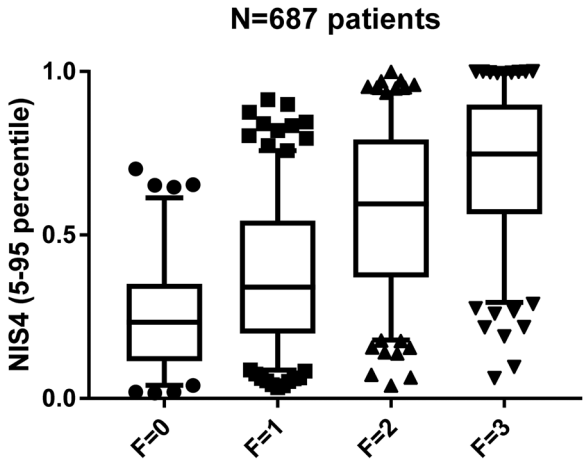
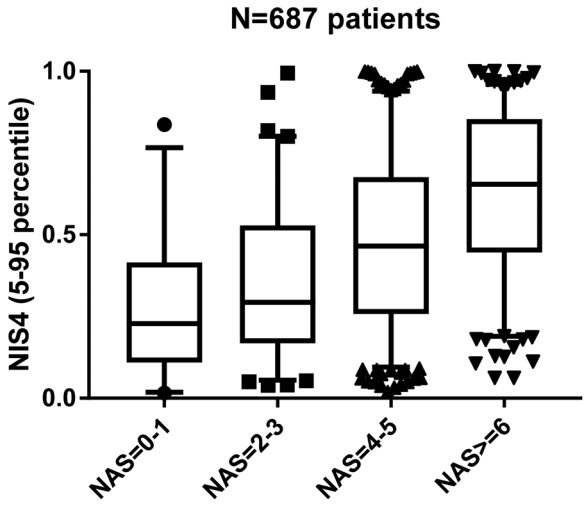
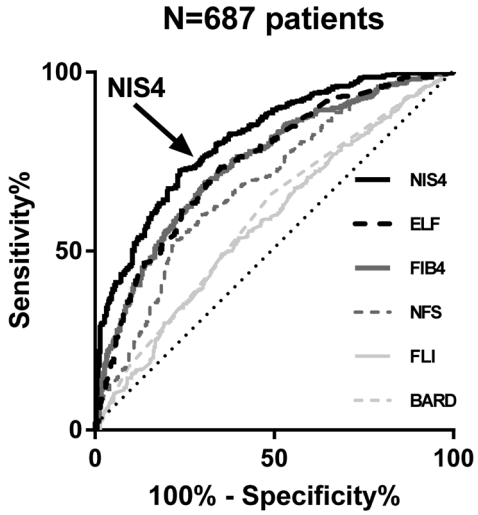
Validation of NIS4 algorithm for detection of NASH at risk of cirrhosis in 467 NAFLD patients prospectively screened for inclusion in the RESOLVE-IT trial
R. Hanf[1], C. Pierre[2], M. Zouher[2], G. Cordonnier[1], J. Brozek[1], E. Praca[1], F.B. Sudrick[1], P. Bedossa[3], Q. Anstee[4], S. Francque[5], S. Harrison[6], V. Ratziu[7], S. Megnien[2], A. Roudot[2], D. Hum[8], A. Sanyal[9]. *[1]GENFIT sa, Loos, France; [2]GENFIT sa, Paris, France; [3]Department of Pathology, Hopital Beaujon, Paris, France; [4]Institute of cellular Medicine, Faculty of Medical Sciences, Newcastle University, Newcastle Upon Tyne, United Kingdom; [5]Antwerp University Hospital, Belgium; [6]Pinnacle Clinical Research, San Antion, United States; [7]Hopital Pitié Salpétrière, Paris, France; [8]GENFIT sa, Loos, France; [9]Virginia Commonwealth University, Richmond, United States*
Email: remy.hanf@genfit.com

Background and Aims: Using the GOLDEN trial as a training cohort, we have previously reported diagnostic performances of a non-invasive score (NIS4) using four circulating biomarkers (miR-34a, Alpha2-macroglobulin/A2M, YKL-40 and HbA1C) for calculation of the risk (0–1) of NASH progression to cirrhosis. The aim of this study was clinical validation of NIS4 in a large independent population of patients prospectively screened for inclusion in RESOLVE-IT trial.
Method: NASH patients At-Risk-of-Cirrhosis (ARC) were defined by NAS ≥ 4 and F ≥ 2 and patients Not-At-Risk-of-Cirrhosis (NARC) by NAS < 4 and/or F < 2. The training cohort (GOLDEN or G) comprised 220 patients (ARC/NARC = 95/125). The validation cohort (RESOLVE or R) comprised 467 patients (ARC/NARC = 255/212). Diagnostic performances (ARC vs NARC) in G and R were compared (AUROC, sensitivity, specificity). Merged cohort (M) with 687 patients was used for optimization of coefficients, assessment of relations with NAS and Fibrosis score (F), and comparison with existing scores.







Results: A higher rate of ARC was obtained in R vs G (55% vs 43%), but distributions of patients according to NAS or fibrosis score in ARC and NARC groups were comparable in the 2 cohorts. In R as in G, circulating levels were higher in ARC vs NARC ($p < 0.0001$) for miR-34a (2.82 ± 0.26 vs 2.54 ± 0.3 log10 copies/µL), A2M (2.61 ± 0.87 vs 2.04 ± 0.78 g/l), YKL40 (119 ± 162 vs 56 ± 41 ng/ml) and HbA1c (6.36 ± 0.97 vs 5.96 ± 0.89%). NIS4 was significantly ($p < 0.0001$) higher in ARC vs NARC patients (0.659 ± 0.015 vs 0.345 ± 0.016). NIS4 showed similar diagnostic performances in G and R cohorts for detection of ARC: AUROC = 0.81 (0.73–0.86) in G and AUROC = 0.81 (0.77–0.85) in R. Comparison of NIS4 in R vs G at optimal cutoff for G, sensitivity (68% vs 74%), specificity (77% vs 82%) total accuracy (72% vs 79%), PPV (78% vs 76%) and NPV (66% vs 81%) were only slightly to moderately affected. In M (n = 687) after optimization, AUROC reached 0.82 (0.78–0.85). At optimal cutoff for M, sensitivity and specificity were 76% and 76% respectively. In M, NIS4 gradually increased with NAS and fibrosis and was more potent than existing scores for detection ARC vs NARC (see figures).

Conclusion: This study validates NIS4 clinical performances for detection of ARC in a large population of patients prospectively screened for suspicion of progressive NASH at 133 hepatology centers in 25 countries. In this context, NIS4 outperforms existing scores, supporting its use in medical practice.

LBP-021

The percentage of patients with HCV infection in need of a liver transplant is rapidly declining while their survival after transplantation is improving: A study based on European liver transplant registry

G. Perricone[1], C. Mazzarelli[1], R. Viganò[1], C. Duvoux[2], P. Cortesi[3], R. Facchetti[3], M. Vangeli[1], V. Karam[4], R. Adam[4], M. Strazzabosco[5], L.S. Belli[6]. *[1]ASST GOM Niguarda, Hepatology and Gastroenterology Unit, Milan, Italy; [2]Henri Mondor Hospital-APHP, Liver Transplant Unit, Creteil, France; [3]University of Milan-Bicocca, Research Centre on Public Health, Monza, Italy; [4]Hôpital Paul Brousse, Centre Hépatobiliaire, Villejuif, France; [5]Yale University, Section of Digestive Diseases, New Haven, United States; [6]ASST GOM Niguarda, Hepatology and Gastroenterology Unit, Milan*

Email: giovanni.perricone@ospedaleniguarda.it

Background and Aims: Direct-acting antiviral (DAA) drugs have dramatically improved the outcome of patients with hepatitis C virus (HCV) infection. Possible changes in liver transplant (LT) indications and of patient survival after LT after the approval of DAAs were analysed.

Method: This is a cohort study based on data from the European Liver Transplant Registry (ELTR). A total of 36.382 adult LTs were performed between January 2007 and June 2017 due to HCV, hepatitis B virus (HBV), alcohol and non-alcoholic steatohepatitis (NASH). The era of LT was divided into interferon (IFN; 2007–2010), protease inhibitor (PI; 2011–2013) and second generation direct-acting antiviral (DAA; 2014- June 2017).

Results: The percentage of LTs due to HCV varied significantly over time ($p < 0.0001$), decreasing from 22.8% in IFN era to 10.6% in the DAA era, while NASH increased. Within the DAA era, the percentage of LTs due to HCV significantly decreased from 21.1% (first semester 2014) to 10.6% (first semester 2017). This decline was more evident in patients with HCV related de-compensation (HCV-DC, -68.8%) than in those with HCC associated to HCV (HCV-HCC, -34.0%). Three-year survival of LT recipients with HCV infection has improved from 65.1% in IFN era to 76.9% and is currently comparable to the survival of patients with HBV infection ($p = 0.3807$).

Conclusion: In Europe the percentage of LTs performed because of HCV infection is rapidly declining. This trend is expected to continue with the increasing access to DAA therapy. For the first time after many years, survival of HCV recipients is improving thanks to the advent of DAAs.

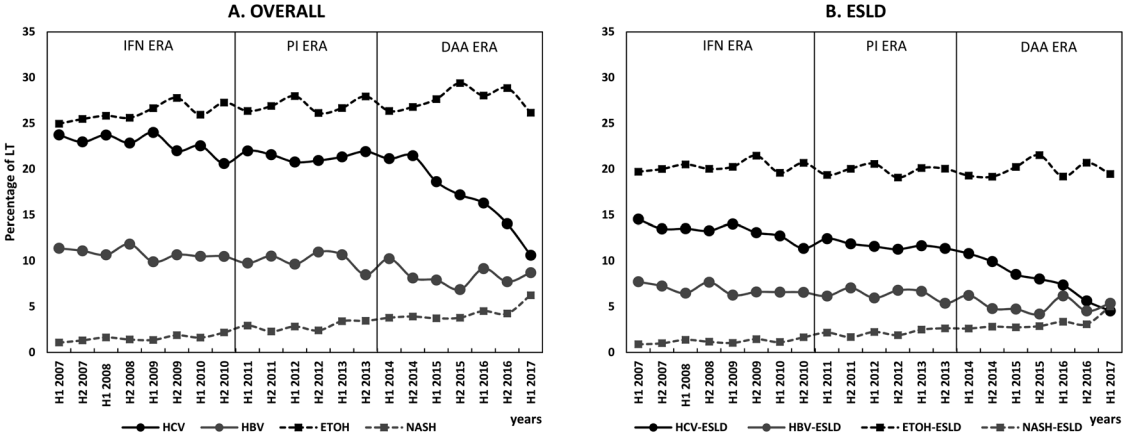


Figure: (abstract: LBP-021): Percentage of LT by etiology of liver disease and indication.X-axis is the semester of LT registration.H1 = first semester; H2 = second semester; LT = Liver transplant; HCV = Hepatitis C; HBV = Hepatitis B; ETOH = alcohol; NASH = Nonalcoholic steatohepatitis.

LBP-022

Mas-related G-protein coupled receptor type D (MrgD) antagonism produces splanchnic vasculature-specific effects, leading to a large reduction in portal pressure in cirrhotic animals

L. Gunarathne[1], A. Zulli[2], T. Qaradakhi[2], R. Smith[2], A.B. Tacey[2], P. Angus[1,3], C. Herath[1]. [1]*The University of Melbourne, Department of Medicine, Austin Health, Heidelberg, Australia;* [2]*The Victoria University, College of Health and Biomedicine, Werribee, Australia;* [3]*Austin Health, Department of Gastroenterology and Hepatology, Heidelberg, Australia*
Email: wgunarathne@student.unimelb.edu.au

Background and Aims: Portal hypertension (PHT) and bleeding from varices is the major cause of morbidity and mortality in patients with cirrhosis. Although the current pharmacological mainstay to reduce portal pressure (PP) by decreasing splanchnic inflow is non-specific beta-blockade, most patients (>60%) do not achieve an optimal response and 15% of patients are unable to tolerate these drugs. In this study, we therefore investigated the role of vasodilatory Mas-related G-protein coupled receptor type D (MrgD) in PHT and whether blockade of this receptor produces a clinically significant reduction in PP in cirrhotic animals.
Method: Liver disease was inducted in male Sprague Dawley rats by bile duct ligation (BDL) surgery or twice weekly carbon tetrachloride (CCl4) injections. Two weeks after BDL and 8 weeks after CCl4 injections, the animals received either the Mas receptor (MasR) antagonist A779 or MrgD antagonist D-Pro^7-Ang-(1-7) (D-Pro) (28 μg/kg/hr) for 2 weeks via subcutaneously implanted osmotic mini pumps. Healthy, sham-operated, BDL and CCl4 animals receiving saline infusion served as controls. After treatment the rats were cannulated to measure PP and mean arterial pressure (MAP). Coloured microsphere technique was used to calculate splanchnic vascular resistance (SVR) and hepatic vascular resistance (HVR). Mesenteric resistance vessels were obtained from a separate group of animals treated in vivo to study vasodilatory response to acetylcholine (Ach).
Results: Both A779 and D-Pro significantly ($p < 0.05$) reduced PP in both models compared to saline-infused controls; however, this reduction was larger in CCl4 rats with MrgD than MasR blockade. Whilst MasR blockade produced an off-target effect by elevating MAP ($p < 0.05$) in BDL rats, the effect of MrgD blockade confined to splanchnic vascular bed. Treatment with both drugs significantly ($p < 0.05$) increased SVR and HVR in both models compared to saline-infused disease controls. However, the increase in SVR with MrgD blockade was greater than that of MasR blockade. Mesenteric resistant vessels isolated from *in-vivo* D-Pro treated rats showed the least relaxation (45%) to Ach whereas those isolated from *in-vivo* A779 treated rats showed a maximum relaxation, similar to that of the disease controls and healthy rats (85%).
Conclusion: We have identified MrgD receptor, a new member of the renin angiotensin system, as a potential therapeutic target to design and develop drugs that can specifically block splanchnic vasodilatation to produce a clinically significant reduction in PP.

LBP-023

HCV treatment with DAA in patients listed for liver transplant does not result in an increased risk of HCC recurrence post-liver transplant

C. Mazzarelli[1,2], F. Invernizzi[3], A. Suddle[2], M.F. Donato[3], L.S. Belli[1], M.D. Cannon[2], S. Marenco[4], D. Angrisani[1], M. Iavarone[3]. [1]*ASST Ospedale Niguarda, Hepatology and Gastroenterology, Milano, Italy;* [2]*King's College Hospital NHS Foundation Trust, Institute of Liver Studies, London, United Kingdom;* [3]*IRCCS Ca' Granda Ospedale Maggiore Policlinico, Hepatology, Milano, Italy;* [4]*Hepatology and Gastroenterology, Policlinico S.Martino, Genova, Italy*
Email: chiaramazzarelli@hotmail.com

Background and Aims: Concerns about an increased risk of Hepatocellular carcinoma (HCC) recurrence in HCV cirrhotic patients treated with direct-acting antiviral treatment (DAA) has been recently raised. Few studies have explored and analyzed the long-term impact of DAA treatment in patients awaiting liver transplant (LT). Aim of this study was to assess the risk of HCC recurrence post-LT in HCC-HCV patients treated with DAA while on the waiting list.
Method: A retrospective analysis of HCV-HCC patients treated with DAA pre-trasplant from June 2014 to June 2017, in 4 different European liver transplant centers (ASST Ospedale Niguarda, Milan Italy, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, King's College Hospital, London, UK and Ospedale S. Martino, Genova, Italy) was performed. Data was analyzed using SPSS version 22.0.
Results: 94 patients with HCC, of whom 95% were within Milan criteria for LT at imaging, received a DAA-based treatment while active on the LT wait list. The demographic and clinical characteristics are reported in the Table. 89/94 (94.7%) achieved SVR-12. After a median follow-up post-LT of 18 months (6–39), 6 (6.4%) patients experienced HCC recurrence: the number of viable nodules and microvascular invasion at explant pathology were the only variables statistically associated with tumor recurrence ($p < 0.001$ and 0.05 respectively) while BMI, diabetes mellitus and DAA treatment regimen were not associated with the risk of HCC recurrence.

Table 1: Demographic and clinical characteristics of the study cohort (n = 94)

	Overall
Median Age, y (IQR)	58 (39–71)
Male Gender, n (%)	75 (79.7)
BMI, (IQR)	25 (17–35)
Diabetes, n (%)	26 (27.7)
Cirrhosis, n (%)	
Child A (CTP score 5–6)	58 (61.7)
Child B (CTP score 7–9)	24 (25.5)
Child C (CTP score ≥10)	12 (12.7)
MELD	10 (6–32)
HCV treatment, n (%)	
SOF + RBV	27 (28.7)
SOF + NS5A inhibitor*±RBV	56 (59.6)
3D or 2 D combo	9 (9.6)
Others	2 (2.1)
Milan transplant criteria in, n (%)	91 (94.9)
Milan transplant critera out/UCSF in, n (%)	3 (5.1)
Largest nodule at listing, cm	2,5 (1–5)
AFP at transplant, ng/ml	8 (2–175)
Bridging treatment, n (%)	75 (79.8)
Time from DAA to transplant, mos	4,5 (0–48)
Time from HCC diagnosis to transplant, mos	13 (0–78)
Number of active nodules at the explant	
No nodules	23 (24.5)
1–3	57 (55.3)
4–6	10 (10.6)
>6	4 (4.3)
Moderate or not-differentiated HCC, n (%)	35 (37.6)
Vascular invasion, n (%)	21 (22.1)
Type of IS post-transplant, n (%)	
CNI (Cya or FK)	65 (69.2)
CNI + MMF or AZA	23 (24.5)
CNI + mTOR	6 (6.3)

Conclusion: In this retrospective study, the achievement of viral eradication of HCC during wait list time) was not associated with an increased risk of HCC recurrence post-LT. In our multi-centric series, we confirmed that tumor burden at explant is the only predictor of recurrence after LT, with no evidence for a negative impact of viral eradication by DAA regimens during the waiting list.

LBP-024

Increased risk of liver cancer in cirrhotic patients associated to direct acting antivirals

Email: mreig1@clinic.ub.es

Background and Aims: Despite the very high efficacy of direct acting antivirals to eradicate hepatitis C virus infection, the impact on hepatocellular carcinoma development remains controversial. We analyzed the clinical and radiological outcomes of cirrhotic patients treated with interferon-free regimens, to estimate the risk of developing de novo hepatocellular carcinoma.
Method: Retrospective, multicenter study of cirrhotic patients treated with direct acting antivirals until October 2015. Clinical and radiologic characteristics before starting interferon-free regimens, at follow-up and at hepatocellular carcinoma development were collected. Hepatocellular carcinoma incidence was expressed as HCC/100 patients-year.
Results: 1,123 patients were included (60.6% males, 83.8% Child-Pugh A). 95.2% achieved sustained virological response. Seventy-two patients developed hepatocellular carcinoma after a median clinical follow-up of 19.6 months, HCC incidence: 3.73 HCC/100 patients-year (95% CI 2.96; 4.70). The median follow-up by imaging has been 12.3 months and hepatocellular carcinoma cases were detected at a median of 10.3 months after starting DAA. Baseline impaired liver function (Child-Pugh B/C vs. A), alcohol intake (vs. no) and clinically significant portal hypertension at baseline (vs. absence) were associated to higher risk. Relative risk was significantly increased in patients with non-characterized nodules at baseline [2.83 (95%CI: 1.55–5.16)] vs those without non-characterized nodules (Figure 1). Hepatocellular carcinoma risk in patients matching the HALT-C or EPIC trials profile (HCC prevention by IFN vs. placebo) was significantly increased as compared to such population (2.53 and 2.26, respectively), irrespective of the presence of non-characterized nodules.

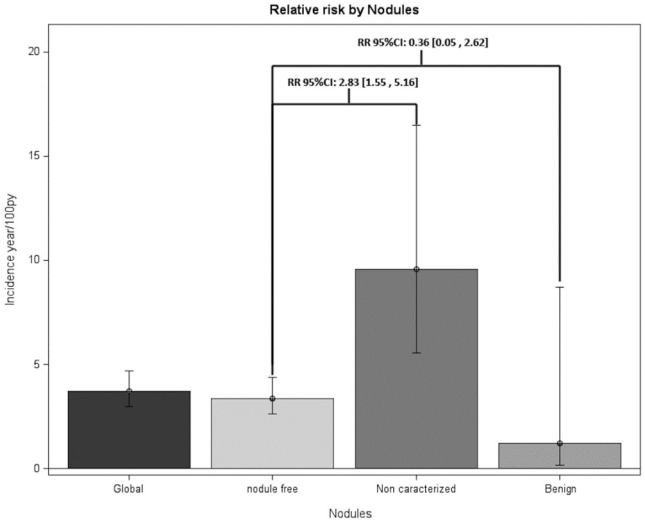

Figure 1: Incidence of HCC per HCC/100PY (95%CI) in the global cohort (black) and divided according to baseline ultrasonographic findings.

Conclusion: These data expose a time association between direct acting antivirals treatment and development of hepatocellular carcinoma. More advanced liver disease and presence of non-characterized nodules prior to therapy are associated to increased risk, but the analysis of the patients matched for EPIC and HALT should prime further research to clarify the mechanisms of cancer emergence associated to antiviral therapy.

LBP-025

Prophylaxis with CMV-hyperimmunglobulin reduces immunologic graft damage in critically ill liver transplant patients

A. Kornberg[1], U. Witt[1], K. Müller[2], M. Achernhammer[1], J. Kornberg[3], K. Thrum[4]. [1]*Technical University Munich, ´Department of Surgery, Munich, Germany;* [2]*FSU Jena;* [3]*LMU Munich, Klinikum Großhadern, Anesthesiology, Munich, Germany;* [4]*Helios Klinikum Berlin, Institute of Pathology*
Email: arnokornberg@aol.com

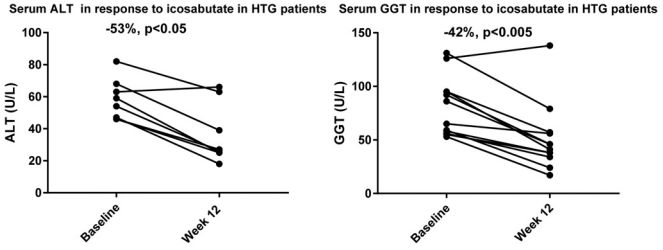
Background and Aims: Liver transplantation (LT) in critically ill cirrhotic patients is associated with high mortality due to sceptical and immunologic complications. Experimental studies suggested that hyperimmunoglobulins (Ig) exert anti-inflammatory and immunosupportive capabilities. We hypothesized, that prophylactic administration of cytomegalovirus (CMV) Ig might be beneficial in immunologically compromised liver transplant patients. This was analysed in a series of critically ill cirrhotic patients.
Method: Forty liver transplant patients with a median MELD score of 38 at LT were included. According to donor/recipient CMV status, 5000IE CMVIg (Cytotect®, Biotest, Germany) was prophylactically administered (D+ and/or R+) daily for a minimum of 7 days post-LT. Immunosuppression consisted of a triple regimen (Tac, MMF, Pred). Serological parameters of pro-inflammatory and -immunologic activation (C-reactive protein [CRP]; procalcitonin [PCT]; interleukin 6 [IL-6]) were continuously assessed. Prognostic factors of outcome were analyzed by uni- and multivariate analysis.
Results: Twenty-four patients received CMVIg (60%) Fatal risk triad (intubation + dialysis + catecholamines) was present in 7 patients of the CMVIg- (29.2%) and 7 of the non-CMVIg-group (43.7%; p = 0.343). Frequency of donor-specific antibodies at LT tended to be higher in the prophylaxis group (29.1% vs. 6.3%; p = 0.07). Rate of biopsy proven allograft rejection was significantly lower in the CMVIg-group (0% versus 37%; $p < 0.001$), despite comparable peak Tac levels (11.1 vs. 12.3 µg/l). None of CMVIg-patients (0%), but 6 and 4 non-CMVIg-recipients (37.5%; 25%; $p < 0.01$) developed CMV and EBV viremia, respectively. Posttransplant peak values of CRP (4.9 vs. 16.3 mg/dl), PCT (10.5 vs. 71.2 ng/ml) and IL-6 (91.7 vs. 333.1 pg/ml) were significantly lower in the prophylaxis group ($p < 0.001$). Sepsis-related mortality rate was significantly higher in the non-CMVIg subset (68% versus 16.6%; p = 0.001). In multivariate analysis, CMVIg prophylaxis was identified as most powerful promoter of survival and freedom of sepsis (HR = 6.0; 95%CI 2.09–17.35; p = 0.001).
Conclusion: Early post-LT prophylaxis with CMVIg reduces pro-inflammatory and immunologic graft damage in critically ill liver transplant patients without any adverse effects. To the best of our knowledge, this has not yet been described. Our data justify validation in a multicenter approach.

LBP-026

A structurally engineered fatty acid, icosabutate, displays optimised absorption, distribution and metabolism properties for targeting hepatic inflammation and normalises elevated liver enzymes in dyslipidemic patients

D.A. Fraser[1], X.-Y. Wang[2], T. Skjaeret[1], J. Kastelein[3], D. Schuppan[2,4]. [1]*NorthSeaTherapeutics, Naarden, Netherlands;* [2]*Institute of Translational Immunology, Mainz, Germany;* [3]*Academic Medical Center, Department of Vascular Medicine, Amsterdam, Netherlands;* [4]*Division of Gastroenterology, Beth Israel Deaconess Medical Center, Boston, United States*
Email: david.fraser@northseatherapeutics.com

Background and Aims: The use of fatty acids as efficacious oral drugs targeting inflammatory/fibrotic liver disease is inherently restricted due to extensive (auto) beta-oxidation as an energy source, systemic distribution and incorporation into complex lipids. Icosabutate is structurally engineered fatty acid (SEFA) designed to overcome these inherent limitations and may offer a novel approach to treat necroinflammation and subsequent fibrosis in NASH. We tested the absorption, distribution, metabolism, excretion (ADME) and hepatic anti-inflammatory properties of icosabutate in rodents in addition to its effects upon elevated liver enzymes in patients with hypertriglyceridemia (HTG).
Method: ADME properties of icosabutate were assessed in rodents *in vivo* and human hepatocytes *in vitro*. Treatment effects [introduced from week 7–12 of a 12-week high-fat (31% of total calories) diet (HFD) in 9-week old C56BL/6J mice] of low-and high-dose icosabutate (56 mg/kg ICOSA-L and 112 mg/kg ICOSA-H orally) vs a GLP-1 agonist (Bydureon, 0.4 mg/kg weekly) on hepatic inflammatory gene expression were also assessed. The liver enzyme response to 12-weeks treatment with icosabutate 600 mg o.d. or placebo was also measured in HTG patients with elevated (>1 to $\leq$ 3 X ULN) alanine aminotransferase (ALT) and gamma-glutamyltransferase (GGT) levels in a phase 2 study (CTN 4016 13201) investigating the hypolipidemic effects of icosabutate.
Results: In contrast to unmodified long-chain fatty acids (LCFA), icosabutate was absorbed via the portal vein (>99%), with rapid hepatic accumulation, minimal systemic distribution and rapid excretion (<95% complete at 48hrs) in rats. In Huh7 cells, minimal incorporation into complex lipids resulted in a high concentration of the bioactive non-esterified fraction (>85%) versus an unmodified LCFA (<10%). HFD fed mice gained significant weight and developed hyperlipidemia and insulin resistance. Icosabutate induced potent decreases in hepatic TNF-alpha ($p < 0.005$ and <0.0001 for ICOSA-L and ICOSA-H, respectively) and IL-1beta transcripts (both $p < 0.01$). Bydureon had no significant effect on either transcript. In patients with HTG and elevated liver enzymes, treatment with icosabutate reduced median ALT by 53% from 56.5 to 26.5 U/l (n = 8, $p < 0.05$) and GGT by 42% from 75.5 to 43.5 U/l (n= 12, $p < 0.005$). Elevated liver enzymes in patients receiving placebo were unchanged [ALT 54.5 and 58 U/l at baseline and week 12 (n = 12, p = 0.98) respectively, GGT 101 U/l at both timepoints (n = 15, p = 0.55)]



Conclusion: Icosabutate overcomes the inherent ADME limitations of unmodified fatty acids as oral drugs targeting inflammatory pathways in the liver. A 600 mg/day dose normalised elevated liver enzymes in dyslipidemic patients. Icosabutate may thus offer a novel and potent therapeutic approach to inflammatory and fibrotic disorders of the liver, including NASH.

LBP-027

Rifaximin reduces the incidence of sepsis and all cause admissions whilst on the liver transplant waiting list

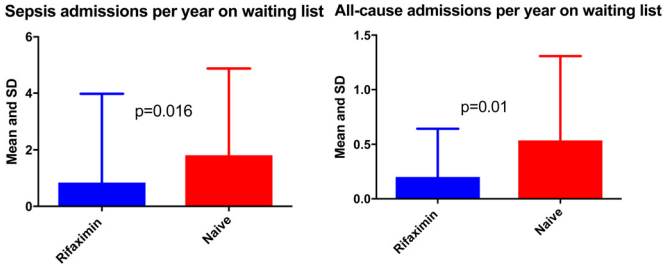
S. Salehi[1], S. Lim[1], M. Heneghan[1], V. Aluvihare[1], N. Heaton[1], V. Patel[1,2], D. Shawcross[1,3]. [1]*Institute of Liver Studies and Transplantation, King's College Hospital, London, United Kingdom;* [2]*Institute of Hepatology, Foundation for Liver Research, London, United Kingdom;* [3]*King's College London, Liver Sciences, 1st Floor James Black Centre, School of Immunology & Microbial Sciences, Faculty of Life Sciences and Medicine, London, United Kingdom*
Email: debbie.shawcross@kcl.ac.uk

Background and Aims: Rifaximin reduces the risk of recurrence of overt hepatic encephalopathy (HE). In UK clinical practice, treatment has been associated with significant reductions in hospitalisation, bed days (including critical care), emergency department attendances

and 30-day readmissions. The aim of this study was to examine the outcomes of patients listed for liver transplantation at King's College Hospital with a diagnosis of HE at listing treated with rifaximin compared to those naïve to the drug. The primary objective was to compare frequency and duration of all cause hospital admissions. Secondary objectives included incidence of sepsis and admissions related to complications of cirrhosis, admissions to critical care and mortality.

Method: The electronic patient records of patients who were listed for liver transplantation over a 2-year period [1st January 2014–31st January 2016] were retrospectively reviewed. Patients were included if they had at least two historic episodes of overt HE or were clinically encephalopathic at the time of transplant assessment.

Results: Of the 622 adult patients listed for transplantation during that time, 101 were listed with a diagnosis of HE. 66 patients were being treated with rifaximin and 35 were naïve. 82% of those on rifaximin and 71% of those on placebo were on concurrent lactulose therapy. The rifaximin-naïve group were marginally younger [49 versus 55; p = 0.006] but otherwise the groups were not statistically different in their characteristics. Alcohol was the most common aetiology and the median maximum grade of HE was 2. The baseline median MELD was 13 (IQR10-16) in the rifaximin-treated cohort and 14 (10–17.5) in the naïve. Patients treated with rifaximin had significantly reduced all-cause admissions on the waiting list (p = 0.01), episodes of sepsis including spontaneous bacterial peritonitis (p = 0.016), admissions related to ascites (p = 0.024), variceal bleeding (p = 0.024) and were less likely to warrant prioritisation (p = 0.04). Mean length of stay was reduced in the rifaximin-treated group (14.4 versus 8.7 days). Overall mortality and admissions related to HE did not differ.



Conclusion: Rifaximin prescribed for the recurrence of overt HE in patients with advanced cirrhosis listed for liver transplantation improved outcomes on the waiting list with a significant reduction in all cause hospital admissions and episodes of sepsis.

Email: jclaria@clinic.ub.es

Background and Aims: Systemic inflammation (SI) is involved in the pathogenesis of acute decompensation (AD) and acute-on-chronic liver failure (ACLF) in cirrhosis. In other diseases (i.e. severe sepsis or pancreatitis) SI activates tryptophan (Trp) degradation via the kynurenine pathway (KP), giving rise to toxic metabolites that cause tissue/organ damage and immunosuppression. We aimed to characterize the poorly known KP in patients with cirrhosis.

Methods: The circulating levels of Trp, metabolic markers of KP activity (kynurenine, kynurenic acid and quinolinic acid), SI (cytokines, sCD163 and sCD206) and oxidative stress (irreversible oxidized albumin) were measured at enrolment in 40 healthy subjects, 39 patients with compensated cirrhosis (no history of AD), 342 patients hospitalized with AD (no ACLF) and 180 patients with ACLF, and repeated in 258 patients during 28-day follow-up.

Results: *First:* among the whole group of patients, KP activity at enrolment was found to be normal in compensated cirrhosis, increased in AD and further increased in ACLF, in parallel with SI and oxidative stress; it was significantly higher in ACLF with kidney failure than in ACLF without kidney failure (Figure 1, values represented in quadratic scale). *Second*: among the patients with AD at enrolment, baseline KP overactivity was significantly higher in patients who did (n = 56) than in those who did not (n = 286) develop ACLF during hospitalization, suggesting that overactivation of the KP precedes ACLF development. *Third*: among "uninfected" patients with ACLF at enrolment (n = 108), those who developed nosocomial infections (n = 61; 56.4%) showed higher baseline KP activity and immune suppression (significantly higher levels of sCD206 and IL-10) than those without nosocomial infections, suggesting a relationship between KP overactivity, immunosuppression and nosocomial infections in ACLF. *Fourth*: among patients with follow-up samples, the 28-day course of AD or ACLF (worsening, improvement, stable) closely correlated with parallel changes in KP activity. *Fifth*: higher baseline KP activity at enrolment independently predicted mortality in patients with AD and in those with ACLF.

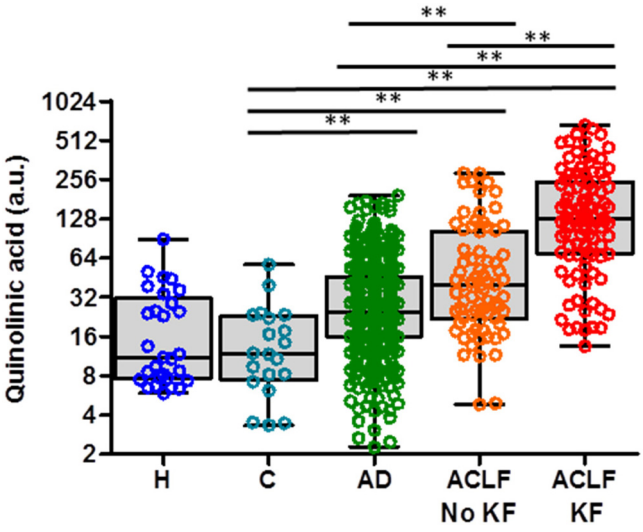

Figure: Serum levels of quinolinic acid at enrolment in healthy subjects (H) and patients with compensated cirrhosis (C), acute decompensation (AD) and acute-on-chronic liver failure (ACLF) without (No KF) and with (KF) kidney failure. Values are in arbitrary units (a.u.) corresponding to peak area/5×10^4 and represented in quadratic scale. **, p < 0.001.

Conclusions: This study shows that features of KP activation appear in patients with AD and culminate in those with ACLF. Moreover, it suggests a role for KP overactivity in the pathogenesis of AD and ACLF, clinical course and mortality.

LBP-029

Viral integration profiles in the plasma cell-free DNA from patients with HBV infection well represent tumor clone compositions during HCC development

D. Zhang[1], W. Chen[1], K. Zhang[2], P. Dong[3], U. Protzer[2], C. Zeng[3]. *[1]Beijing Institute of Genomics, Chinese Academy of Sciences, Key Laboratory of Genomic and Precision Medicine, Beijing, China; [2]Technical University of Munich/ Helmholtz Zentrum München, Institute of Virology, Munich, Germany; [3]Beijing You'an Hospital Affiliated with Capital Medical University, Department of Hepatology, Beijing, China*
Email: dakezhang@gmail.com

Background and Aims: Host genome integration of HBV sequence is considered significant in shaping the immune response to HBV antigens and the development of hepatocellular carcinoma (HCC). Detection and characterization of the integration events in plasma will provide a non-invasive approach for disease monitoring.

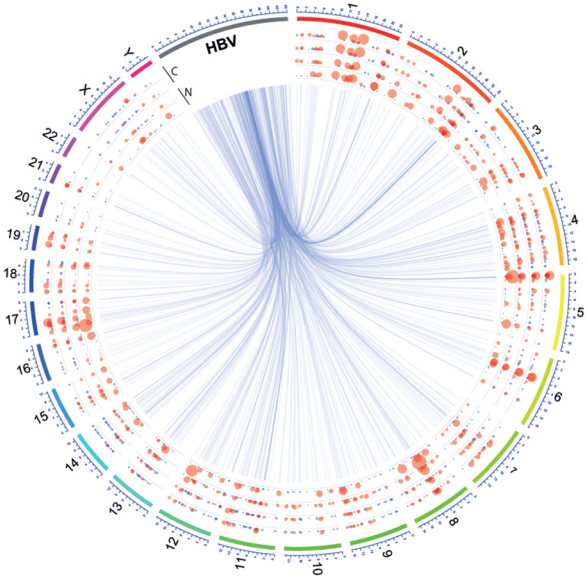

Figure 1: All integrations connecting the viral and human genomes.

Method: We developed a probe-based capture strategy to enrich integrated HBV DNA for deep sequencing analysis of viral and host genome integration sites in paired patient samples including tumour, liver tissue adjacent to tumor and plasma.

Results: In 20 paired tumour and liver tissues, integrations had been detected in all 17 HBV positive HCC but not in any of negative controls. Each patient had 2 tumor samples and 2 normal samples analyzed and in total 424 integrations were identified with an average coverage of 138. Further attempt to monitor viral integrations in plasma showed that, all HCC patients had integrations detected in cfDNA samples. Particularly, over 70% of integrations in tumour tissues were also found in paired plasma cfDNA with significant high abundance. Meanwhile, none of the 70 integration events specific to paired normal tissues was observed in plasma cfDNA. Notably, integration candidates in the plasma from chronic hepatitis B patients showed the same viral breakpoint distribution as those in tumour tissues, with hotspot around nt1600–1900, but without prominent abundance observed. Furthermore, we paired host breakpoints according to their distance in human genome and then grouped into 4 viral patterns according to junction mapping features. Particularly, the majority of Pattern I events (81.2%, 112/138) retained the complete opening reading frame for HBV surface proteins.

Conclusion: The heterogeneity of integration profiles indicated the complexity of integration occurrence in hepatocyte clonal expansion, with possibly distinct biological consequences. Monitoring changes in plasma circulating integration events may serve as a biomarker for liver immune responses, hepatocyte clonal expansion, and tumour development in chronic hepatitis B patients.

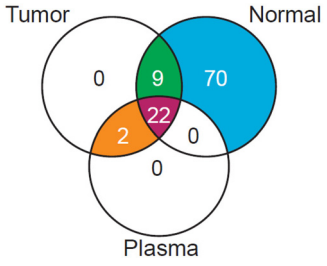

Figure 2: Detection of integration in plasma samples from HCC patients.

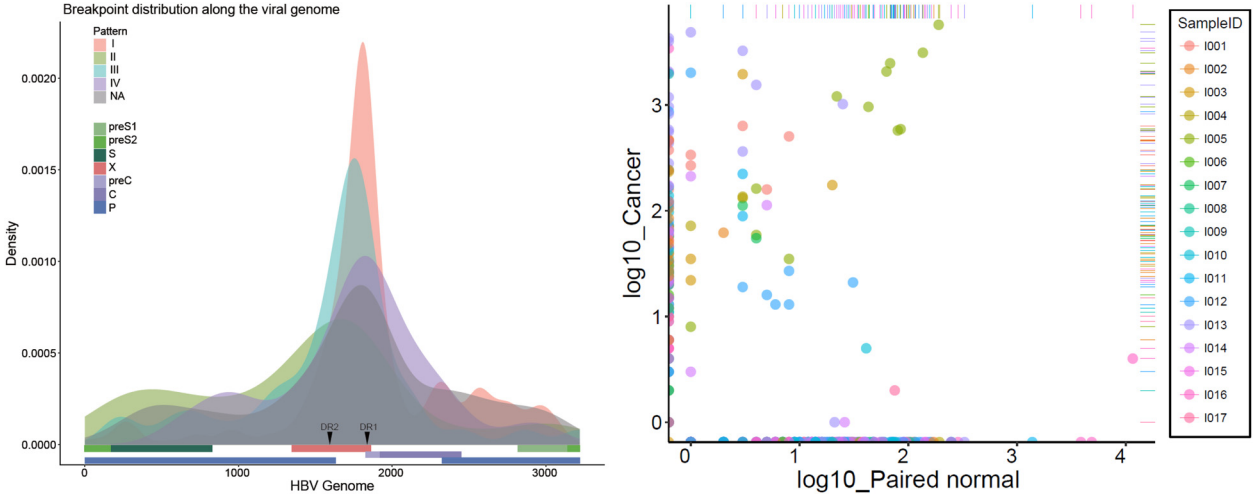

Figure 3: (abstract: LBP-029): Hotspot of breakpoints of integrations in HBV genome (left) and sequencing coverage of integration events in tumor and paired normal tissues (right).

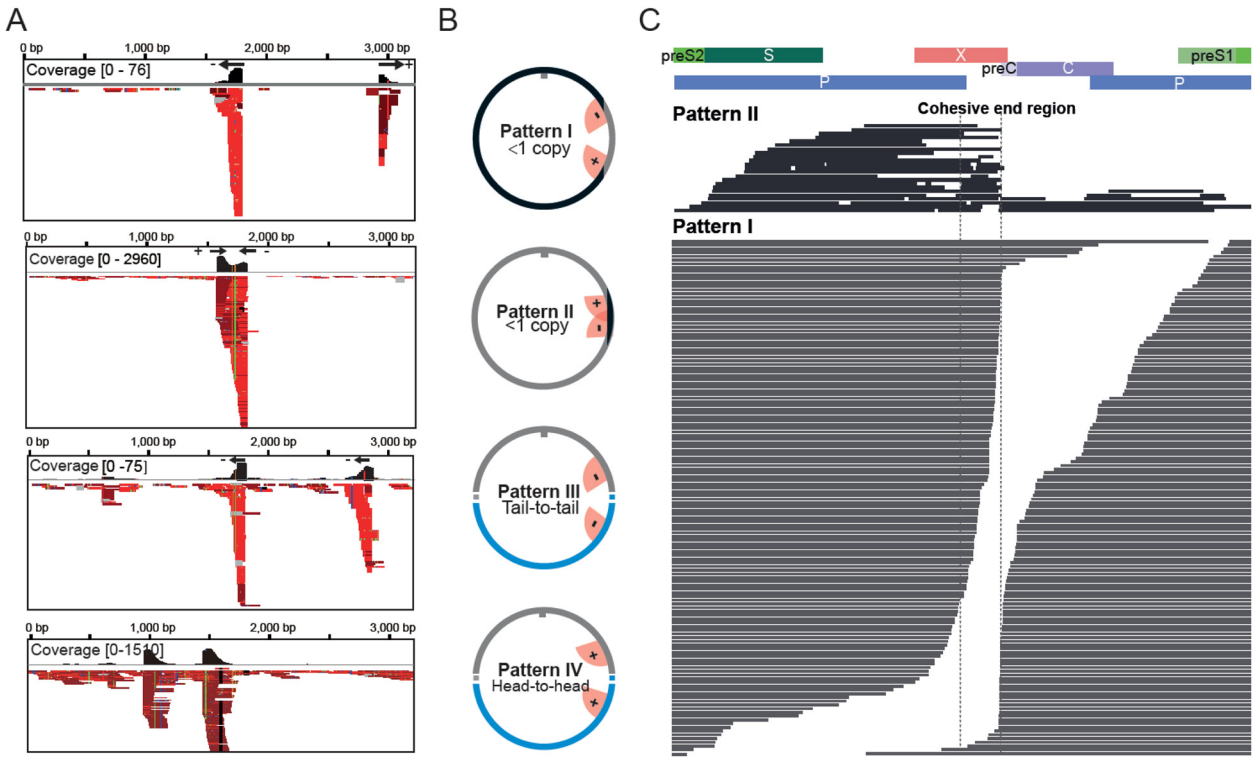

Figure 4: (abstract: LBP-029): Integration patterns according to features of junction mapping in HBV genome.

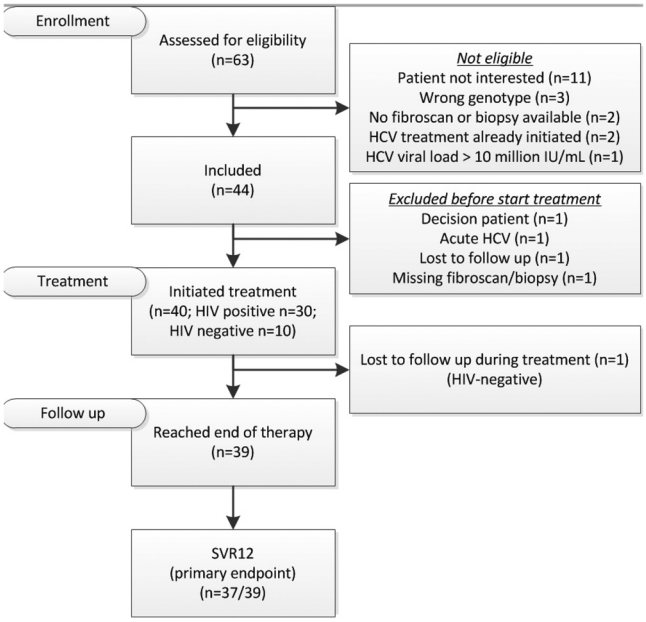
Email: a.boerekamps@erasmusmc.nl

Background and Aims: Direct-acting antiviral therapy (DAA) for hepatitis C infection (HCV) is cost-effective but the budget impact can be substantial. For non-cirrhotic patients shortening treatment to 8 weeks of ledipasvir-sofosbuvir (LDP/SOF) may be a valid option, as demonstrated by high sustained virological response (SVR) rates in genotype 1. We hypothesized that 8 weeks of LDP/SOF is effective for non-cirrhotic genotype 4 patients as well.

Method: Single arm prospective multicentre clinical trial in 10 centres (clinicaltrialregister.eu 2016-000318-31). Non-cirrhotic DAA-naive chronic HCV genotype 4 infected patients received 8 weeks of LDP/SOF 90/400 mg QD. Inclusion criteria were HCV RNA <10 million IU/ml and FibroScan (FS) <12.5 kPa. The primary endpoint was the SVR 12 weeks after treatment (SVR12) in the on-treatment (OT) population. A cure of the baseline HCV virus but a diagnosis of a HCV *re*infection at SVR12 was not considered treatment failure. Secondary endpoints were SVR12 in the HIV-positive patients and in patients with HCV RNA <6 million IU/ml. With 41 evaluable patients, the study would be 90% powered for non-inferiority (d = 10%) compared with a fixed SVR12 of 95%.

Results: From 4/2016 to 6/2017, 63 patients were screened, 44 enrolled and 40 started therapy (Figure 1). Most were male (n = 34) and Caucasian (n = 32). Mean age was 51 years (±10). 21 were men who have sex with men (MSM), 5 were ex-intravenous drug users. Median time since HCV diagnosis was 4 years (IQR 4.5–7.6), HCV load was 1.1E6 IU/ml (IQR 3.4E5-3.6E6) and FS was 5.6 kPa (IQR 4.5–7.6). 30 were HIV-positive, all on cART with mean CD4 807 cells/µl and HIV viral load <50 c/ml in all but 1. One patient got lost to follow-up (HCV at week 4 < 15 IU/ml). In the OT population of 39 patients, 33 were HCV RNA negative and 6 HCV RNA positive at SVR12. In 4 of these 6 a HCV reinfection was confirmed; by genotyping in 2 patients (both genotype 1 at SVR12) and by phylogenetical analysis in 2 patients with genotype 4 at SVR12. Thus, therapy for the baseline virus was successful 37/39 or 95% of patients (exact 95% CI 83–99%). Unfortunately, the lower limit of the 95% CI of the SVR12 was <85%. Therefore, non-inferiority could not be demonstrated. In the 2 failures, HCV RNA at baseline was 9.8E5 and 8.7E6 IU/ml and no resistance-associated mutations (RAMs) were detected at SVR12. SVR12 was 28/30 for HIV-positive and 9/9 in HIV-negative patients (p = 1.0). All reinfections were observed in MSM which, given the short follow-up period, resulted in a very high reinfection incidence of 49.7/100 PYFU for this group.



Conclusion: 8 weeks of LDP/SOF was highly effective and no RAMs were detected in the 2 failures.

LBP-031

A deep-learning approach for pattern recognition allows rapid and reproducible quantification of histological NASH parameters: Integration into the QuPath platform

E. Rexhepaj[1], D. Nathalie[1], N. Benoit[1], H. Alison[1], B. Carole[1], R. Walczak[1], S. Megnien[1], D. Hum[1], B. Staels[2], J. Brozek[1]. *[1]GENFIT sa, Loos, France; [2]Institut Pasteur de Lille, Inserm UMR101, CHU Lille, Université Lille, EGID, Lille, France*
Email: elton.rexhepaj@genfit.com

Background and Aims: The histological evaluation of nonalcoholic steatohepatitis (NASH) activity index by microscopy is time-consuming and limited by inter/intra observer variability. This is mainly due to significant subjectivity in the interpretation of histological patterns. Deep-Learning (DL) technologies have been recently used to quantify the typical histological patterns of NASH in a reproducible manner. The aim of this work was to establish pattern recognition models to reproduce manual annotations of disease activity (ballooning and inflammation) scoring in NASH animal models. Finally, we illustrate how such models can be integrated in a open-source computational pathology software (QuPath) to increase user acceptance and experience.

Method: Animal models mimicking NASH were used to evaluate ballooning and inflammation. An expert evaluated the ballooning and inflammation scores for all animals included in the study. Additionally, DL models were constructed to detect ballooned hepatocytes and inflammatory cells. A first cohort (n = 33) was selected as a training set to calibrate the inflammation and ballooning grade prediction upon two independent cohorts (n = 180) were used to validate predictions.

Results: The DL algorithms showed excellent accuracy at predicting cell histological patterns related to ballooning (Accuracy = 92.1%) and inflammation (Accuracy = 91%). In the independent validation cohorts, excellent agreement was observed between the manually scored and fully-automated annotations of ballooned hepatocytes (K = 0.84, K = 0.81). Moreover, an excellent correlation was also observed between manual and WSI-based automated scoring of inflammation (Rho = 0.907).

Conclusion: Automated scoring of ballooning and inflammation showed a high correlation with manual annotations. In comparison with manual annotations, DL-based scoring systems integrated in QuPath allow an exhaustive and reproducible analysis of all cells in a biopsy. For example, they give special attention to specific regions of cells more difficult to interpret by experts. These prediction scores are now ready to be used for high-throughput activity scoring in pre-clinical studies or as companion diagnostic tools for clinical applications.

LBP-032

Safety and efficacy of ravidasvir plus sofosbuvir 12 weeks in non-cirrhotic and 24 weeks in cirrhotic patients with hepatitis C virus genotypes 1, 2, 3 and 6: The STORM-C-1 phase II/III trial

I. Andrieux-Meyer[1], S.-S. Tan[2], N. Salvadori[3], F. Simon[1], T.R. Cressey[3,4,5], H.R.H.M. Said[6], M.R.A. Hassan[7], H. Omar[8], H.P. Tee[9], W.-K. Chan[10], K.L. Goh[10], S.F.S. Omar[11], A. Background and Aims: In low and middle income countries, affordable direct-acting antivirals for the treatment of hepatitis C virus (HCV) infection are urgently needed. The combination of ravidasvir, a pangenotypic NS5A inhibitor, and sofosbuvir has shown excellent efficacy and safety in HCV patients with genotype 4 (Esmat 2018). The STORM-C-1 trial aims to assess the safety and efficacy of sofosbuvir plus ravidasvir in Malaysia and Thailand where genotypes 1 and 3 are prevalent.

Method: STORM-C-1 is a two-stage, open label, multicentre clinical trial. HCV patients with no cirrhosis (Metavir F0-F3) or compensated cirrhosis (Metavir F4 and Child-Turcotte-Pugh class A) were eligible, regardless of HCV genotype (GT), HIV infection status or prior interferon-based treatment. Once-daily sofosbuvir (400 mg) and ravidasvir (200 mg) was given for 12 weeks if no cirrhosis and 24 weeks if compensated cirrhosis. Patients with no current injection drug use at the eligibility visit who received at least one dose of a study drug were included in the intent to treat (ITT) analysis. The primary endpoint was a sustained virologic response at 12 weeks post-treatment (SVR12). Patients with missing SVR12 outcome were considered as failures. A sample size of 300 patients ensured sufficient precision in the SVR12 rates overall and within key subgroups to proceed safely to the second stage of the study.

Results: From October 2016 to June 2017, 301 patients were enrolled and 300 were included in the ITT analysis: 230 (77%) were males; median age was 47 years; 97 had HCV GT1a, 28 GT1b, 2 GT2, 158 GT3 and 15 GT6; 81 (27%) had compensated cirrhosis; 90 (30%) were co-infected with HIV; and 99 (33%) had prior interferon-based treatment. Overall, 291/300 patients (97.0%) achieved SVR12

(95% confidence interval [CI]: 94.4% to 98.6%). In particular, 51/53 GT3 cirrhotic patients (96.2%) achieved SVR12 (95% CI: 87.0% to 99.5%). In the per protocol analysis, 288/293 patients (98.3%) achieved SVR12 (95% CI: 96.1% to 99.4%). Three patients prematurely discontinued study treatment due to adverse events. There were no deaths and no discontinuations due to serious adverse events related to study treatment.

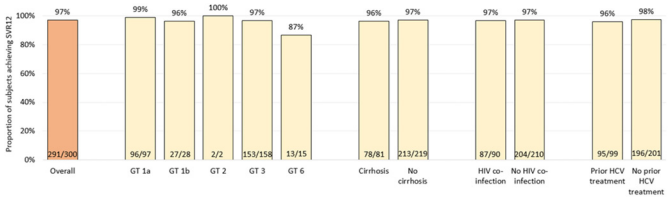

Figure: SVR12 rates overall and within key subgroups in the intent to treat analysis.

Conclusion: With 12 weeks of treatment in non-cirrhotic and 24 weeks in cirrhotic patients, sofosbuvir plus ravidasvir was highly effective, regardless of HCV GT, HIV infection and previous interferon experience. Treatment was well tolerated in all subgroups.

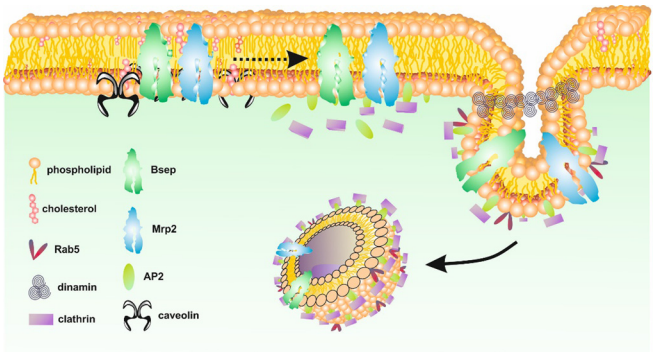
Internalization of canalicular transporters in estradiol 17ß-D-glucuronide-induced cholestasis involves shift from "raft" to "non-raft" membrane domains and clathrin-mediated endocytosis

G.S. Miszczuk, I. Barosso, R. Andermatten, M.C. Larocca, J. Marrone, R.A. Marinelli, A.C. Boaglio, E.S. Pozzi, M.G. Roma, F.A. Crocenzi.
Institute of Experimental Physiology (CONICET-UNR), Faculty of Biochemical & Pharmaceutical Sciences, Rosario, Argentina
Email: fcrocen@unr.edu.ar

Background and Aims: Impaired canalicular secretion due to exacerbated endocytosis of canalicular carriers relevant to bile formation, such as Bsep and Mrp2, is a main, common pathomechanism in both experimental and human cholestasis. Nevertheless, the mechanisms governing this process are unknown. We studied the involvement of clathrin- and caveolin-mediated endocytosis in estradiol 17β-D-glucuronide (E17G)-induced cholestasis, an experimental model which partially mimics pregnancy-induced cholestasis.
Method: E17G was administered to isolated rat hepatocyte couplets (IRHC), sandwich-cultured rat hepatocytes (SCRH), isolated and perfused rat livers (IPRL), and whole rats. Clathrin involvement in E17G-induced endocytosis of Bsep and Mrp2 was evaluated in IRHC by using either the inhibitor of clathrin-mediated endocytosis (CME), monodansylcadaverine (MDC), or a K^+ depletion protocol, whereas caveolin involvement was evaluated by using the specific inhibitors, filipin and genistein. In SCRH, CME was blocked by knockdown of the clathrin adaptor protein AP2 with specific siRNAs. Bsep/Mrp2 localization was studied in IRHC by immunofluorescence staining followed by confocal microscopy, and statistical comparison of the densitometric profiles along a line perpendicular to the canaliculus (Mann-Whitney test). Colocalization of Mrp2 with the components of CME machinery AP2, Rab5, and clathrin was evaluated in SCRH in confocal images, by using the plugins "Image calculator" and "AND". In liver tissue, distribution of Bsep and Mrp2 between caveolin-enriched, "raft" plasma membrane microdomains and clathrin-enriched, "non-raft" ones was assessed by western blot of these carriers in "raft" and "non-raft" fractions obtained by detergent treatment of highly purified plasma membranes.
Results: MDC and K^+ depletion, but not filipin or genistein, prevented E17G-induced endocytosis and the functional failure of Bsep and Mrp2 in IRHC. Immunofluorescence and confocal microscopy studies showed that, in E17G-treated IRHC, there was a significant increase in colocalization of Mrp2 with clathrin, AP2, and Rab5. Knockdown of AP2 in SCRH completely prevented E17G-induced Bsep and Mrp2 endocytosis. MDC significantly counteracted the impairment in bile flow and biliary output of Bsep and Mrp2 substrates, as well as the endocytosis of these carriers induced by E17G in IPRL. Bsep and Mrp2, which were mostly present in "raft" membrane domains in control rats, were largely redistributed to "non-raft" domains in livers from E17G-treated rats, from where they can be readily recruited for CME.



Postulated mechanism of E17G-induced endocytosis of the canalicular transporters Bsep and Mrp2. These transporters, which are normally enriched in raft microdomains, suffer a shift towards non-raft microdomains, where the components of the clathrin-dependent endocytic machinery are recruited, leading to their endocytosis.

Conclusion: Clathrin-mediated endocytosis is involved in the internalization of Bsep and Mrp2 in E17G-induced cholestasis. The shift of these transporters from "raft" to "non-raft" lipid domains could be a prerequisite for the transporters to be endocytosed under cholestatic conditions.

Different micro-environtmental factors induce proliferation, epithelial-mesenchymal transition (EMT) and senescence of primary cultures of human biliary tree stem/progenitor cells (hBTSCs), recapitulating the pathological features typical of human cholangiopathies

D. Costantini[1], G. Carpino[2], V. Cardinale[3], D. Overi[4], L. Nevi[1], S. Di Matteo[1], S. Safarikia[1], F. Melandro[5], P.B. Berloco[5], E. Gaudio[6], D. Alvaro[1]. [1]*Sapienza University of Rome, Department of Medicine and Medical Specialties, Rome, Italy;* [2]*"Foro Italico" University of Rome, Department of Movement, Human and Health Sciences, Division of Health Sciences, Rome, Italy;* [3]*Sapienza University of Rome, Department of Medico-Surgical Sciences and Biotechnologies, Polo Pontino, Latina, Italy;* [4]*Sapienza University of Rome, Department of Anatomical, Histological, Forensic Medicine and Orthopedics Sciences, Rome, Italy;* [5]*Sapienza University of Rome, Department of General Surgery and Organ Transplantation, Rome, Italy;* [6]*Sapienza University of Rome, Department of Anatomical, Histological, Forensic Medicine and Orthopedics Sciences, Division of Human Anatomy, Department of Anatomical, Histological, Forensic Medicine and Orthopedics Sciences, Rome, Italy*
Email: daniele.costantini@uniroma1.it

Background and Aims: The activation of human biliary tree stem/progenitor cells (hBTSCs) located in peribiliary glands (PBGs) have been recently described in different cholangiopathies, including Primary Sclerosing Cholangitis (PSC) and Cholangiocarcinoma (CCA). In these pathologies, hBTSCs also display features of EMT, senescence and dysplasia. The aim of the present study was to investigate putative agents reproducing in primary cultures of hBTSCs the pathologic features observed in PBGs of human cholangiopathies.
Method: hBTSCs were isolated from donor organs (n = 6), cultured in self-renewal control conditions (Kubota's Medium, KM) and exposed (from 24 hours to 10 days) to increasing concentrations of

lipopolysaccharides (LPS), oxysterols, hydrophobic biliary salts, or high glucose. Viability (MTS assay), Population Doubling (PD), the expression (RT-qPCR) of pluripotency, transit-amplifying compartment, EMT, pNF-kB and HDAC6 genes and senescence associated secreted phenotype (SASP) by IF and ELISA were examined.
Results: Glycochenodeoxycholate (0.5 mM), LPS (200 ng/ml), oxysterols [(+)-4-Cholesten-3-one (0.14 mM), Cholesta-4,6-dien-3-one (0.14 mM), 5α-Cholestan-3-one (0.14 mM) or high concentrations of Glucose (28 mM) did not affected the viability of hBTSCs. LPS, Cholesta-4, 6-dien-3-one and Glucose induced a significant increase of cell proliferation after 10 days of exposure ($p < 0.01$). The MTS assay confirmed a high proliferation rate after chronic exposure (10 days) to LPS, oxysterols, or high glucose ($p < 0.01$). Cholesta-4, 6-dien-3-one determined a significant increase of markers of transit-amplifying compartment and EMT ($p < 0.05$) while, bacterial LPS and high Glucose determined an increased expression of PCNA and EMT genes. Senescent cells increased after 10 days of exposure to each of the investigated factor compared to controls ($p < 0.01$). LPS, Cholesta-4, 6-dien-3-one and high Glucose induced enhanced IL-6 secretion compared to controls ($p < 0.01$). In addition, conditioned cell cultures expressed high levels of pNF-kB and HDAC6 ($p < 0.01$), and traces of LC3 protein suggesting inflammation-induced autophagy.
Conclusion: We identified different micro-environmental factors capable to induce in hBTSCs proliferation, enhanced expression of pluripotency and transit-amplifying genes, EMT and senescence, recapitulating the pathologic features described in PBGs of human cholangiopathies. IL-6, the overexpression of pNF-kB and HDAC6 and activation of autophagy are involved in these pathologic changes.

THU-003
Transcriptional repressors Zeb1 and Zeb2 regulate collagen production in drug-induced hepatic stellate cell activation in mice

I. Mannaerts, L. Stradiot, N. Eysackers, L. van Grunsven.
Vrije Universiteit Brussel, BMWE-LIVR, Brussel, Belgium
Email: inge.mannaerts@vub.ac.be

Background and Aims: Upon liver injury, hepatic stellate cells become activated myofibroblast-like cells. They lose their vitamin A storing capacity and become collagen producing cells with migratory capacities. This transdifferentiation has been compared to an epithelial to mesenchymal differentiation. This is a strictly orchestrated process, in which a role for E-box repressors, including Snail family members and Zeb proteins, and a role for the miR-200 family has been established. Both the transcriptional repressors and microRNAs that regulate the epithelial to mesenchymal differentiation are transforming growth factor-β sensitive regulators. In this study we investigated the role of Zeb proteins (δef1 and Sip1) and miR-200 family members during stellate cell activation, migration and fibrosis.
Method: BalbC mice were used to isolate primary hepatic stellate cells, cells were activated by culture in fetal bovine serum containing medium. Repeated carbontetrachloride administration to mice induced liver fibrosis and liver cell types were isolated from these mice using the recently published UFACS3 flow cytometry protocol. The role of ZEB proteins was investigated by siRNA mediated silencing in vitro and in vivo. In vivo targeting of the siRNA to stellate cells was obtained by coupling vitamin A to liposome carriers. Effects of ZEB knock down were evaluated by real time polymerase chain reaction, immunohistochemistry, western blot and migration and proliferation assays.
Results: An siRNA mediated silencing of Zfhx1 repressors induced a strong up-regulation of E-cadherin and resulted in a mild decrease of stellate cell activation marker Acta2. In addition, ectopic expression of miR-200c also induced E-cadherin mRNA and protein expression and reduced stellate cell migration in a transwell migration assay. Finally, we have used vitamin-A coupled liposomes to knock down Zeb1 and Zeb 2 in vivo in a chronic fibrosis model. Selective delivery was confirmed by lowered RNA levels of Zeb1 and Zeb2 in stellate cells, but not in other non-parenchymal cells. While the silencing Zeb1 and Zeb2 was modest, a significant reduction in collagen1a1 and collagen3a1 was observed.
Conclusion: E-box repressors Zeb1 and Zeb2 are important players in the regulation of stellate cell activation in vitro and in vivo.

THU-004
Dechipering the role of Axin2/Lgr5+ pericentral hepatocytes

L. Planas-Paz, T. Sun, M. Pikiolek, V. Orsini, Y. Yang, F. Cong, J. Tchorz.
Novartis, Basel, Switzerland
Email: lara.planas_paz@novartis.com

Background and Aims: The liver has an intrinsically high capacity to regenerate both during homeostasis and in response to various distinct etiological insults. Hepatocytes throughout the liver lobule can re-enter the cell cycle to proliferate and restore liver mass. Axin2+ pericentral hepatocytes have been proposed as a novel liver stem cell population refuelling the entire hepatocyte pool during homeostasis. However, existing Axin2 lineage tracing mice suffer from a heterozygous deletion of Axin2, a known tumour suppressor. We identified Lgr5 as a marker of Axin2+ pericentral hepatocytes and, using Lgr5 lineage tracing experiments, showed that pericentral hepatocytes are not liver stem cells.

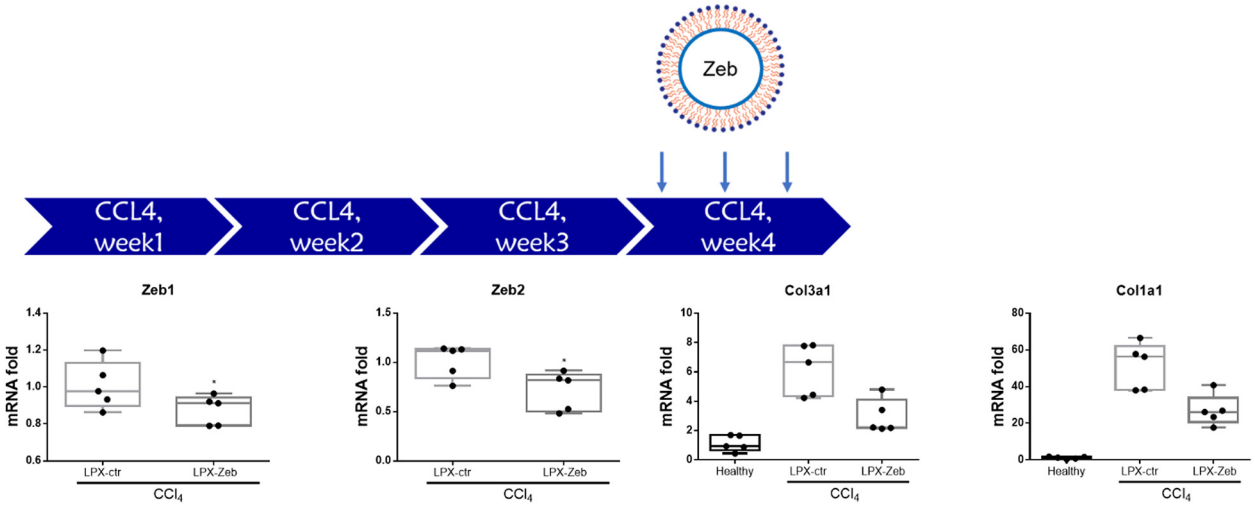

Figure: (abstract: THU_003)

Method: We generated a novel BAC-transgenic Axin2 lineage tracing model that does not suffer from heterozygous deletion of Axin2. We performed Axin2 lineage tracing in stomach, intestine and liver in homeostasis, as well as during regeneration from a diet-induced injury in the liver.
Results: Our Axin2 lineage tracing model confirmed expansion of Wnt-dependent tissue stem cells in the gut and stomach identified with previous Axin2 or Lgr5 lineage tracing. In contrast, we did not observe a significant expansion of Axin2+ hepatocytes during liver homeostasis over 10 months. Moreover, EdU labelling experiments revealed no zonal dominance during this process. While Axin2+ hepatocytes significantly expanded during DDC-induced liver regeneration, they never reached far into the parenchyma or periportal space.
Conclusion: Together, our data argue against the hypothesis that pericentral hepatocytes represent a liver stem cell niche.

THU-005
A combined laser microdissection and proteomic analysis method for identification of liver tumors signatures

E. Henriet[1], A.A. Hammoud[2], J.-W. Dupuy[3], B. Dartigues[3], Z. Ezzoukhry[2], N. Dugot-Senant[4], T. Leste-Lasserre[5], M. Nikolski[3], B.L. Bail[2,6], J.-F. Blanc[2,6], C. Balabaud[2], P. Bioulac-Sage[2,6], A.-A. Raymond[2,4,7], F. Saltel[2,7]. *[1]BaRITon INSERM 1053, Bordeaux Cedex, France; [2]BaRITOn INSERM 1053; [3]CGFB Bordeaux; [4]TBM Core US 005; [5]Institut Magendie; [6]CHU Bordeaux; [7]Equal work*
Email: anne-aurelie.raymond@inserm.fr

Background and Aims: Since several years, research efforts concentrated on the identification of genomic abnormalities in tumors offering the prospect of personalized treatments and thus a better management of patients. However, proteins expression is the downstream result of these combined genomic anomalies in tumors and is essential for a better understanding of the mechanisms of cancer initiation, tumoral progression, metastatic scattering and to identify new biomarkers and pharmacological targets.
Method: Mass spectrometry is the method of choice to identify, characterize and quantify the proteins in a complex sample. The Oncoprot platform (http://www.tbmcore.u-bordeaux.fr/oncoprot/) developed a method combining laser microdissection and mass spectrometry analysis to compare the proteomic profiles of tumors. This procedure has been optimized for the study of FFPE tissue sections even on small material obtained from biopsy.
Results: We made the proof of concept on Hepatocellular adenomas (HCA), rare benign tumors that constitute a heterogeneous entity, divided into several groups based on patho-molecular features (1) HCA with inactivating mutations of HNF1A, (2) Inflammatory HCA with diverse mutations leading to the activation of STAT3, (3) HCA with activating beta-catenin. In the case of unclassified HCA (UHCA), which were identified by default, a high risk of bleeding remained a clinical issue. The objective of this study was to explore UHCA proteome in the purpose of identifying specific biomarkers. We compared tumoral and non-tumoral proteins expression levels in HCA, H-HCA, IHCA, b-HCA, and UHCA. Using the Oncoprot's process, we searched for proteins specifically deregulated in UHCA. First, we demonstrated that proteomic profiles allow us to discriminate between known HCA subtypes by the identification of classical biomarkers of each HCA subgroup. We revealed specific upregulation of the synthesis of the arginine pathway associated with an overexpression of argininosuccinate synthase (ASS1) and arginosuccinate lyase (ASL) in UHCA. Moreover, arginine is the substrate for nitric oxide synthesis, a factor involved in vascular permeability. ASS1 immunohistochemistry identified all the UHCA, of which 64.7% presented clinical bleeding manifestations.
Conclusion: In conclusion, we demonstrated the power of mass spectrometry coupled with laser microdissection to identify tumoral signatures and robust biomarkers. We can now answer to other clinical needs to propose new biomarkers for diagnosis, prognosis and to predict the response to treatments.

THU-006
Identificiation of compounds targeting CD133-positive hepatogellular carcinoma while minimizing the damage on hepatocytes by phenotypic high-content screening

H.R. Seo[1], Y. Song[1], I. Choi[2], S.-H. Kim[1]. *[1]Institut Pasteur Korea, Cancer Biology Research Laboratory, Gyeonggi-do, Republic of South Korea; [2]Institut Pasteur Korea, Bioinformatics, Gyeonggi-do, Republic of South Korea*
Email: shr1261@ip-korea.org

Background and Aims: Cancer stem cells (CSCs) are considered the "Achilles heel" due to their strong resistance to chemotherapy and radiotherapy. Thus, the recent advancements in the use of liver cancer stem cells (LCSC) to develop efficient and organized means to an antitumor agent is quickly gaining recognition as a novel goal. In our previous study, we characterized CSCs in primary hepatocellular carcinoma (HCC) and identified CD133 as a CSC cell-surface marker. In this study, we proposed to use non-target based high throughput screening approach to specifically target AFP$^+$/CD133$^+$ HCC present in mixed populations of HCC cells with hepatocytes.
Method: To find hit compound, which specifically targets AFP+/CD133+ HCC without damaging hepatocytes, mixed cell culture system were developed. Using this system, high throughput screening was performed. The first hit compounds were validated through dose response curve analysis with fluorescence image-based phenomic screening. Secondary hits from dose response curve study were validated through drug sensitivities in liver cancer stem cell spheroids, dose response curve study in sorted cells with CD133 (CD133$^-$ and CD133$^+$ HCC cells), and analyzing the CD133 protein levels. Final hit was validated with xenograft model.

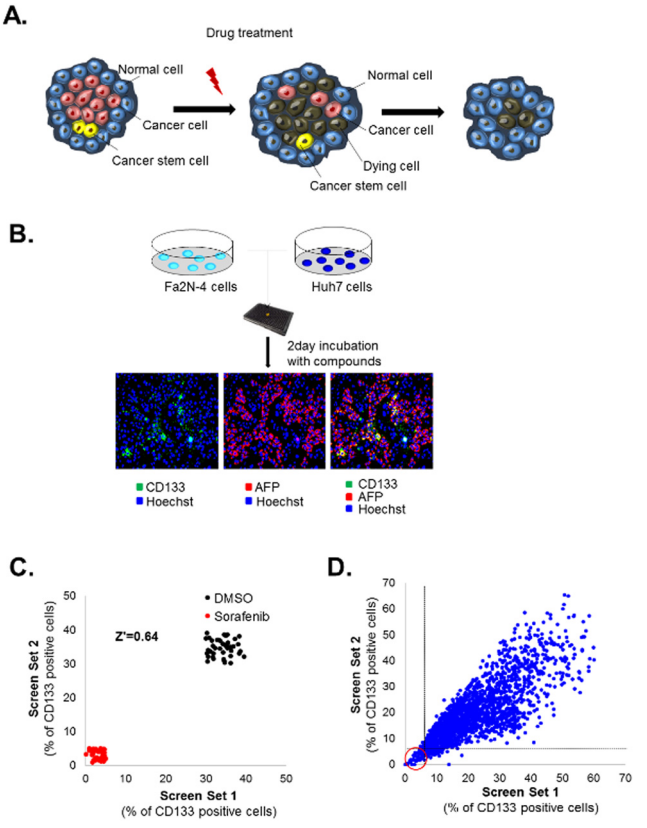

Figure 1: Hepatocellular carcinoma (HCC)-mixed culture system for liver cancer stem cells (LCSCs)-targeting drug screening.

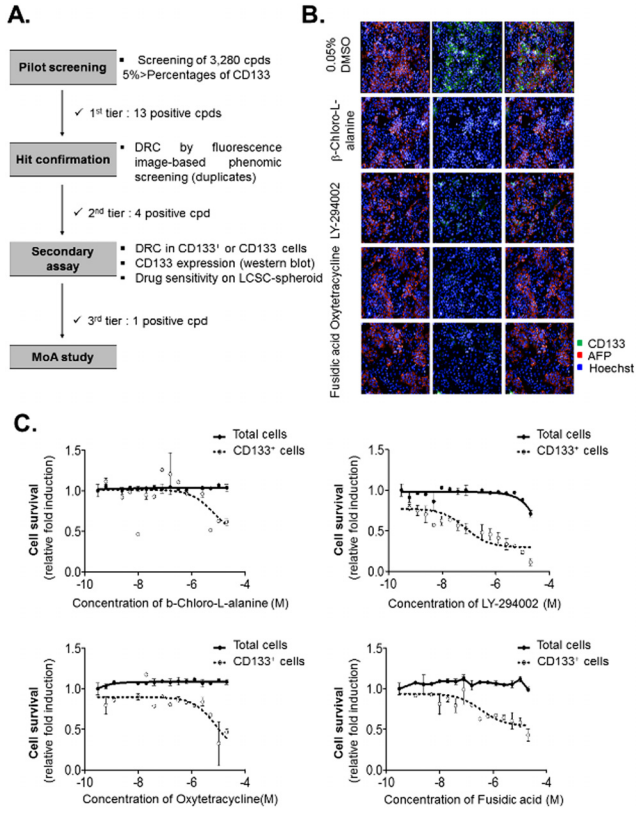

Figure 2: Four hit compounds from HCC-mixed LCSC-targeting screening.

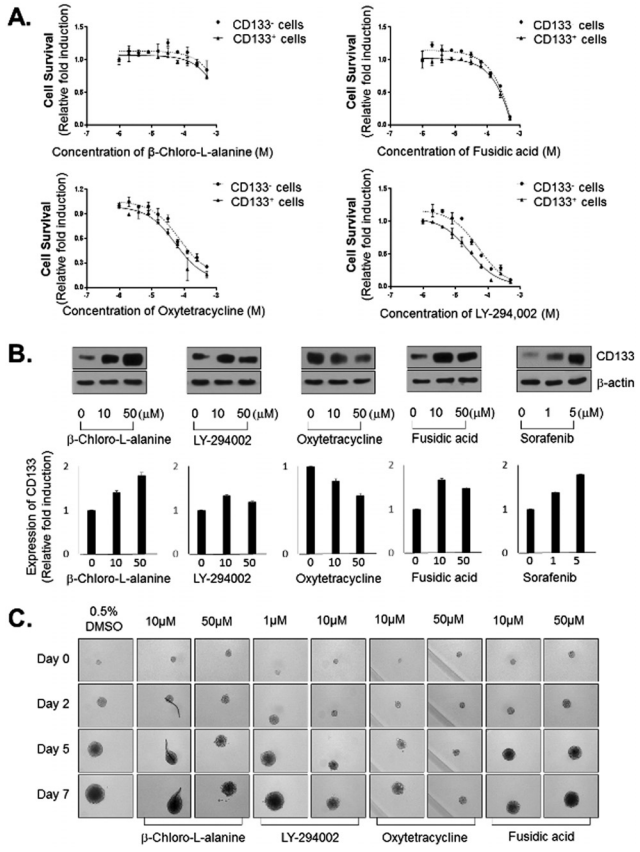

Figure 3: Suppressing LCSC properties of 4 hit compounds.

Results: To determine whether oxytetracycline targets LCSC, we examined whether oxytetracycline treatment could change the CD133 expression, spheroid forming ability as well as the levels of stem cell-related markers. Treatment of spheroid-forming LCSC with oxytetracycline effectively decreased the spheroid formation as well as the $CD133^+$ cell population. Oxytetracycline treatment suppressed expression of CD133 without changing of expression of other stem cell-related markers. Importantly, these series of phenomena by treatment of oxytetracycline occurs because of alteration of CD133 protein stability by oxytetracycline. Alterations in the malignant properties of $AFP^+/CD133^+$ HCC by oxytetracycline were also investigated by xenograft assay in nude mice. Treatment of oxytetracycline significantly attenuated tumor formation and $CD133^+$ cell population in xenograft mice.

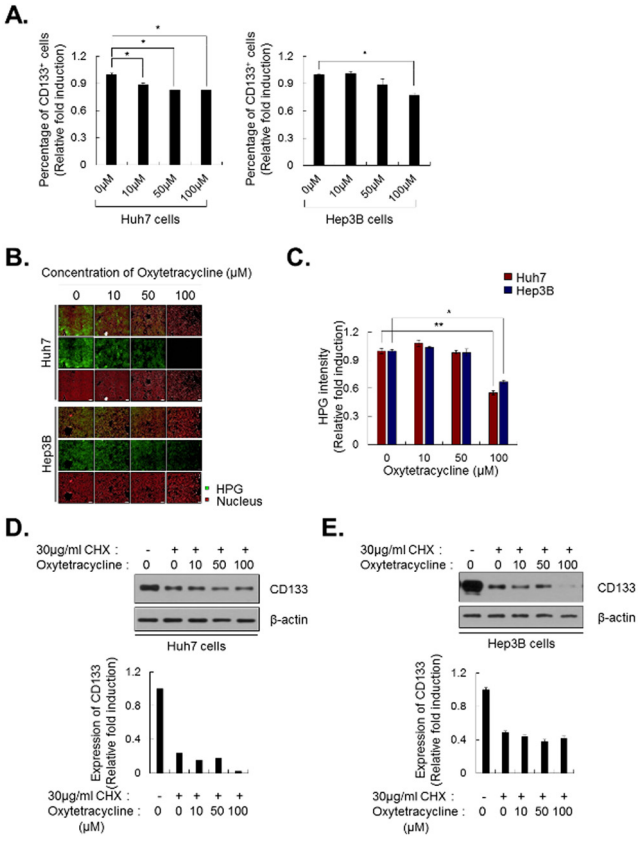

Figure 4: Decrease of CD133 levels by oxytetracycline.

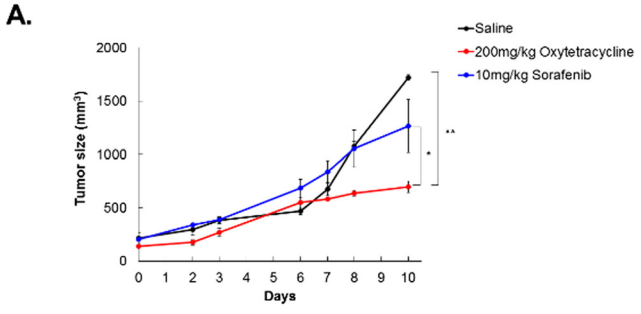

Figure 5: Decrease of tumor size and $CD133^+$ population in mouse model.

Conclusion: These results indicate that the oxytetracycline suppresses stemness and malignancies in HCC cells through destabilization of CD133 in LCSC population, providing novel therapeutic strategies targeting specifically cancer stem-like cells.

Table 1: (abstract: THU-006): List of primary hit compounds

	Name of compounds	Mechanism of action
1	5'-Amino-5'-deoxyadenosine p-toluenesulfonate salt	Adenosine analog.
2	trans-Azetidine-2,4-dicarboxylic acid	mGluR1 and mGluR5 metabotropic glutamate receptor agonist
3	Chlormethiazole hydrochloride	GABA(A) agonist; glycine receptor modulator
4	beta-Chloro-L-alanine hydrochloride	Alanine aminotransferase inhibitor
5	1,10-Diaminodecane	Inverse agonist at the polyamine recognition site of the NMDA glutamate receptors
6	LY-294,002 hydrochloride	Specific phosphatidylinositol 3-kinase (PI3K) inhibitor.
7	Pentamidine isethionate	NMDA glutamate receptor antagonist
8	PAPP	Selective 5-HT1A serotonin receptor agonist
9	Mebendazole	Glucose transport inhibitor
10	Oxytetracycline	Ribosomal protein synthesis inhibitor
11	Fusidic acid sodium salt	Protein synthesis inhibitor GTPase coupled
12	(S)-(-)-Atenolol	Adrenergic receptor antagonist
13	Tetramisole hydrochloride	Alkaline phosphatase inhibitor

THU-007

Negative allosteric modulators of metabotropic glutamate receptor subtype 5 protect against hepatic ischemia/reperfusion injury

C. Berardo[1], V. Siciliano[1], L.G. Di Pasqua[1], P. Richelmi[1], F. Nicoletti[2,3], M. Vairetti[1], A. Ferrigno[1]. *[1]University of Pavia, Internal Medicine and Therapeutics, Pavia, Italy; [2]Neuromed, Pozzilli, Italy; [3]University of Rome, La Sapienza, Physiology and Pharmacology, Roma, Italy*
Email: clarissa.berardo01@universitadipavia.it

Background and Aims: The negative allosteric modulator (NAM) of metabotropic glutamate receptor subtype 5 (mGluR5) 2-methyl-6-(phenylethynyl) pyridine (MPEP) improves viability of anoxic hepatocytes. In microglia and astrocytes, ATP production and release were reduced by MPEP. Since ATP depletion is involved in ischemic damage, aims of this study were: to understand the mechanism of MPEP-mediated ATP depletion, to compare different NAMs with regard to protection against ischemia and to assess liver functionality in an *ex vivo* model of ischemia/reperfusion (I/R) injury.
Method: Isolated hepatocytes from male Wistar rats were exposed to 90 min anoxia at 37°C, with NAMs: MPEP and 3-((2-methyl-4-thiazolyl)ethynyl)pyridine (MTEP) at 3–30 µM, Fenobam (Fen) at 1-10-50-100 µM. Hepatocytes viability was evaluated by trypan blue exclusion and LDH release. Isolated mitochondria from rat livers were treated with MPEP, MTEP, Fen at 0.3-3-30 µM. Mitochondrial respiratory control ratio, membrane potential, ROS production and F_1F_O-ATPase activity were gauged, using a respiration chamber, the rhodamine spectrofluorometric method, the H_2DCFDA assay and an enzymatic spectrophotometric kit, respectively. ATP was assessed by the luciferin/luciferase method in isolated hepatocytes, mitochondria as well as in an acellular buffer containing 10 µM ATP and MPEP, MTEP, Fen at 0.3-3-30 µM. Wildtype and mGluR5 knockout livers from Balb c mice were isolated, subjected to I/R and treated with MPEP 0.3 µM; LDH, AST and TNF-alpha release were evaluated.
Results: MPEP 30 µM, MTEP 3 µM and Fen 50 µM improved significantly the viability of anoxic hepatocytes respect to anoxic controls. ATP content was monitored before and after N_2 insufflation. MPEP significantly lowered ATP content respect to oxygenated controls; MPEP-treated cells showed a slower decline in ATP after N_2 insufflation. The same trend was observed for MTEP but not for Fen. In mitochondria, MPEP induced a dose-dependent ATP depletion, without affecting mitochondrial functionality. In an acellular solution only MPEP and MTEP reduced ATP content. The addition of MPEP during I/R significantly reduced LDH, AST and TNF-alpha release respect to ischemic controls.
Conclusion: Isolated hepatocytes were protected by MPEP, MTEP and Fen against ischemic injury. Although an MPEP-dependent ATP depletion occurred in isolated hepatocytes, mitochondria and acellular solutions, mitochondrial functionality was not affected and, in an *ex vivo* model, MPEP was able to reduce the hepatic I/R injury.

THU-008

Rapid generation of somatic liver knockouts using multiplex CRISPR/Cas9 editing

K.-D. Bissig, D. Moore, J.C. Marini, S. Elsea, B. Bissig, X. Legras, F. Pankowicz, K. Kim, C.S. Martins, M. Barzi, R. Wooton-Kee, W. Lagor. *Baylor College of Medicine, Houston, United States*
Email: bissig@bcm.edu

Background and Aims: Despite advances in gene editing technologies, generation of tissue-specific knockout mice remain time-consuming and expensive and so far, knockouts for more than three genes in parallel have not been established.
Method: Here, we describe a novel technique termed Somatic Liver Knockout (SLiK), which uses CRISPR-Cas9 genome editing in adult mice to generate full-liver knockouts for any desired gene or genes in just a few weeks.
Results: To demonstrate the utility of SLiK, we generated two distinct mouse models for genes not amenable to conventional gene knockout – argininosuccinate lyase (*Asl*) and ATP-binding cassette, sub-family B member 11 (*Abcb11*). Furthermore, we were able to use SLiK to rapidly generate mice with five genes simultaneously knocked out from the murine liver.
Conclusion: Our studies demonstrate broad applicability of SLiK ranging from disease modeling for inborn errors of metabolism to more complex pathway analysis requiring multiple knockouts in parallel.

THU-009

Common immunological and cellular pathways of human alcoholic hepatitis and murine models of alcohol consumption

A. Vogle, E. Burnett, H. Fey, C. Aloman. *Rush University Medical Center, Internal Medicine, Chicago, United States*
Email: voglealyx@gmail.com

Background and Aims: Murine models of chronic alcohol consumption often use ethanol containing isocaloric liquid diets (Lieber-DeCarli, Nanji) or ethanol-in-water (Meadows-Cook). Isocaloric diets produce steatosis and minimal inflammation, while ethanol-in-water causes only minimal histological liver damage. These models are used to investigate new treatments for alcoholic hepatitis but it is unclear whether these models have similar immunological changes and early fibrogenesis. In this study we assessed the degree of similarity of

immunological changes and fibrogenesis of each model with alcoholic hepatitis.
Method: C57BL/6 mice were alcohol-fed via Lieber-DeCarli or Nanji isocaloric liquid diet for 4 weeks or per Meadows-Cook method for 12 weeks. Liver histology was assessed by H&E and Oil Red-O staining. Transcripts for chemokines and cytokines, T-cell immune responses, endothelial adhesion molecules, and fibrogenic markers were assessed by qPCR of liver tissue. Murine data from each diet was compared to both alcoholic hepatitis and healthy subjects' human microarray data from the public domain (GSE28619).
Results: There is extensive variability of chemokines, cytokines and adhesion molecules mRNA despite minimal histological changes observed in murine models: (1) CCL2, CCL20, and CXCL10 mRNA are up-regulated in human alcoholic hepatitis and only the Nanji diet induces up-regulation in CCL2 and CCL20 while CXCL10 is down-regulated. (2) As reported, TNFα mRNA is not affected in alcoholic hepatitis patients while in the Lieber-DeCarli diet it is up-regulated. (3) E-selectin is the only common change of adhesion molecules in every murine group and alcoholic hepatitis. Surprisingly, transcriptional control of hepatic Th1 immune response is only minimally affected in alcoholic hepatitis patients, while it decreased in isocaloric diets. Similar control for Th2 is observed in isocaloric models and human disease, while decreases in Th17 are only seen in alcoholic hepatitis. Unexpectedly, in spite of almost no hepatic histological features, Meadows-Cook diet, and not isocaloric diets, mimic human alcohol-induced fibrogenesis when fibrogenic marker transcripts are measured.
Conclusion: Any investigation of new treatments of alcoholic hepatitis in the existing murine model of alcohol consumption should take into account the extensive variability of immunological and fibrogenesis mechanisms between murine models themselves and between murine models and human alcoholic hepatitis.

THU-010
Demethylation increases the expression of type 3 inositol 1, 4, 5-trisphosphate receptor in hepatocytes

R.M. Florentino[1], A. França[2], A.C.M.L. Filho[1], M.C. Fonseca[3], A.G. Oliveira[1], C.X. Lima[4], P.V.T. Vidigal[5], M. de Fátima Leite[1]. *[1]UFMG, Physiology and Biophysics, Belo Horizonte, Brazil; [2]UFMG, Molecular Medicine, Belo Horizonte, Brazil; [3]CNPEM, LNBio, Campinas, Brazil; [4]UFMG, Surgery, Belo Horizonte, Brazil; [5]UFMG, Pathological Anatomy and Forensic Medicine, Belo Horizonte, Brazil*
Email: rodrigomachado@ufmg.br

Background and Aims: Calcium regulates a wide range of activities in hepatocytes, from secretion to metabolism to proliferation. The type 1 and the type 2 inositol 1,4,5-trisphosphate receptor (InsP3R) are the only intracellular calcium channels present in hepatocytes, which lack the type 3 InsP3R (InsP3R-3) isoform under normal conditions, but show its increased expression in several models of hepatocellular diseases. Bioinformatics analysis demonstrates that the InsP3R-3 promoter region has a large number of CpG islands, likely sites of methylation that supress its expression under physiological condition. Moreover, we also observed that the levels of methylation at the InsP3R-3 promoter region are lower in patients with hepatocarcinoma than healthy controls. Thus, our aim is to investigate whether demethylation of cytosine sites at InsP3R-3 promoter region regulates its expression in hepatocytes, and whether it is involved in hepatocarcinogenesis.
Method: To induce demethylation, swiss male mice were treated, intraperitoneally, with 5′-azacitidine (5′-aza) and the $InsP_3R$-3 expression level was assessed by real-time PCR, western blotting, immunofluorescence and immunohistochemistry. Calcium signaling in hepatocytes was evaluated *in vivo,* with fluo-4/AM, after vasopressin stimulation. The proliferative capacity of the liver was assessed at 24 and 48 hours after partial hepatectomy. To determine the $InsP_3R$-3 expression level in hepatocarcinogenesis, immunohistochemistry was performed in human liver sections from pre-neoplastic and neoplastic stage.
Results: Treatment with 5′-aza increased the expression of liver $InsP_3R$-3 (control = 1.0 ± 0.1 a.u.; 5′-aza = 1.7 ± 0.2 a.u, $p < 0.05$ and $n = 5$) and its expression was shown to be concentrated at the pericentral but abscent at the periportal region. Similarly with the InsP3R-3 expression pattern, the amplitude of calcium signalling was greater in hepatocytes located at the pericentral region (control = 13.1 ± 0.9 a.u.; 5′-aza = 40.8 ± 1.7 a.u, $p < 0.05$ and $n = 5$). Livers that express InsP3R-3 showed increased proliferative capacity compared to control (control = 47.8 ± 3.1 positive cells; 5′-aza = 75.7 ± 3.5 positive cells, $p < 0.05$ and $n = 5$). Moreover, we found that $InsP_3R$-3 expression is observed not only in neoplastic but also in pre-neoplastic stages.
Conclusion: We show that methylation regulates the expression of $InsP_3R$-3 in the hepatocytes, causing an increase in liver proliferation rate.

THU-011
Correction of ATP7B restores its sub-cellular localisation in hepatocytes from Wilson's disease induced pluripotent stem cells

J. Yang[1], M.A. Esteban[2], H.-F. Tse[3]. *[1]Departmemnt of Medicine, the University of Hong Kong, Hong Kong SAR, China; [2]Guangzhou Institutes of Biomedicine and Health, Chinese Academy of Sciences, Guangzhou, China; [3]Queen Mary Hospital, the University of Hong Kong, Hong Kong SAR, China*
Email: jyyang@hku.hk

Background and Aims: Wilson's disease (WD) is an inherited liver disorder caused by mutations in ATP7B, whose malfunction leads to copper accumulation throughout the body and results in varied clinical phenotypes including liver failure and neuropsychiatric manifestations. Induced pluripotent stem cell (iPSC) technology combined with targeted genetic modifications offer the prospect of autologous transplantation using differentiated cells derived from corrected patient-specific iPSCs, with potential application in treatments for inherent disorders. Here, we aimed to correct ATP7B genetically in a footprint-free manner with CRISPR/Cas9 and *piggyBac* or ssODNs in iPSC from a WD patient.
Method: We employed CRISPR/Cas9 and *piggyBac* or ssODNs to achieve footprint-free correction of a homozygous point mutation (R778L) of ATP7B of WD iPSCs. The resulted iPSCs were subjected to off-target analysis in the top potential sites via Sanger sequencing, detection of external sequences by PCR, as well as karyotype analysis, and test of pluripotency by immunofluorescences and teratoma assay. Then, the corrected iPSCs were differentiated into hepatocyte-like cells (iHeps) and subjected to phenotype analysis.
Results: After several rounds of screening, we obtained seamless corrected iPSCs of ATP7B from both approaches, which showed robust efficiency in targeted genome editing. The resulting iPSCs were free of external sequences, show no signs of specific cleavage in the top potential off-target sites, retained full pluripotency and normal karyotypes, and could differentiate into functional iHeps efficiently, which displayed markers of primary human hepatocytes including α1-antitrypsin and albumin, stored glycogen and lipids, and secreted albumin. Importantly, these genetically corrected iHeps had restored ATP7B normal subcellular location, displaying around 90% co-localization (versus 30% co-localization in uncorrected iHeps) with the trans-Golgi network marker p230.
Conclusion: Our results highlight the potential of using combinations of CRISRP/Cas9 and *piggyBac* or ssODNs to produce footprint-free, genetically corrected patient-specific iPSCs. Our results also provide an important proof of principle for employing CRISPR/Cas9 to obtain genetically corrected iHeps for autologous cell-based therapies for other hereditary liver disorders.

Email: patrick.soussan@inserm.fr

Background and Aims: Regulation of alternative splicing (AS), in which transregulatory splicing factors play a critical role, coordinates the transcriptome of eukaryotes. Impairment of AS has been recurrently associated to liver disease development. The aim of this study was to investigate the expression of splicing factors and its significance on AS regulation at different stages of the course of liver disease toward hepatocellular carcinoma (HCC).
Method: A panel of 10 splicing factors was studied by western blot in 6 liver disease mouse models including chronic inflammation, fibrosis, two models of steatosis and cancer and compared to their own littermate controls. Impact on AS regulation of 7 genes associated with liver disorder was studied by RT-qPCR. Then, splicing factors expression (PSF, SRSF6 and SRSF3) and AS regulation of *SRSF3*, *INSR* and *SLK* genes were assessed by RTqPCR in a French cohort of 179 HCC patients and correlated with clinical and biological parameters.
Results: Unique signature of splicing factors modulation (upregulation in 85% of cases) was characterized in each studied mouse model of liver disease. Surprisingly, 5/10 splicing factors were deregulated in NAFLD mouse model while only 2/10 were observed in both liver cancer models. Disruption of AS regulation of 7 selected genes, associated with liver disease, was not thoroughly concordant with the splicing factors expression signature. Quantification of 3 splicing factors and AS regulation of INSR and SLK genes, frequently modulated in liver disease mouse models, revealed their upregulations in tumor compared to non-tumor regions of HCC patients. Splitting results according to clinical and biological parameters of HCC showed that tumor recurrence was associated with AS regulation of INSR and unexpectedly, a correlation between upregulation of splicing factors expression in tumors and overall patient survival within 60-months follow-up post-surgical resection of HCC.
Conclusion: All liver injuries induced in mice differentially altered the expression of a splicing factors panel. Despite the intricate relationship between splicing factors expression and AS regulation, association with survival rate of HCC patients opens a new field on their contribution to the course of liver disease.

Improving the efficacy of hepatocyte transplantation using alpha-1 antitrypsin as an immune modulator

C. Lee[1], A. Dhawan[2], C. Filippi[1], R. Mitry[1], V. Iansante[1], R.F. Dacosta[1], S. Lehec[1], A. Chandrashekran[1], T. Strom[3], M. Koulmanda[3], E. Fitzpatrick[2]. [1]*Dhawan Lab, Institute of Liver Studies, King's College London, London, United Kingdom;* [2]*Paediatric Liver, GI and Nutrition Centre, King's College Hospital, London;* [3]*Departments of Medicine and Surgery, The Transplant Institute, Institute, Beth Israel Deaconess Medical Center/Harvard, Medical School, Boston, United States*
Email: emer.fitzpatrick@kcl.ac.uk

Background and Aims: For patients with liver-based metabolic disorders, hepatocyte transplantation can be an effective bridge until a liver becomes available. However, long term function of transplanted hepatocytes has not been achieved. This is partly attributed to activation of innate immune response that leads to rapid clearance of hepatocytes shortly after transplantation. Alpha-1 antitrypsin (AAT) is a natural immune modulator with anti-inflammatory effects. Our aim was to determine if AAT could improve engraftment of transplanted hepatocytes and investigate its mechanism of action.
Method: ***In Vitro:*** A tubing loop model was used to analyse activation of the immune response when human hepatocytes (HH) were in contact with ABO-matched blood and 4 mg/ml AAT. Platelet and

white cell counts, complement and cytokine expression were analysed. ***In vivo:*** Primary rat hepatocytes were isolated from 250 g male Sprague Dawley rats. Female littermates underwent tail vein injection of AAT (120 mg/kg) or saline (control) prior to the intrasplenic transplantation of 2×10^7 eGFP male hepatocytes. At 24 h, 48 h and 1 wk, liver was collected for immunohistochemical analysis and DNA isolated for Y chromosome (SRY) gene expression. Hepatic mononuclear cells (HMNC's) were isolated and immune cell infiltration analysed using flow cytometry. Blood samples were used to analyse cytokine expression analysed using a Milliplex Map rat cytokine/bead panel.
Results: ***In Vitro:*** In the loop model, HH elicited a significant drop in platelet count with thrombus formation compared to controls (51×10^9 cell/L ± 15 vs 173×10^9 cell/L ± 8, $p < 0.001$, $n = 6$). Loops containing AAT and HH showed no drop in platelet count with no thrombus formation (140×10^9 cell/L ± 13, $p > 0.05$, $n = 6$). AAT treatment decreased IL-1β(1.7 vs 3.9 ng/ml), IL-6(0.4 vs 1.1 ng/ml) and IFN-γ (0.4 vs 1.3 ng/ml, $p < 0.05$, $n = 5$) and increased anti-inflammatory IL-1RA compared to non-treated loops (913 vs 719 ng/ml)($n = 5$, $p < 0.05$). ***In vivo*** There were significantly more eGFP hepatocytes in AAT treated livers compared to untreated at 24 h and 48 h (24 hrs; 4.5 ± 1.4% vs 1.0 ± 0.2%, $^{**}p < 0.01$ and 48 hrs 2.1 ± 0.5 vs 1.0 ± 0.3%, $^{*}p < 0.05$). Engraftment of male hepatocytes detected using SRY was 10-fold higher in the AAT treated group at 48 h compared to control and 4-fold higher at 1 wk ($n = 3$). AAT decreased the percentage of CD86 + ve activated macrophages compared to untreated controls at 48 hrs (10% vs 14.6%), 1-week (2.3% vs 6.9% and 1 month (2.1% vs 3.6%). AAT also decreased concentrations of pro-inflammatory cytokines in vivo; IL-1β, IL-1, IL-6 and IL-2 compared to controls 1 h post transplantation.
Conclusion: AAT improves engraftment of transplanted hepatocytes by inhibition of inflammatory cytokines and immune cell infiltration. AAT may significantly prolong cell survival and function, improving the clinical outcomes of the technique for children with liver based metabolic disease.

THU-014

Rab35 drives Hepatocellular Carcinoma development via action of Erk1/2 pathway

X. Wang, X. Xie, R. Fei, N. Wu, X. Cong, L. Wei, H. Chen. *Peking University Hepatology Institute, Peking University People's Hospital, Beijing, China*
Email: chenhongsong2999@163.com

Background and Aims: The Rab family of GTPases regulate many major biological processes in both tumorigenesis and tumor progression. Rab35, a member of Ras-related small GTPase family, has been reported to play a role in several cancer types. However, its biological functions and the underlying molecular mechanisms in hepatocellular carcinoma (HCC) remain unknown.
Method: The mRNA expression pattern of Rab35 in HCC tumor was analyzed by bioinformatics analysis of RNA Sequencing (RNA-seq) data of liver hepatocellular carcinoma (LIHC) in the Cancer Genome Atlas (TCGA) project. Its expression was further validated by QRT-PCR analysis of an independent HCC cohort and HCC cell lines. Then, Rab35 was knocked down in HCC cell lines using lentivirus mediated CRISPR/Cas9. The impact of Rab35 silence on the clonogenic growth and migration of HCC cell lines was used to determine its importance in the HCC. At last, we also examined the Erk1/2 phosphorylation level while overexpressing or knocking-down Rab35 in HCC cell lines.
Results: In this study, we found that the expression of Rab35 was elevated in HCC tissues and HCC cell lines. Strikingly, the Rab35 mRNA level is significantly correlated with the overall survival time of HCC patients in both TCGA LIHC cohort and an independent HCC cohort. Rab35 overexpression is tightly linked to high mortality in both cohorts. We further proved that overexpression of Rab35 promoted the clonogenic growth and migration of the HCC cells, while knocking down the expression of Rab35 inhibited the clonogenic growth and migration of the HCC cells. Moreover, we found that Rab35 overexpression significantly increased Erk1/2 activation monitored by p-Erk1/2 in Huh7 and MHCC-97H cell lines. In contrast, Rab35 knocking down substantially impaired Erk1/2 activation.
Conclusion: These results suggest that the Rab35 could driver Hepatocellular Carcinoma development via activation of Erk1/2 signaling pathway.

THU-015

hASCs-derived exosomes rescuing rats with acute liver failure by releasing lncRNA H19

Y. Jin, H. Li, X. Wang, C. Chen, Q. Fu. *Shanghai Public Health Clinical Center, Fudan Universitym Shanghai, China*
Email: 1182008211@qq.com

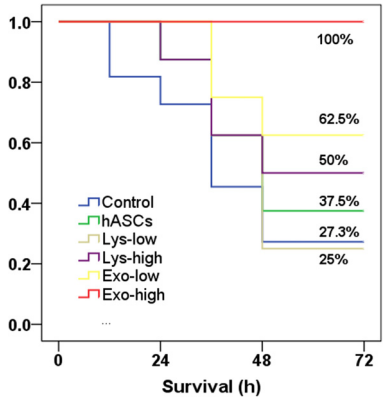
Background and Aims: It has been confirmed that the stem cells promote the regeneration of damaged tissues mainly through the "paracrine effect". As the major carrier responsible for exocytosis of the stem cells, exosome is highly likely to play an important role in stem cell therapy.
Method:

(1) Human adipose-derived stem cells (hASCs) were separated from human adipose tissues and used to prepare hASCs exosomes with modified multi-ultrafiltration concentration method of our research group.
(2) 78 rats with acute liver failure were randomly assigned to 5 groups to receive treatment with the same volume of low concentration (20 μg/rat) and high concentration (100 μg/rat) of hASCs exosomes, low concentration (20 μg/rat) and high concentration (100 μg/rat) of hASCs lysis buffer as well as hASCs (2×10^6 cells/rat) or phosphate buffer solution (PBS), respectively, through femoral vein infusion. The survival rate of rats was observed, and analyses on gene sequencing and signal pathways conducted to explore the potential mechanism of hASCs exosomes in treating the rat models with acute liver failure.
(3) 25 rats with acute liver failure rats were randomly assigned to 3 groups to receive the treatment of the same volume of hASCs exosomes (100 μg/rat), hASCs exosomes with silent H19 gene (100 μg/rat) or phosphate buffer solution (PBS), respectively, by femoral vein infusion. The survival rate of the rats was analyzed.

Results:

(1) The rat survival curves showed that rat survival rate was 100% and 62.5% respectively in the high concentration and low concentration hASCs exosome group, significantly higher than in the PBS control group (27.3%) ($P < 0.05$); According to the results of gene sequencing for rat liver tissues, hASCs exosome transplant significantly upregulated the genes associated with blood coagulation function and drug metabolism pathways, and dramatically downregulated the genes related to inflammatory responses and chemokine signaling pathways (Figure 1).
(2) Signaling pathway analysis revealed an evident upregulation in long chain non-coding RNA (lncRNA) H19 in the liver tissues of rats in hASCs exosome groups, which is likely associated with the upregulation of pathways related to blood coagulation function as well as drug metabolism. A decrease in the rat survival rate to 40% was observed in the rats with acute liver failure when treated with H19 gene silencing hASCs, with a statistical significance as compared with the hASCs exosome groups (Figure 2).

Conclusion: hASCs exosomes can accelerate the regeneration of the damaged liver cells and improve the survival rate of rats with acute liver failure probably by upregulate the pathways associated with blood coagulation function and drug metabolism as a result of lncRNA H19 release.



THU-016

A novel Akt activator SC79 prevents lethal hepatic failure induced by Fas-mediated apoptosis of hepatocytes

W. Liu, Z.-T. Jing, S.-X. Wu, Y. He, W. Chen, X.-J. Lin, X. Lin. *Fujian Medical University, Key Laboratory of Ministry of Education for Gastrointestinal Cancer, Fuzhou, China*
Email: linxu70@126.com

Background and Aims: Acute liver failure (ALF) remains a serious clinical problem for which the underlying pathogenesis remains unclear and effective therapies are lacking. Fas receptor/ligand (Fas/FasL) system, which is negatively regulated by AKT pathway, is known to play a prominent role in hepatocytic cell death. The aim of this study is to investigate the effects and mechanisms of a novel of Akt activator SC79 in regulating Fas/FasL-mediated apoptotic signaling and death in hepatocytes.
Method: HepG2 and primary mouse hepatocytes (PMHs) were treated with agonistic anti-Fas antibody CH11or Jo2 respectively, cell apoptosis were measured by TUNEL and Annexin V binding assay. Protein level or modification were detected by western blot. Mice were pretreated intraperitoneally with SC79 or DMSO before administration of Jo2 antibody, mice were sacrificed at various time points after Jo2 injection, serum ALT and AST were determined.
Results: SC79 protected hepatocytes from agonistic anti-Fas antibody CH11- or Jo2-induced apoptosis and significantly prolonged the survival of mice with a lethal dose of Jo2. Under Fas signaling stimulation, SC79 inhibited Fas aggregation, prevented recruitment of the adaptor molecule Fas-associated death domain (FADD) and procaspase-8 into the death-inducing signaling complex (DISC), but enhanced recruitment of cellular FLICE-inhibitory protein S and L ($FLIP_{L/S}$) at the DISC. Confirmedly, all the SC79-induced hepatoprotectiveand DISC interruptive effects could be reversed by the Akt inhibitorLY294002.
Conclusion: SC79 prevents hepatocytes from Fas-induced lethal hepatic apoptosis. The potent alleviation of Fas-mediated hepatotoxicity by SC79 highlights the potential of our findings for immediate therapeutic translation.

Email: jsharon_sharon@yahoo.co.in

Background and Aims: Transforming Growth Factor Beta (TGF-beta) belongs to a superfamily of cytokines that exerts pleiotropic effects on different processes and cell types in the liver. During cancer progression while TGF-beta signaling induces tumor suppressor effects at pre-neoplastic and early tumor stages, cytostatic effects of TGF-beta are often lost in progressed stages due to (epi-) genetic disruption of several members of the (TGF-beta) signaling pathway. This progressed stage is characterized by activation of a "late TGF-beta signature" which promotes the phenotypic switch from tumor suppressor to promoter of cancer. Consequently, cancer cells display an epithelial-mesenchymal-transition (EMT) phenotype by acquiring pro-metastatic properties.
Method: Newly generated primary (HCC & CCA) and established cell lines (PLC & HuCCT-1) were exposed to TGF-β1 and TGF-β2 (1 ng/ml) for 72 hr. Next Generation Sequencing Analysis was performed to identify significant differences in gene expression patterns. Appropriate statistical and bioinformatics tools (IPA) was used to study pathways and networks to understand how they these genes interact biologically. The effect of TGF-β on tumor-initiating potential was determined by colony and sphere formation assays. Invasive and migratory properties were determined using the wound healing assay.
Results: Treatment with TGF-β1 and TGF-β2 led to a significant reduction in colony and spheroid forming ability in all investigated cell lines. Consistent with the reduced *in vitro* tumorigenicity and spherogenicity, a drastic effect of TGF-β1 on the putative tumor-initiating cell population was observed, reflected by the down-regulation of stemness markers CD133 and EpCAM. Interestingly, treatment with TGF-β1 led to a significant increase in the expression of CD44 accompanied by the activation of established epithelial-mesenchymal-transition markers (Vimentin). A significant down-regulation of E-Cadherin paralleled by upregulation in SNAIL transcription factor was seen. Consequently, enhanced migratory and invasive properties of HCC and CCA were observed evidenced by increased wound healing and invasion. In addition, pathways enriched with differentially expressed genes known to be involved in EMT (P13K, WNT/β-Catenin pathway) were identified by NGS analysis.
Conclusion: In conclusion, we here confirm the cytostatic effect of TGF-β1 and TGF-β2 by reducing the frequency of cancer cells in both HCC and iCCA. Further, TFG-β1 seems to be an important regulator in progressed PLCs. These context-dependent dichotomic effects should be considered in TGF-β based therapeutic approaches. We would further validate the obtained findings in vivo using a battery of different xenotransplantation models representing the observed in vitro findings.

THU-018

Amiodarone-induced adipose tissue endoplasmic reticulum stress and lipolysis may contribute to hepatic lipid accumulation

I. Houri, E. Hubel, R. Avraham, I. Zvibel, O. Shibolet. *Tel Aviv Sourasky Medical Center, Gastroenterology, Tel Aviv*
Email: inbalhourio@gmail.com

Background and Aims: Amiodarone is a widely used anti-arrhythmic drug. One of its common side effects is liver lipid accumulation and steatosis. We have previously shown that amiodarone induces endoplasmic reticulum (ER) stress and activates the unfolded protein response (UPR) in an acute model of liver damage. Hepatic lipid accumulation may be due to de novo triglyceride synthesis or to increased uptake of adipose-tissue-derived free fatty acids (FFA). We investigated the effects of amiodarone on hepatic lipogenesis and on adipose tissue lipolysis and secretion of FFA in a newly established chronic model of amiodarone injury.
Method: A chronic model of amiodarone-induced liver damage and lipid accumulation was implemented by daily intraperitoneal injection of amiodarone (150 mg/g BW per day) for four days.
Results: Mice treated with amiodarone had increased hepatic triglycerides (TG) and reduced serum TG compared to controls. There was increased ER stress/UPR in the livers of mice that received

amiodarone, as well as reduced hepatic lipogenesis. In addition, amiodarone significantly induced hepatic gene expression of FFA binding proteins CD36 and Fatty acid binding protein 4 (FABP4) and increased protein levels of CD36, suggesting increased uptake of FFA. Investigating the effect of amiodarone on visceral adipose tissue, we detected increased expression of ER stress markers and reduced gene expression of adipose tissue-specific markers (Leptin, Adiponectin and Fabp4), demonstrating for the first time that amiodarone can induce ER stress in adipose tissue. Adipose ER stress was shown to stimulate lipolysis, and indeed, we have found increased lipolysis following amiodarone treatment, demonstrated by increased serum FFA and increased expression of pHSL.
Conclusion: We have shown a novel mechanism involved in amiodarone-induced hepatic lipid accumulation, mediated by amiodarone induction of adipose tissue ER stress and lipolysis and followed by increased hepatic uptake of FFA.

THU-019

Effect of melatonin on the circadian clock pathway in liver fibrosis and progression to hepatocarcinoma

B.G. Fernández[1], D.I.S. Paniagua[1], I. Crespo[1], B.S. Miguel de Vega[1], D.M. Sánchez[1], F. Jorquera[2], J. González-Gállego[1], M.J.T. González[1]. *[1]CIBEREHD. Institute of Biomedicine, University of León, León, Spain; [2]Department of Gastroenterology, University Complex Hospital of León, León, Spain*
Email: bgonf@unileon.es

Background and Aims: Recent studies suggest a relationship between circadian rhythms and pathologic processes, including fibrosis and cancer. The main regulator of clock genes is the heterodimer BMAL1-CLOCK, which regulates the expression of transcriptional repressors cryptochrome (CRY) and period (PER). The nuclear receptor REV-ERB plays pivotal role in the modulation of the circadian rhythm as a negative regulator. Melatonin exhibits antifibrotic and oncostatic features, playing a protective role in a wide range of liver diseases. The aim of this study was to determinate the effect of melatonin on the circadian clock pathway disturbances in liver fibrosis and hepatocarcinoma (HC).
Method: Fibrosis was induced in C57BL/6J mice with CCl_4 twice a week for 4 or 6 wk; melatonin was given at 5 or 10 mg/kg/day i.p. beginning 2 wk after the start of CCl_4 administration. We investigated whether melatonin has its antifibrotic effect through the modulation of the REV-ERBα expression, using a REV-ERB agonist, SR9009 in human stellate cells LX2. Cells were exposed to the ligand at 10 μM during 24 h. Melatonin groups received the indole at 100 or 500 μM two hours after SR9009. HC was induced in ICR mice receiving DEN once a week for 8 wk; melatonin was given at 5 or 10 mg/kg/day i.p. beginning 4 wk after the onset of DEN administration and ending at 10, 20, 30 and 40 wk. The expression of circadian clock markers was analyzed by qRT-PCR and Western-blot.
Results: The expression of CLOCK, BMAL1, REV-ERB, PERs and CRYs were deregulated in CCl_4 animals and in DEN-treated mice since the first time-points, reaching a higher effect at 6 and 40 wk, respectively. These alterations were significantly prevented in animals receiving melatonin. REV-ERBα expression was significantly increased in CCl_4 animals, and melatonin abolished this effect. SR9009-treated LX2 cells showed an increase in the expression of clock markers CLOCK, BMAL1, PER and CRY, which were similar to those observed in cells receiving melatonin.
Conclusion: The results of this study confirm that circadian rhythms play a crucial role in fibrosis and carcinogenesis. Restoration by melatonin of the clock genes disruption reveals novel molecular pathways that may account for the protective effect of the indole.

This work was supported by AECC and CEPA Fundation, Spain.

THU-020

Unravelling the role of the Hedgehog siganlling pathway in the hepato-ovarian axis

C. Rennert[1,2], F. Eplinius[3], U. Hofmann[4], W. Schmidt-Heck[5], A. Ricken[3], R. Gebhardt[6], M. Matz-Soja[6]. *[1]Saxonian Incubator for Clinical Translation (SIKT), Leipzig University, Leipzig, Germany; [2]Department of Hepatobiliary and Transplantation Surgery, Faculty of Medicine, University Hospital Leipzig, Leipzig; [3]Institute of Anatomy, Faculty of Medicine, Leipzig University, Leipzig, Germany; [4]Dr. Margarete Fischer-Bosch Institute of Clinical Pharmacology, University of Tübingen, Stuttgart, Germany; [5]Leibniz Institute for Natural Product Research and Infection Biology, Hans Knöll Institute, Jena, Germany; [6]Rudolf-Schönheimer-Institute of Biochemistry, Faculty of Medicine, Leipzig University, Leipzig, Germany*
Email: christiane.rennert2@medizin.uni-leipzig.de

Background and Aims: The Hedgehog signalling pathway is known to be involved in embryogenesis, development, and carcinogenesis. Because of its role in cancer development and progression it has become an interesting target for anti-cancer therapy. The inhibition of Smoothened, a Hedgehog receptor, shows promising preliminary results in clinical trials. However, inhibition of Hedgehog signalling pathway may have adverse side effects in the remaining body.
Method: Our previous work in adult mice showed hepatic Hedgehog signalling to be involved in the control of the insulin-like growth factor axis and the lipid metabolism. We here investigated mice with an embryonic and hepatocyte-specific Smoothened deletion (SAC mice), and mice with a conditional, hepatocyte-specific deletion of Smoothened at 8 weeks of age (SLC mice).
Results: Deletion of Smoothened resulted in masculinization and infertility in female mice. We detected an androgenisation characterized by a 3.3-fold increase of testosterone in female SAC-KO mice at 12 weeks of age. The changes obviously resulted from a surprisingly induced steroidogenic gene expression (Star, Cyp17a1) in hepatocytes, but not in classic steroidogenic organs (ovary and adrenal gland). Along with the elevated testosterone levels the female SAC-KO mice showed signs of infertility. The animals lacked oestrus cyclicity and their reproductive organs were immature. In the ovaries, folliculogenesis was impaired and no corpora lutea were seen. These findings resemble polycystic ovarian syndrome (PCOS). They could be widely confirmed in the SLC mice. The female SLC-KO mice showed a similar induction of steroidogenic gene expression in the liver and a reduced number of corpora lutea in the ovaries after an extended period of 8 months.
Conclusion: In summary, down-regulation of hepatic Hedgehog signalling leads to an impaired hormonal balance by induction of steroidogenesis in the female liver and results in androgenisation and infertility. This indicates that the liver may crucially influence reproduction under disease conditions.

THU-021

WDHD1 is a candidate driver gene in Hepatocellular Carcinoma

J. Cai[1], K. Zhang[1], Y. Tian[2]. *[1]Peking University International Hospital, Department of Hepatobiliary Surgery, Beijing, China; [2]Peking University International Hospital, Department of Hepatobiliary Surgery, Beijing, China*
Email: caijun9527@sina.com

Background and Aims: Cell cycle checkpoint pathways are key to ensure that the genome is accurately replicated. Dysfunctions or mutations of these pathways are important in the pathogenesis of malignant tumors. WDHD1 (WD repeat and high mobility group [HMG]-box DNA-binding protein 1) is an adaptor molecule crucial for DNA replication and play a role in G1 checkpoint control. But, it has not been fully understand how WDHD1 involved in the carcinogenesis and progress of HCC. Here, we aim to study the importance of WDHD1 in the HCC.
Method: The mRNA expression pattern of WDHD1 in HCC tumor was analyzed by bioinformatics analysis of RNA Sequencing (RNA-seq)

data of liver hepatocellular carcinoma (LIHC) in the Cancer Genome Atlas (TCGA) project. It was further validated by QRT-PCR analysis of an independent HCC cohort and HCC cell lines. WDHD1 was knocked down in HCC cell lines using lentivirus-mediated shRNA. The impact of WDHD1 silence on the in vitro clonogenic growth, and on cell cycle and replication of HCC cell lines was used to determine its importance in the HCC.
Results: The mRNA level of WDHD1 was dramatically higher in HCC tumor tissues than in normal liver tissues according to both the LIHC RNAseq data and the QRT-PCR analysis of an independent HCC cohort. Strikingly, the WDHD1 mRNA level significantly correlated with the recurrent-free survival time of HCC patients in both TCGA LIHC data set and our own HCC cohort. WDHD1 overexpression is significantly linked to high mortality in both cohorts. Moreover, all six analyzed HCC cell lines cell overexpressed WDHD1. The clonogenic potential of SK-HEP-1 and Huh7 was significantly inhibited after knockdown of WDHD1 with shRNA. Notably, knockdown of WDHD1 led to an increase in the G1 arrest and decrease in BrdU incorporation. These results demonstrate an important role of WDHD1 in the G1 cell cycle control and S-phase entry of HCC cells.
Conclusion: These results suggest that the WDHD1 is a candidate driver gene in Hepatocellular Carcinoma that involved in cell cycle control.

THU-022
Investigating the effect of adrenomedullin on hepatic NF-kB activation by 2D and 3D hepatic cell cultures

S.D. Martin[1], E. Caon[2], D. Gabbia[1], G. Zigiotto[1], Z. Zhang[3], L. Frenguelli[1], W. Al-Akkad[2], S. Sarcognato[4], G. Maria[4], G. Mazza[5], M. Pinzani[2], K. Rombouts[2]. *[1]University of Padova, Department of Pharmaceutical and Pharmacological Sciences, Padova, United Kingdom; [2]University College London, Institute for Liver and Digestive Health, London, United Kingdom; [3]University College London, Institute for Liver and Digestive Health, London, United Kingdom; [4]University of Padova, Department of Medicine, Italy; [5]Institute for Liver and Digestive Health, London, United Kingdom*
Email: k.rombouts@ucl.ac.uk

Background and Aims: Adrenomedullin (ADM) is a neuropeptide exerting multiple effects through autocrine/paracrine mechanisms. ADM plays an immunomodulatory role and has anti-inflammatory activity in various diseases but its role has not been investigated in liver diseases. We assessed the hepatic ADM expression in different inflammatory liver diseases (HCV, AIH, NASH) and the mechanism(s) by which ADM affects NF-kB activation in classical 2D and a new 3D model.
Method: Immunofluorescence analysis was performed on liver tissue samples to assess ADM expression and α-SMA colocalization. HepG2 and LX2 were exposed to LPS (1 ng/mL), ADM (10–7M) for 24 hrs, ADM (10–7M) for 4 hrs followed by LPS for 24 hrs. ICC for p65 nuclear translocation and QRT-PCR was performed. Human liver 3D scaffolds were obtained by decellularization of healthy and cirrhotic livers. LX2, a hHSC cell line, or primary hHSCs were cultured on scaffolds for 10 days. Primary hHSC in healthy scaffolds were treated as above, or with LPS for 1–3 hrs, PDGF-BB (1–10 ng/mL), or TGFbeta1 (2–5 ng/mL) for 24 hrs. Human HSCs in cirrhotic scaffolds were exposed to ADM for 4 hrs. QRT-PCR was performed.
Results: Human HSCs ADM-related fluorescence intensity in NASH patients (n = 5) was less than in HCV (n = 5) and AIH (n = 5) patients, but the degree of colocalization was similar in all patients. ADM pretreatment of LX2 and HepG2 in 2D, followed by LPS exposure significantly reduced p65 nuclear translocation and increased NF-kB inhibitor IkBα gene expression. LPS treatment in HepG2 decreased ADM expression whereas exogenous ADM pretreatment counteracts this effect. ADM gene expression was decreased in TGFbeta1 and LPS-treated hHSCs cultured in 2D and was upregulated in 3D vs 2D. In contrast, TGFbeta1 and PDGF-BB-treated hHSCs in 3D showed a reduced ADM gene expression. ADM pretreatment in hHSCs in healthy scaffolds increased ADM gene expression, reduced NFKB1, but not NFKB2, and completely abrogated the effect of subsequent exposure to all stimuli. ADM gene expression was upregulated in hHSCs in cirrhotic scaffolds vs healthy scaffolds and exogenous ADM treatment favoured hHSCs deactivation in cirrhotic liver scaffolds.
Conclusion: This study shows that ADM expression changes with respect to the aetiology of liver inflammation. ADM leads to a reduction in activation of the canonical NF-kB pathway in hepatic cells in both 2D and 3D cultures. These findings suggest that the ADM system as a possible pharmacological target for the management of inflammatory liver diseases.

THU-023
DNA methylation profiling of hepatitis C virus patients treated with direct acting antivirals identifies consistent methylation changes in livers and blood

A. Vasanthakumar[1], D. Quarless[1], E. Dilmukhametova[1], M. Abunimeh[1], C. Konefal[1], S. Abel[1], K. Idler[1], G. Lauer[2], A. Kim[2], R. Chung[2], D. Cohen[1], J.W. Davis[1], E. Dumas[1], J.F. Waring[1]. *[1]AbbVie; [2]Harvard Medical School*
Email: aparna.vasanthakumar@abbvie.com

Background and Aims: Chronic Hepatitis C virus (HCV) infection can induce progressive liver fibrosis which often leads to cirrhosis and liver failure. Direct acting antiviral (DAA) treatment regimens show high sustained virological response rates in HCV-infected patients, yet their impact on long-term clinical outcomes is unknown. Numerous studies have demonstrated that epigenetic mechanisms, e.g. DNA methylation (DNAm), control molecular events underlying liver disease development and progression. We hypothesize that DNAm associates with clinical outcomes after DAA treatment, including immune changes and liver fibrogenesis. Our main objectives were to investigate whether peripheral blood (PB) DNAm functions as a surrogate for liver DNAm and to detect longitudinal DNAm changes in PB following DAA treatment.
Method: PB and liver fine needle aspirates (L-FNA) were obtained from patients receiving the 3-DAA regimen which included paritaprevir (identified by AbbVie & Enanta) [#NCT02476617]. PB was collected on day0 (D0), end of treatment (EOT/Week 12), post-treatment weeks 12 and 24 (PTW12 and PTW24). For a subset of subjects, L-FNAs were collected at D0 and PTW12. DNAm was assayed by bisulfite pyrosequencing and Illumina EPICarrays.
Results: An *IFNL3* locus is known to associate with response to interferon therapy. We previously demonstrated *IFNL3* genotype-associated differential methylation in PB, and were able to replicate the finding in the current study (Table 1). Notably, the L-FNA samples demonstrated similar differential DNAm (Table 1), which supports the hypothesis that PB is a surrogate for liver DNAm at this locus. Genome-wide DNAm data were normalized and QC-d using established protocols. Comparison of PB DNAm at D0vsEOT, D0vsPTW12, and D0vsPTW24 generated 93, 91, and 1862 differentially methylated positions (DMPs) at FDR = 10%. Several DMPs were located near promoters of genes associated with inflammation and liver disease, including *IL20RA*, which was hypermethylated, and *MPO* which was hypomethylated post-treatment. Ongoing work is examining common DMPs in liver and PB.
Conclusion: This is the first study to demonstrate that genotype-associated DNAm changes upstream of the *IFNL3* gene in PB are preserved in liver. Time-dependent regional DNAm changes were observed in promoters of genes associated with inflammatory and liver functions, which supports the significance of longitudinal DNAm data to elucidate DAA treatment related long-term clinical outcome features.
Disclosures: AbbVie funded the study and participated in the study design, research, analysis, data collection, interpretation of data, and review and approval of the abstract. AV, DQ, ED, MA, CK, SJA, KBI, DEC, JWD, EOD, and JFW are AbbVie employees and may hold AbbVie

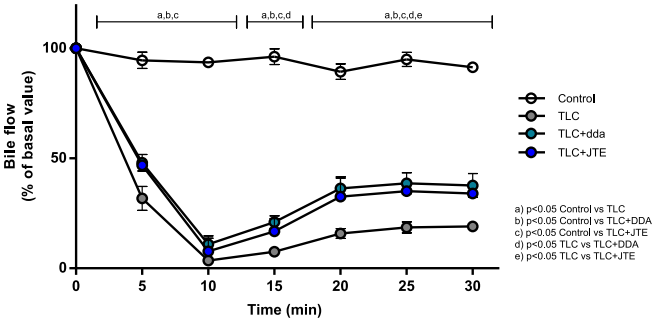
Involvement of sphingosine-1P receptor 2 (S1PR2) in taurolithocholate-induced impairment of multidrug resistence-associated protein 2 (Mrp2) in rat

R. Andermatten, N. Ciriaci, M.V. Razori, G. Miszczuk, I. Barosso, E.S. Pozzi. *Instituto de Fisiología Experimental, CONICET-UNR, Rosario, Argentina*
Email: esanchez@fbioyf.unr.edu.ar

Background and Aims: Taurolithocholate (TLC), a cholestatic bile salt, induces internalization of Mrp2. Signaling proteins, such as PI3K/AKT, participate in this cholestasis but the initial receptor/s remain/s unknown. We focused our study in adenylyl cyclase (AC)/PKA, recently involved in estrogen-induced cholestasis, and in potential TLC receptors. S1PR2 arose as a possible initial TLC receptor since it interacts with bile salts and potentially activates AC.
Method: Isolated rat hepatocyte couplets were preincubated with the S1PR2 antagonist JTE-013 (JTE, 10 μM), AC inhibitor MDL12330 (MDL, 20 μM) or PKA inhibitor KT5720 (KT, 250 nM) and then exposed to TLC (2.5 μM). Couplets were also co-preincubated with JTE and either MDL, KT or PI3K inhibitor wortmannin (W, 100 nM). Changes in Mrp2 activity were evaluated by assessing the canalicular vacuolar accumulation (cVA) of glutathione methylfluorescein (GMF), an Mrp2 substrate. Mrp2 localization was studied by immunofluorescence, followed by confocal microscopy. PKA and AKT activation were determined by western blot using an antibody against phospho PKA substrate and phospho AKT. In isolated rat liver, cholestasis was induced by intraportal injection of TLC (4.5 μmol/liver). Inhibitors JTE or DDA (AC inhibitor) were administered 10 min before TLC. Finally, biliary flow was measured for 30 min in 5 min-periods.
Results: (% of control ± SEM; n = 3–9) Treatment with JTE, MDL, KT and W partially prevented TLC-induced impairment in Mrp2 activity: TLC (55 ± 2a), TLC + JTE (79 ± 2a,b), TLC + MDL (80 ± 9a,b), TLC + KT (74 ± 10a,b), TLC + W (77 ± 6a,b). JTE preventive effects did not improve the actions of MDL, KT or W: TLC + JTE + MDL (84 ± 6a,b), TLC + JTE + KT(76 ± 3a,b), TLC + JTE + W (79 ± 6a,b), suggesting that S1PR2, AC, PKA and PI3K share the same pathway. Activation of PKA induced by TLC decreased in presence of JTE: TLC (248 ± 15a), TLC + JTE (138 ± 33b). The same phenomenon occurs with AKT phosphorylation: TLC (584 ± 23a), TLC + JTE (161 ± 27a,b). Localization studies showed that JTE, MDL, KT and W prevented the delocalization of Mrp2 induced by TLC. TLC diminished bile flow (see figure). JTE or DDA only increased recovery after the initial drop. a: $p < 0.05$ vs control, b: $p < 0.05$ vs TLC.



Conclusion: Interaction of TLC with S1PR2 would be one of the first events in the signaling pathway that leads to Mrp2 activity impairment, followed by AC, PKA and PI3K/AKT activation. This pathway would be implied in retaining Mrp2 in an intracellular domain rather than promoting canalicular transporter desinsertion.

The analysis of delta40p53, one of p53 splicing isoforms, in hepatocellular carcinoma cells

H. Nakao[1], A. Ota[2], T. Ohashi[3], R. Kitano[3], M. Sakamoto[3], Y. Sumida[3], Y. Nakade[3], K. Ito[3], M. Yoneda[3]. *[1]Aichi medical University, Division of Hepatology and Pancreatology, Department of Internal Medicine, Nagakute, Japan; [2]Aichi Medical University, Department of Biochemistry, Nagakute, Japan; [3]Aichi Medical University, Division of Hepatology and Pancreatology, Nagakute, Japan*
Email: hnakao@aichi-med-u.ac.jp

Background and Aims: Splicing isoforms of certain genes impact on genetic biodiversity in mammals. The tumor suppressor *TP53* gene plays an important role in the regulation of tumorigenesis in hepatocellular carcinoma (HCC). Though delta40p53α (Δ40p53) is the naturally occurring p53 isoforms that lacks N-terminal transactivation domain, yet little is known about the role of Δ40p53 in the development of HCC. The aim of this study is to clarify the role of Δ40p53 in HCC.
Method: To accomplish this study, we established $p53^{+/\Delta 40}$ HepG2 cells, which was heterozygous endogenous exon 2-deleted p53 HepG2 cell using Cre/loxP system. Also, we established $p53^{-/-}$ HepG2 cells, which endogenousTP53 were knocked out by using CRISPR-Cas9. Other cell lines used in this study were HuH-1 ($TP53^{WT}$), HepG2 ($TP53^{WT}$), Hep3B ($TP53^{-/-}$), HuH-7($TP53^{Y220C}$), and PLC/PRF/5 ($TP53^{R249S}$). For cell proliferation assay, MTT assay and Clonogenic

assay were used. Annexin V and caspase-3/7 activity assay were performed for apoptosis assay. FACS and SA-β-galactosidase assay were used for cellular senescence analysis. Transient *p53* knockdown was performed using *p53* siRNA. Quantitative RT-PCR was used for mRNA analysis and Western blot analysis was used for protein analysis.

Results: The clonogenicity and MTT assays showed that tumor cell growth was suppressed in the $p53^{+/\Delta 40}$ cells. The β-galactosidase assay revealed that the percentage of SA-β-gal-positive cells was significantly higher in $p53^{+/\Delta 40}$ clones compared to control clones. Western blot showed that protein expression of $p21^{WAF/CIP1}$, but not those of BAX and PUMA, significant increase in $p53^{+/\Delta 40}$ clones. Caspase-3/7 activity and the percentage of apoptotic cells did not significantly increase in the $p53^{+/\Delta 40}$ clones compared to control clones, suggesting that the growth suppression was not a result of increased apoptosis. The mRNA of IL-8, MDM2, $p21^{WAF/CIP1}$ and FAS were increased in $p53^{+/\Delta 40}$ clones. These results indicated that cellular senescence is accelerated in the $p53^{+/\Delta 40}$ clones. Besides, the tumor suppressor activity of Δ40p53 was shown in TP53 knockdown condition using siRNA and exogenous expression of Δ40p53. Moreover, Δ40p53 itself exerted tumor activity in TP53-deleted cells, $p53^{-/-}$.

Conclusion: Δ40p53 suppressed tumor cell proliferation and induces cellular senescence in HCC cells.

THU-027

CCNT1 mediates mTor inhibitor related antiviral effects in HCV genotype 2a

A. Frey, M. Trippler, G. Gerken, K. Herzer. *University Hospital Essen, Department of Gastroenterology and Hepatology, Essen, Germany*
Email: kerstin.herzer@uk-essen.de

Background and Aims: The mTor inhibitor Everolimus is in use for immunosuppression (IS) after liver transplantation (LT). However, its effect on HCV replication and reinfection after LT, in particular in the context of antiviral treatment, still remains to be clarified. Previously, we were able to show that mTor inhibitors reduce the viral load in HCV genotype (GT) 2a patients *in vivo* and the replication activity *in vitro*. Aim of this study is to elucidate the molecular background of the effect of mTor inhibitors on the GT2a HCV replication activity.

Method: The viral load of 20 GT2 patients with a HCV reinfection after LT was determined by qRT-PCR before and 8 weeks after addition of everolimus (EVR) to a tacrolimus (TAC) – based immunosuppression. The GT2a HCV replicon cell line (Huh7.5 JFH/SG-Feo) was treated for 48 h with the mTor inhibitors EVR and sirolimus (SRL). HCV replication activity was quantified by luciferase assay. A gene expression profile was generated using GeneChip® Human Transcriptome Array 2.0 and qRT-PCR. A Cyclin T1 (*CCNT1*) knockdown was generated by siRNA. The protein expression of *CCNT1* and *GAPDH* as loading control was analyzed by western blot.

Results: HCV viral load of GT2a patients was significantly reduced ($p \leq 0.0001$) after conversion to an EVR based immunosuppression regime. *In vitro* mTor-inhibitor application to GT2a replicon cells decreased HCV replication activity to 60% ($p \leq 0.0005$). A hierarchical cluster analysis revealed the viral replication related cell factor *CCNT1* as significantly regulated after EVR treatment. In vitro, the *CCNT1* expression increased up to 1.5-fold (EVR: $p \leq 0.005$, SRL: $p \leq 0.05$) compared to controls. A *CCNT1* knockdown (average: 60%; $p \leq 0.01$) in GT2a cells completely abolished the antiviral effect of mTor inhibitors on HCV replication activity (EVR: $p \leq 0.05$; SRL ≤ 0.05).

Conclusion: The herein presented results suggest that mTor inhibitors impair HCV replication activity via *CCNT1* upregulation. Further factors are likely to be involved in these regulatory mechanisms and are currently under further investigation.

Cerium oxide nanoparticles protect against oxidant mediated injury and recover kinase activity of multiple pathways in human-derived hepatocellular carcinoma cells

M.P. Corominas[1], S.C. Restoy[1], G. Casals[1], D. Oró[1], J. Ribera[1], E. Casals[2], P. Casado-Izquierdo[3], G.F. Varo[1,4], P. Cutillas[3], V. Puntes[2,5,6], W. Jiménez[1,4]. *[1]Biochemistry and Molecular Genetics Service, Hospital Clínic de Barcelona, Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD), Barcelona, Spain; [2]Vall d'Hebron Insitute of Research (VHIR), Barcelona, Spain; [3]Barts Cancer Institute, Queen Mary University of London, London, United Kingdom; [4]Department of Biomedicine, University of Barcelona, Barcelona, Spain; [5]Institut Català de Nanociència i Nanotecnologia (ICN2), Bellaterra, Spain; [6]Institut Català de Recerca i Estudis Avançats (ICREA), Barcelona, Spain*
Email: mperramon@clinic.cat

Background and Aims: Cerium oxide nanoparticles (CeO_2NPs) possess powerful antioxidant properties, thus emerging as a therapeutic tool in conditions characterized by presence of reactive oxygen species (ROS), including liver disease. Here, we assessed whether CeO_2NPs are able to prevent or attenuate oxidant injury in the human hepatic cell line HepG2. The aim of the study was to elucidate whether CeO_2NPs display beneficial effects in hepatic human cells and investigate the basic mechanisms involved in this phenomenon.

Method: The effect of CeO_2NPs on cell viability and ROS scavenging in H_2O_2- or lipopolysaccaride (LPS)-treated HepG2 cells was determined using MTS technique and Dichloro-dihydro-fluorescein diacetate assay, respectively. In addition, the differential expression of proinflammatory and/or oxidative stress-related genes was analyzed by Real-time polymerase chain reaction (PCR) and an oxidative stress gene expression PCR array. Finally, a phosphoproteomic analysis was conducted in order to find out which kinase signalling pathways are modulated by CeO_2NPs.

Results: CeO_2NPs did not modify HepG2 cell viability in basal conditions but restored H_2O_2- and LPS-induced cell death. Moreover, CeO_2NPs prevented H_2O_2-induced overexpression of genes with oxidase activity, including myeloperoxidase (MPO) and Prostaglandin-Endoperoxide Synthase 1 (PTGS1). This was also observed on analyzing inducible nitric oxide synthase (iNOS). Furthermore, H_2O_2 significantly induced an increase in the intensity of phosphorylation which was partially or totally reverted following CeO_2NPs exposure in 39 of a total of 3254 identified and quantified peptides. These peptides were related to cellular proliferation, stress response, cytoskeleton signalling, and gene transcription regulation. In addition, a Kinase Substrate Enrichment Analysis revealed that CeO_2NPs acted modulating MAP/ERK, AKT, CK2A1, and PRKCA signalling pathways, reverting H_2O_2 effects

Conclusion: CeO_2NPs protect human-derived hepatocytes from exogenous and endogenous oxidative damage via reduction of ROS generation and inflammatory gene response regulating MAP/ERK, AKT, CK2A1, and PRKCA signalling pathways.

Acknowledgments: This work was supported by two grants from MINECO (SAF15-64126-R and P74844I/15/00777).

Interaction between hepatic sinusoidalendothelial cells and monocytes modulates IL33 driven Th2 dependent liver fibrogenesis

J. Reissing, M. Inzaugarat, M. Frissen, L. Lijun, D. Kroy, M.-L. Berres, A. Wree, C. Trautwein, Z.H. Wolfgang. *Klinik für Gastroenterologie, Stoffwechselerkrankungen und Internistische Intensivmedizin, Aachen, Germany*
Email: jreissing@ukaachen.de

Background and Aims: We have previously shown that Th2-polarized CD4+ T-cells are involved in the establishment and

progression of liver fibrosis. We could demonstrate that Th2-inducing and related cytokines correlate with the stage of fibrosis. IL33 as a key driver of Th2 response also has promigratory effect. IL33 level is elevated intrahepatically as well as the systemically in late stages of fibrosis. In vitro studies corroborated that human macrophages and monocytes have the capacity to secrete IL33. Given the fact that monocyte infiltration is pivotal during liver Fibrogenesis we sought to investigate how human monocyte migrate across hepatic sinusoidal endothelial cells (HSEC) impacts on the secretion of IL33. Furthermore we studied the direct role of HSEC in IL33 biology during liver injury.

Method: CD14+ monocytes were isolated from healthy donors and either cultured with serum and liver supernatant of diseased patients or prompted to trans-well migration assay. To this end HSEC were seeded onto membranes with 3 μm pores until grown confluent. After co-incubation postmigratory monocytes were harvested and characterized by qPCR and ELISA. In order to simulate liver environment the lower compartment of this trans-well assay was supplemented with liver supernatant. Accordingly, we evaluated the contribution of HSEC to IL33 secretion upon different stimuli.

Results: Conditioned liver supernatant but not serum of patients with fibrosis led to the release of IL33 by CD14+ monocytes. Transendothelial migration across activated HSEC increased the IL33 expressed. In line postmigratory monocytes displayed less CD14 and higher CD64 surface expression indicating maturation towards a macrophage phenotype. Blocking experiments yielded that IL1β and IFNγ contained in the liver supernatant but not TLR4 ligands such as LPS lead to the induction of IL33 expression. Besides indirect mechanisms HSEC also directly contributed to raised IL33 levels. In trans-well migration assays TNFα stimulated HSECs enable exclusively Th2 polarized CD4+ T-cell, but not naïve Th0 or Th1 cells, to transmigrate.

Conclusion: IL33 expressing cell types including monocytes and HSEC form a gradient of IL33 facilitating T-cell recruitment to the liver dependent on various inflammatory stimuli present in injured tissue. In conclusion HSEC and monocyte interaction controls IL33 driven liver fibrogenesis.

THU-030

Stereochemistry enhances pharmacological properties of APOC3 antisense oligonucleotides

L. Apponi[1], N. Iwamoto[2], M. Frank-Kamenetsky[1], H. Yang[1], M. Braun[1], A. Shah[1], D. Butler[3], G. Lu[1], V. Vathipadiekal[1], S. Menon[1], K. Bowman[4], L. Pittet[5], J. Zhang[1], Z. Zhong[1], C. Vargeese[6], S. Standley[1]. *[1]Wave Life Sciences, Biology, Cambridge, United States; [2]Wave Life Sciences, Oligo Chemistry and Biochemistry Research, Cambridge, United States; [3]Wave Life Sciences, Medicinal Chemistry, Cambridge, United States; [4]Wave Life Sciences, Process Development, Cambridge, United States; [5]Wave Life Sciences, Alliance and Program Management, Cambridge, United States; [6]Wave Life Sciences, Drug Discovery, Cambridge, United States*
Email: lapponi@wavelifesci.com

Background and Aims: Apolipoprotein C-III (ApoC-III) is a protein produced by hepatocytes in the liver that regulates plasma triglycerides. Human genetic studies have established the role of ApoC-III in hypertriglyceridemia and cardiovascular disease. ApoC-III therapeutics currently in clinical trials utilize stereorandom antisense oligonucleotides (ASOs) to target APOC3 mRNA. By contrast, the aims of this preclinical study were to develop a stereopure oligonucleotide targeting APOC3 mRNA and to determine whether stereochemistry enhances pharmacological properties of APOC3 ASOs.

Method: Stereopure APOC3 ASOs were generated using Wave Life Sciences' proprietary technology that enables precise control of stereochemistry. Stereorandom and stereopure APOC3 ASOs were tested *in vitro* and *in vivo*. *In vitro* potency of APOC3 ASOs was measured using Hep3B human hepatocytes. *In vivo* activity of GalNAc-conjugated APOC3 ASOs was measured using mice harbouring the human APOC3 transgene. Mice were dosed s.c. with APOC3 ASOs, and liver APOC3 mRNA levels were measured by qPCR, and serum hApoC-III protein levels were measured by ELISA. ASO liver exposure was measured by hybridization ELISA.

Results: Stereopure and stereorandom ASOs had similar *in vitro* potencies. Both stereorandom and stereopure GalNAc-conjugated APOC3 ASOs demonstrated >90% knockdown of serum hApoC-III *in vivo* at one week after treatment in human APOC3 transgenic mice. However, treatment with stereopure ASOs extended the duration of effect by 4 weeks compared to treatment with stereorandom ASOs. A dose response study of these ASOs in human APOC3 transgenic mice demonstrated a dose-response relationship for all three ASOs. The stereopure ASO was significantly more active than the stereorandom ASOs at the 1 mg/kg dose. At this dose, stereorandom ASOs showed ~45% reduction of liver mRNA and 70% reduction of serum hApoC-III protein, while the stereopure ASO showed 75% reduction of mRNA and 90% reduction of serum hApoC-III protein. ASO liver exposure demonstrated a PK/PD correlation for stereorandom and stereopure ASOs. Furthermore, liver exposure of stereopure ASOs was up to 4.5-fold greater than stereorandom ASOs.

Conclusion: These results suggest that stereochemistry increases both the duration and the potency of APOC3 ASOs, thereby potentially enhancing the pharmacological properties of ASOs for APOC3 targeting in the clinic.

THU-031

Hypoxia strongly modulates hepcidin mRNA expression via macrophage-hepatocyte crosstalk

I. Silva[1], T. Peccerella[2], G. Millonig[1], H. Seitz[1], S. Mueller[1], V. Rausch[1]. *[1]Center for Alcohol Research and Salem Medical Center, University of Heidelberg, Heidelberg, Germany; [2]Salem Medical Center and Center for Alcohol Research and Liver Disease, University of Heidelberg, Heidelberg, Germany*
Email: ines.silva@uni-heidelberg.de

Background and Aims: Liver-secreted hepcidin is the systemic masterswitch of iron homeostasis and its dysregulation is a key event for carcinogenic iron accumulation in most of chronic liver diseases. Hepcidin is strongly upregulated by iron, inflammation, cytokines or H_2O_2 but the role of liver monocyte-derived macrophages and Kupffer cells on hepcidin regulation under (patho)physiological conditions is poorly understood. We here investigate the cellular crosstalk involved in hepatic hepcidin regulation by developing an *in vitro* co-culture model of hepatocytes and macrophages mimicking physiological cell distribution and oxygen levels.

Method: Huh7 cell and THP-1 monocytes differentiated into macrophages were directly co-cultured at a physiological (10:1) or inflamed (4:1) cellular proportion under normoxic (21% O_2) or hypoxic conditions (1 or 5% O_2) over 24 h. The incubation of Huh7 cells with macrophage conditioned medium was also investigated. Hepcidin mRNA levels were assessed by qRT-PCR, cellular hypoxia was confirmed by staining of pimonidazole adducts and increased levels of H_2O_2 were detected by Prx2 immunoblotting. Contribution of STAT3 and BMP/SMAD pathway on the transcriptional upregulation of hepcidin was analyzed by STAT3, pSTAT3, pSMAD1/5/8 and SMAD1 western blot. A cytokine array was carried out to assess the role of macrophage-secreted cytokines.

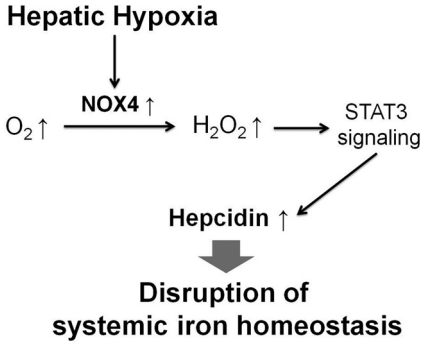
Results: We first demonstrated that the presence of macrophages leads to significantly increased hepcidin mRNA levels. This effect was even potentiated when co-cultivated cells were maintained under low O_2 levels (1% and 5% O_2) and the induction of hepcidin was more pronounced under 1% O_2 as compared to 5%O_2. Interestingly, hepcidin was also upregulated when exposed to macrophage-conditioned medium suggesting the role of a soluble and secreted factor in mediating hepatocyte hepcidin regulation. Western Blot analysis points towards the involvement of STAT3 and BMP signaling pathway, since pSTAT3 and pSMAD1/5/8 are increased in co-cultures or Huh7 cells treated with macrophage-conditioned medium. Finally,

the induction of Prx2 and IL-1β under these conditions suggests a synergistic role H_2O_2 or an H_2O_2-releasing oxidase on hepcidin regulation.
Conclusion: Our findings underscore the importance of the hepatocyte/macrophage crosstalk for hepatic hepcidin regulation that include a secreted factor (IL-1β, TGF-β) and H_2O_2 release by oxidases such as NOX2 under (patho)physiological low oxygen levels.

THU-032
Hypoxia enhances H2O2-mediated upreguation of hepcidin: potential role of oxidases in iron regulation

I. Silva, V. Rausch, T. Peccerella, G. Millonig, H. Seitz, S. Mueller. *Center for Alcohol Research and Salem Medical Center, University of Heidelberg, Heidelberg*
Email: ines.silva@uni-heidelberg.de

Background and Aims: The liver-secreted peptide hepcidin plays a major role in the regulation of iron homeostasis being also critical for the pathological liver iron accumulation in alcoholic liver disease (ALD). Iron, inflammation, cytokines or H_2O_2 are able to induce hepcidin expression, however the role of hypoxia alone and in combination with low levels of H_2O_2 is poorly understood. We here study hepcidin signaling in liver cells under hypoxia and H_2O_2 and the involvement of oxidases, such as NOX4, as potential upstream hepcidin regulators.
Method: Two hypoxic systems (hypoxia chamber and the enzymatic GOX/CAT system) were used to maintain low oxygen level (5% O_2) over 24 hours in Huh7 cells and in primary human hepatocytes, the later system also allowing the control low steady state (ss) H_2O_2 levels. The role of hypoxia on hepcidin promoter activity was assessed by transfecting the cells with Luciferase reporter hepcidin promoter constructs. Transfection of hepatoma cells with ODD-GFP constructs was carried out in order to competitively inhibit HIF1α degradation. The involvement of the liver expressed NADPH oxidase 4 (NOX4) as well as urate oxidase (UOX) was assessed by overexpressing NOX4 or UOX promoter constructs. Hepcidin and NOX4 mRNA levels were studied by qRT-PCR. Cellular hypoxia was confirmed by staining of pimonidazole adducts and H_2O_2 levels were analyzed by Prx2 western blot.



Results: We first show that hypoxia generated either by hypoxia chamber or the GOX/CAT system induced hepcidin mRNA in Huh7 cells and primary human hepatocytes over 24 h. Hypoxia-mediated induction of hepcidin was further potentiated during co-exposure of cells with low ss H_2O_2 levels predominantly at the transcriptional level via STAT3 signaling pathway. Both, Prx2 oxidation and STAT3 phosphorylation mirrored intracellular H_2O_2 and changes in hepcidin mRNA levels. Notably, NOX4 was also strongly upregulated in hepatocytes during hypoxia, suggesting a mechanistic role in mediating hepcidin upregulation. Overexpression of NOX4 increased hepcidin mRNA and this effect was even higher at low O_2 levels. Moreover, similar results were obtained after overexpression of UOX in Huh7 cells. Blockage of HIF1α degradation caused indeed specific HIF1α accumulation, however hepcidin upregulation was not detected. This clearly showed that hypoxia-mediated hepcidin regulation occurs independently of HIF1α.
Conclusion: We here show that hypoxia drastically enhances the H_2O_2-mediated induction of hepcidin via STAT3 in hepatocytes. Our data suggest that oxidases such as NOX4 play a major role in the regulation of hepcidin.

THU-033
Reduced PI3K pathway in NK cells of F4-NAFLD patients inhibited mTOR expressions and was correlated with their impaired function

J. Amer[1], A. Salhab[2], R. Safadi[1]. [1]*Hadassah Hebrew University Hospital, Jerusalem, Israel;* [2]*Hadassah Hebrew University Hospital, Jerusalem*
Email: johnnyamer@hotmail.com

Background and Aims: Stimulation of Natural Killer cells (NK, $CD56^+$) directly kill the activated hepatic stellate cells (HSCs). We investigated changes in insulin receptor on NK cells as a potential cause for their impairment in Nonalcoholic-Fatty Liver-Disease (NAFLD).
Methods: Fresh peripheral blood NK cells isolated from healthy volunteers and 72 NAFLD patients (histology documented adults lacking full criteria of metabolic-syndrome), and characterized by flow-cytometry.
Results: Histologic progression of liver injury significantly correlated with elevated pro-inflammatory serum cytokines and insulin resistance. NK cells stimulation marker (CD107a) over-expressed in low-fibrosis patients, but kept low in advanced-fibrosis (*NK impairment*). Insulin receptors expressed on 68.6 ± 8% of healthy peripheral $CD56^{dim}$ population ($CD16^+$), but significantly reduced in all NAFLD stages. Western blot analysis of NK cells form NAFLD patients with F4 fibrosis showed to have dramatically reduction in PI3K pathway. ERK/MAP kinase pathway showed also reductions in these patients. These results were correlated with inhibitions in mTOR activity ($p = 0.001$). NK stimulations with insulin (physiologic levels) reversed these effects. Compared to normal HOMA NK-cells by *in-vitro* co-culture with HSCs, high-HOMA $CD56^{dim}$ cells (with F3-F4) exhibited increased apoptosis and fail to block HSCs activation. While insulin incubation stimulated NK cell activation and killing of HSCs. Rapamycin reduced $CD56^{dim}$ expressions of insulin receptors (mimicking NAFLD insulin resistance) and prevented the insulin stimulation effect on NK cells.
Conclusion: Insulin exposure stimulates NK cells to enhance HSCs killing and prevent fibrosis progression. Insulin receptors mediate NK cell stimulation by insulin via PI3K pathway and as a consequence the mTOR pathway. Systemic Insulin-Resistance in NAFLD includes the NK cells. Therefore, insulin fails to stimulate NK cells due to low insulin receptor NK expressions and or low serum insulin levels, which leads to cirrhosis and probably cancer.

THU-034
Constructing a cell-type resolved human liver proteome atlas

L. Niu[1,2], P. Geyer[1,2], M. Mann[1,2]. [1]*University of Copenhagen, Novo Nordisk Foundation Center for Protein Research, Copenhagen, Denmark;* [2]*Max Planck Institute of Biochemistry, Proteomics and Signal Transduction, Planegg, Germany*
Email: lili.niu@cpr.ku.dk

Background and Aims: The liver lobule is composed of parenchymal cells (hepatocytes and bile duct cells) and non-parenchymal cells (liver sinusoidal endothelial cells, Kupffer cells and hepatic stellate cells). In contrast to hepatocytes, which occupy almost 80% of the liver volume, non-parenchymal cells only contribute 6.5%. Although hepatocytes perform the majority of numerous liver functions, it has been increasingly recognized that hepatocytes together with non-parenchymal cells cooperate to achieve a wide variety of vital functions in liver homeostasis. Disturbance or malfunction of any of these cells can contribute to multiple diseases, such as non-alcoholic fatty liver disease, cirrhosis and hepatocellular carcinoma.

Modern mass spectrometry (MS)-based proteomics is a powerful tool to globally investigate the biological functions of individual cell types in mammalian organs. Characterizing nearly complete proteomes of the different liver cell types would dramatically aid in understanding their functions at the molecular level. In the past, several murine deep liver proteomes have been described, providing new insight into functions of the liver. The most comprehensive MS-based human liver proteome so far is generated by The Human Proteome Organization (HuPO)-a database called "Liverbase". However, its coverage of expressed liver proteins is still far from complete.
In this study, we aim to use MS-based proteomics to systematically characterize cell-type resolved human liver proteomes.
Method: Isolated primary cell types as well as corresponding immortalized cell lines are being analysed in great depth by next-generation proteomic technology. Human liver tissue samples from healthy and cirrhotic patients are also included in our study to compare their differences in protein expression and metabolic pathways.
Results: Our preliminary results indicate that more than 10,000 proteins can be quantified in cell types as well as in liver tissues, which should lead to the largest and most accurate reflection of the human liver to database. We plan to make this in-depth and user-friendly database will be public available, to be used as a resource by the whole community. It can also be used to perform comparative analysis to reveal cell-type-specific proteomic profiles as well as the "division of labour" and biological processes among distinct cell types. The comparison between healthy and cirrhotic liver tissue identifies differential protein expression profiles and altered metabolic pathways.
Conclusion: Upon completion, our extensive liver protein database will represent a very broad proteome map of the human liver at cell-type resolution. This MS-based liver proteome atlas will serve as a reference database for basic research as well as biomarker discovery studies in the context of liver disease.

Metabolic rewiring and de novo lipogenesis induced by Glucokinase expression in hepatocarcinoma cell line

B. Panthu[1], G. Rautureau[2], C. Jacquemin[1], B. Elena-Herrmann[2], P. Andre[1], O. Diaz[1], V. Lotteau[1]. *[1]INSERM U 1111 – CNRS UMR5308 Université Lyon 1, ENS de Lyon, Centre de Recherche International en Infectiologie, Lyon, France; [2]Institut des Sciences Analytiques, UMR 5280 CNRS, Villeurbanne, France*
Email: vincent.lotteau@inserm.fr

Background and Aims: Human hepatocarcinoma cell lines are in vitro models for the study of lipid metabolism, hepatic steatosis and carcinogenesis. However, these cells have an unbalanced lipid metabolism that is strongly dependent on exogenous fatty acids to synthesize triglycerides and lipoproteins. This motivates the need for a physiologically relevant hepatocyte *in vitro* model allowing a deep analysis of the cellular mechanisms that regulate glycolysis, *de novo* lipogenesis and lipoprotein synthesis in normal and pathological situations.
Method: Like virtually all cancer cells, hepatocarcinoma cells express the "cancer-type" hexokinase isoenzyme HK2. Here, we restored the hepatic hexokinase isoenzyme (glucokinase, GCK) expression in the paragon hepatocarcinoma cell line Huh7 invalidated for HK2 by CRISPR-Cas9. Endo- and exo-metabolites have been analysed by a combined approach of biochemistry and high-field Nuclear Magnetic Resonance metabolomics.
Results: Metabolomic analysis highlighted that although glucose consumption remains identical in HK2-Huh7 and GCK-Huh7 cells, a profound metabolic remodelling toward *de novo* lipogenesis occurred in GCK-Huh7 cells. Accompanying *de novo* lipogenesis are an increased consumption of pyruvate by mitochondria, a truncated TCA cycle at the level of succinate dehydrogenase with a reduced mitochondrial respiration and activated pentose phosphate and glutamine pathways. This drastic metabolic remodelling sensitized GCK-Huh7 cells to both fructose-induced lipid accumulation and viral infection.
Conclusion: Restoring GCK expression in current hepatoma cells has induced a large scale metabolic remodelling with a balanced lipid metabolism mimicking *in vivo* lipogenesis. This physiologically-relevant hepatocyte model will certainly provide improved clues to control liver inflammation, NASH and tumorigenesis.

THU-036

Role of septin 9 in interferon gsignalling and the development of cholangiocarcinoma

J. Peng[1,2], D. Ouazib[1,2], Y. Ding[1,2], N. Benzoubir[1,2], D. Samuel[3], A. Gassama[1,2]. *[1]INSERM, Unité 1193, Université Paris-Saclay, Villejuif, F-94800, France, Villejuif, France; [2]Univ Paris-Sud, UMR-S 1193, Université Paris-Saclay, Villejuif; [3]AP-HP Hôpital Paul-Brousse, Centre Hépato-Biliaire, Villejuif, F-94800, France, Inserm, Unité 1193, Université Paris-Saclay, Villejuif, F-94800, France, Villejuif, France*
Email: yifanding903@gmail.com

Background and Aims: Hepatobiliary cancer comprises a heterogeneous group of malignancies. Our proteomic study revealed that septin 9 was found among of proteins only detected in Cholangiocarcinoma (CCA) tissue. Thus suggesting that septin 9 might contribute to the progression of CCA.
Septin 9 is a member of a conserved family of GTP-binding proteins that have roles in cytokinesis, vesicle trafficking and cell migration. Although the potential role of septin 9 in carcinogenesis has remained unspecified. We identified different partners of septin 9 including molecules of phosphoinositides signalling. These studies revealed a role of septin 9 in the regulation of interferon γ (IFNγ) signaling.
The aims of this study is to determine the function of septin 9 in CCA and its identified partners in the regulation of IFNγ signalling.
Method: We used MzChA-1 cells (Biliary adenocarcinoma cell line) and Hela cells to perform the study. Cells were transfected using the cDNA and siRNA of septin 9 and its partners. Proteins were analysed by immunoblot or immunofluorescence. Immunohistochemistry was performed on paraffin sections tissus array of CCA.
Results: Our results show the association of septin 9 with PIs specially PtdIns5P. Upon stimulation of cells with IFNγ, we observed a recruitment of septin 9 and PtdIns5P in the perinuclear area. Septin 9, regulated STAT1 phosphorylation after INFγ treatment.
IFNγ treatment induced PD-L1 (Programmed death-ligand 1) expression at membrane which expression is considered as an adaptive resistance mechanism that protects tumor cells from T cell-mediated-destruction and promotes cancer progression. Interestingly, flow cytometry analysis showed Septin 9 expression upregulated PD-L1 after IFNγ treatment. Furthermore, we showed a new role of septin 9 in endosomal trafficking which is responsible of accumulation of PDL1.
PD-L1 expression was analyzed in different type of CCA and the data were correlated with clinicopathological features, density of tumor-infiltrating lymphocytes (TILs). PDL1 expression is higher in CCA than the other liver cancers. Of interest a positive relationship was observed between PD-L1, the number of CD3 and CD8 TILs and septin 9 expression.
Conclusion: We identified a new molecular cascade that regulate endolysosomal trafficking and responsible for PDL1 disregulated in CCA. Together these findings have provided the rationale for further development of diagnosis markers and immunotherapy treatments against CCA.

THU-037

Molecular and histological characterization of the pathological events in a model of cirrhosis and hepatocarcinoma

M.P. Castro-Gil[1], J.E. Torres-Mena[1], C.D. López[1], S. Muñoz-Montero[2], R.M. Salgado-Curiel[3], E. Krötzsch[3], J.I. Pérez-Carreón[1]. *[1]National Institute of Genomic Medicine, Liver Diseases Laboratory, Mexico city, Mexico; [2]National Institute of Genomic Medicine, Computational Genomics, Mexico City, Mexico; [3]National Institute of Rehabilitation, Laboratory of Connective Tissue, Mexico City, Mexico*
Email: polesia77@gmail.com

Background and Aims: Despite the increasing knowledge in the basis of hepatocellular carcinoma (HCC) there are few studies comprising molecular and histological features in a carcinogenic development scheme. One of the constitutive properties of pre-neoplastic and neoplastic nodules in rat hepatocarcinogenesis models is the expression of the enzyme Gamma Gluatmyltranferase (GGT). On the other hand, the expression of the biliary/progenitor cell marker Keratin 19 (K19), has gained importance in the field because it is associated with a poor prognosis. In a healthy liver, both markers are only expressed in cholangiocytes and hepatic progenitor cells. Nevertheless, they can be observed in neoplastic hepatocytes. Our Aim was to determine the transcriptome profile of pre-tumoral and tumoral lesions GGT/K19 positive, and their surrounding context in collagen deposition in a rat model of hepatocarcinogenesis.
Method: Hepatocarcinogenesis was induced in Fisher 344 rats using the Schiffer's protocol that consists in weekly intraperitoneal injections of diethylnitrosamine (DEN) which causes cirrhosis at 12 weeks (pretumoral) and multifocal HCC at 18 weeks (tumoral). Normal livers of non-treated rats were used as controls. Fibrosis process (i.e. collagen deposition) and hepatic damage were evaluated through 2 histologic methods; Herovici's staining and GGT histochemistry. GGT/K19 lesions were captured using laser microdissection and RNA obtained from these samples was sequenced by NGS (RNA-Seq).
Results: Normal liver tissues presented GGT and collagen deposition only in bile ducts and blood vessels, while pretumoral tissues presented type III collagen around nodules. The amount of collagen increased in tumors as compared to the pretumoral tissues and presence of both, type I and type III collagen was observed. Type III collagen is not as stiff as type I, it is linked with recent and acute healing processes. Type I collagen is related to a mature healing state. Previous studies have revealed that lax environments are associated with progenitor characteristics. This statement may justify the presence of pretumoral and tumoral lesions GGT/K19 positive. RNA sequencing data were analyzed through a principal component analysis (PCA), showing that samples cluster in two main groups; Normal Liver and Liver Lesions. The lack of distinction between pretumoral and tumoral lesions by PCA may be the consequence of the same phenotypical selection criteria. Further gene enrichment analysis may provide differences within the tissular context that might contribute to understanding liver carcinogenesis.
Conclusion: Schiffer's protocol is a hepatocarcinogenesis model useful for the study of the progression of pretumoral lesions with progenitor characteristics. The tumorigenic state of these lesions may be influenced by extracellular characteristics such as the type of collagen deposition.

THU-038

The emerging realm of morphogens in the adult liver of mice and human – a deep insight into distribution, interaction and regulation

E. Schröder[1], C. Rennert[2], J. Böttger[1], D. Meierhofer[3], R. Gajowski[3], C. Stöpel[4], H. Stefan[4], W. von Schönfels[5], C. Schafmayer[5], M. Brosch[6], J. Hampe[6], R. Gebhardt[1], M. Matz-Soja[1]. *[1]Rudolf-Schönheimer-Institute of Biochemistry, Faculty of Medicine, Leipzig, Germany; [2]Saxonian Incubator for Clinical Translation (SIKT), Leipzig University; [3]Max Planck Institute for Molecular Genetics, Mass Spectrometry Faculty, Berlin, Germany; [4]Institute for Computer Science, Leipzig University, Leipzig, Germany; [5]Department of General Surgery and Thoracic Surgery, University Hospital Schleswig-Holstein, Kiel, Germany; [6]Medical Department 1, University Hospital Dresden, Dresden, Germany*
Email: madlen.matz@medizin.uni-leipzig.de

Background and Aims: Morphogens like Hedgehog (Hh) and Wnt/β-Catenin (Wnt) are known to govern developmental processes in embryogenesis, tissue differentiation and regeneration. More recently, the impact of those morphogens on adult cell physiology and metabolism has sparked increasing interest. Most metabolic pathways in the liver are strongly zonated, partially caused by adapting to changing contents of nutrients and oxygen within the porto-central axis. The question of how morphogens contribute to the lobular distribution of metabolic pathways, is part of an evolving field in science since the last decade. Initially, the pericentral located Wnt pathway was thought to be exclusively responsible for liver zonation of ammonia and glucose metabolism. Recently, our group demonstrated that the Hh pathway has an immense impact on lipid metabolism in the adult liver of mice and man. For a better understanding of metabolic liver zonation under morphogenic control, we aimed to demonstrate the mutual impact and zonal distribution of Hh and Wnt/β-Catenin signaling.
Method: To address this question, human material was used as well as different mouse models were bred, which allow a hepatocyte-specific modulation of these pathways in adult mice. To depict the porto-central distribution of different pathway markers, liver slices were stained by immunohistochemistry and analyzed by the modular software tool TiQuant. This tool allows an efficient quantification of biological tissues based on volume data obtained by biomedical image modalities. In addition, proteome profiling of murine liver samples was used to study the global impact of morphogens on the metabolic liver function.
Results: The immunohistological analysis indicates where central proteins of Hh and Wnt are localized and how they influence each other upon pathway modulation. Furthermore, the outcome of the proteome approach provides deep insights on how morphogens regulate the liver metabolism in detail and contribute to a better understanding of the fine tuning mechanism in metabolic zonation of the liver.
Conclusion: Our results give a deep insight for the first time into the distribution, interaction and localization of morphogenic pathways like Wnt and Hh in the adult liver of mice and humans. From the results we conclude a strong crosstalk between Wnt and Hh signaling pathways which orchestrate the metabolic zonation of the liver.

THU-039

Direct and indirect hepatoprotective mechanism of CBLB502 a TLR5 agonist

N. Melin[1], R. Fahrner[2], A. Keogh[1], M. Medova[1], Y. Zimmer[1], D. Aebersold[1], D. Candinas[1], G. Beldi[1], D. Stroka[1]. *[1]University of Bern, Department for BioMedical Research, Bern, Switzerland; [2]Uniklinikum-jena, Klinik für Allgemein-, Viszeral- und Gefäßchirurgie, Jena, Germany*
Email: nicolas.melin@dbmr.unibe.ch

Background and Aims: CBLB502 is a synthesized peptide from bacterial flagellin known to be an agonist of toll-like receptor 5 (TLR5) showing protective properties in various model. Here we investigated its potential hepatoprotective effect and mechanism of action.

Method: A mouse model of partial liver ischemia reperfusion (I/R) was used to assess the hepatoprotective effect of CBLB502 against acute liver injury and assessed by serum ALT/AST levels and tissue myeloperoxidase activity. Hepatic NF-kappaB and Stat3 signaling was evaluated by western blot and q-PCR. Serum cytokine were measured by cytokine bead array.
Results: Preliminary data show that in mice treated with 0.2 mg kg^{-1} CBLB502 I.P., there is a beneficial influence on clinical symptoms of hepatic ischemia reperfusion injury by reducing ALT/AST and myeloperoxidase activity. Direct protective mechanism, was shown by induction of NF-kappaB signaling in hepatocytes and liver as well as downstream cytoprotective genes. In parallel, TLR5 induced cytokine response was accessed showing increased in various serum cytokines and IL-22 level was the most striking (2 μg/ml). IL-22 produced by cells found in colon and MLN was shown to activate Stat3 signaling in hepatocyte thus inducing hepatoprotection through an indirect mechanism.
Conclusion: I/R injury associated with hepatic resections and liver transplantation remains a serious complication in clinical practice. Hepatic damage could potentially be diminished by prior activation of an innate immune response targeting TLR5.

THU-040

Towards understanding the mechanisms of chlorpromazine-induced hepatic toxicity using a human HepaRG-based model

J. Brzeszczynska, K. Morgan, F. Brzeszczynski, K. Samuel, P. Hayes, J. Plevris. *University of Edinburgh, Hepatology Laboratory, Edinburgh, United Kingdom*
Email: j.plevris@ed.ac.uk

Background and Aims: We have previously shown, using impedance biosensor technology, that chlorpromazine (CPZ) induces early, dose-dependent disruption of tight junctions even at sub-toxic CPZ levels (25 μM).[1] In this study we investigated the molecular mechanisms that may mediate the hepatic alterations induced by CPZ in the human HepaRG model and in particular those related to inflammation and oxidative stress.
Method: HepaRG cells were exposed to CPZ concentrations of 25, 50 and 100 μM for 24 h. Cell viability was assessed by ATP-depletion assay (CellTiter-Glo). Assessment of cytoskeleton intergrity was performed by TJ-associated/F-actin expression following CPZ challenge. A number of molecular markers were analysed using qPCR (N = 3). The fold change in expression of target genes relative to the internal control genes (TOP1, UBC and GAPDH) was calculated. QRT-PCR data were presented as the fold change in gene expression normalised to the average value of 3 common endogenous reference genes and relative to control (untreated cells).
Results: CPZ induced extensive cell death at 100 μM. At concentrations of 25 and 50 μM, cell viability by ATP-depletion assay was not significantly impaired. As previously demonstrated, cytoskeletal changes suggestive of tight junction disruption were seen. CPZ provoked a dose dependent inflammatory response [3-fold at 25 μM and 10-fold at 50 μM) for IL-6 as well as 2.7-fold at 25 μM and 8-fold at 50 μM for TNFα. This response was associated with 0.5-fold down regulation of HNF4α transcript and cytochrome 3A4 at 50 μM. mRNA expression of bile canalicular transporters ABCB11 (bile salt exporter pump), ABCB4 (phospholipids transporter) and ABCB1 (drug efflux transporter) was decreased. 50 μM of CPZ induced 20-fold increase in the expression of ABCB11 likely to represent a hepatoportective response to accumulation of toxic bile acids (BA). GGT1 a key anti-oxidative compound was up regulated. Expression of Bax (pro apoptotic gene) was increased at 50 μM, while the Bcl2 anti apoptotic gene was upregulated in 25 and 50 μM CPZ treated cells. AIF1 and p53 gene expressions were unchanged. Nrf2 was up regulated by 2.3-fold in 50 μM CPZ treated cells.
Conclusion: Our results show that an inflammatory response is induced by CPZ at 25 and 50 μM, resulting in activation of anti oxidant and anti apoptotic defence pathways Nrf2 and Bcl2 with evidence of intracellular oxidative stress perhaps caused by accumulation of bile acids with reduction of cytochrome 3A4 activity and adaptive upregulation of GGT1. In conclusion we demonstrate that CPZ appears to cause disruption of hepatic cytoskeleton through an inflammatory response and induction of intracellular oxidative stress.

Uncovering the liver Notch code using high-throughput reporter imaging on micropatterns

J. Mašek[1], C. Vervuurt[1], S. Hankeova[2], U. Lendahl[2], A. Lindqvist[2], E. Andersson[1]. *[1]Karolinska Institute, Department of Sciences and Nutrition, Huddinge, Sweden; [2]Karolinska Institute, CMB, Stockholm, Sweden*
Email: jan.masek@ki.se

Background and Aims: Notch signaling is a key communication system in animals, which can, when disturbed, drive both liver disease and cancer. Mutation of either *JAGGED1* or *NOTCH2* leads to the dominant genetic multisystemic disorder Alagille syndrome (also known as arteriohepatic dysplasia) characterised by impaired biliary development (1). We have recently shown that homozygous Jag1H268Q mutation mimics Alagille syndrome in mouse, including cholestasis, bile duct paucity and heart defects (2). This mutation generates a hypomorphic ligand with impaired capability to induce Notch signaling, and hampered ability to interact with specific Notch receptors: Jag1H268Q binds Notch2, but not Notch1, and to a lesser degree Notch3. Almost all Notch receptors and ligands are expressed in developing embryonic liver (3, 4). However, the parameters dictating the output of Notch receptor-ligand interaction diversity – the "Notch code" – remains poorly understood.

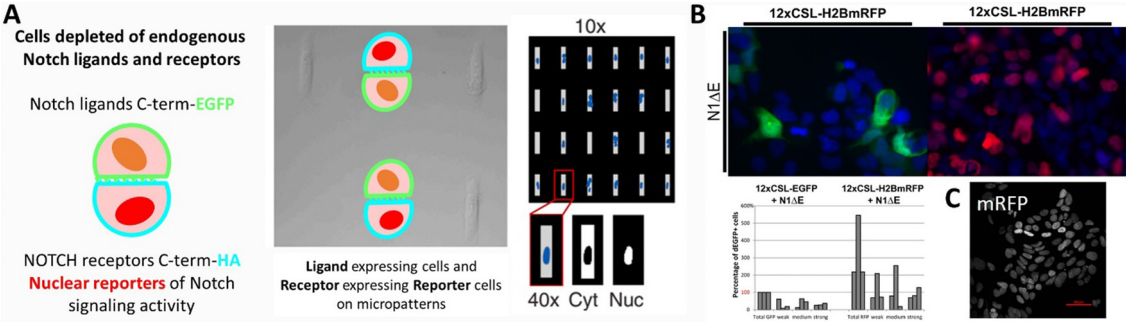

Figure: (abstract: THU-041)

Our aim is to address the combinatorial code of individual Notch ligands and receptors, in a clean system and with single-cell resolution, allowing us to predict and fine tune Notch signaling.
Method: We are generating a cell line, devoid of all endogenous Notch sinaling components, using CRISPR/Cas9 technology. Individual receptors and ligands will then be re-introduced in defined combinations, allowing us to assess their output using high-throughput microscopy on micropatterns.
Results: We have developed high-throughput reporter imaging on micropatterns that allows for quantification of Notch signaling in individual cells or doublets of cells.
Conclusion: We have achieved reproducible measurement of Notch signalling activity by stable integration of our new 12xCSL-H2B-mRFP reporter into HEK293 Flp-in cells.
High-throughput reporter imaging on micropatterns. (**A**) Schematic representation of the planned experiment. 16,000 fibronectin-coated patches per slide allow for automated, high-throughput assessment of Notch signaling strength and duration. Adapted from (5). (**B**) Comparison of signal robustness in response to Notch stimuli (constitutively active Notch1 - N1dE) between the 12xCSL-d1EGFP and newly generated 12xCSL-H2BmRFP reporters in transient transfection. Nuclear reporter signal will be easier to quantify in an automated fashion. (**C**) Different levels of endogenous Notch activation in stable12xCSL-H2BmRFP reporter line generated using HEK Flp-IN system (Thermo Fisher Scientific).

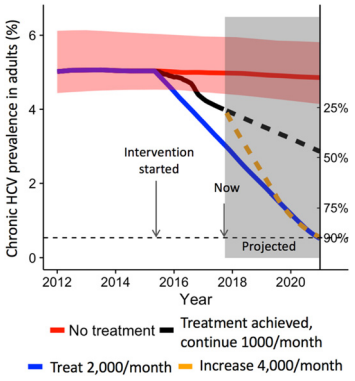
THU-047

Interim evaluation and projected impact of the hepatitis C virus elimination program in Georgia

J. Walker[1], L. Gvinjilia[2], M. Nasrullah[3], A. Gamkrelidze[4], J. Morgan[5], P. Vickerman[1]. *[1]University of Bristol, Population Health Sciences Bristol, United Kingdom; [2]CDC Foundation, Tbilisi, Georgia; [3]CDC, Division of Viral Hepatitis, United States; [4]National Center for Disease Control and Public Health, Tbilisi, Georgia; [5]CDC, Global Disease Detection, Division of Global Health Protection, Tbilisi, Georgia*
Email: jogwalker@gmail.com

Background and Aims: Georgia has one of the highest hepatitis C virus (HCV) prevalence rates in the world, with >5% of the adult population (~150,000 people) chronically infected. In April 2015, the Georgian government, in collaboration with CDC and other partners, launched a national program to eliminate HCV through scaling up HCV treatment and prevention interventions, with the aim of achieving a 90% reduction in prevalence by 2020. We evaluate the impact of the HCV treatment program as of 30 September 2017, and assess the feasibility of achieving the elimination goal by 2020.
Method: We developed a dynamic HCV transmission model that aims to capture the current and historical epidemic dynamics of HCV in Georgia, including the main drivers of transmission. Using the 2015 national sero-survey and prior surveys conducted among people who inject drugs (PWID) from 1997–2015, the model was calibrated to data on HCV prevalence by age, gender and PWID status, and the age distribution of PWID. We use the model to project the interim impact of treatment strategies currently being undertaken as part of the ongoing Georgia HCV elimination program, while accounting for treatment failure/loss to follow up, in order to determine whether they are on track to achieving their HCV elimination target by 2020, or whether strategies need to be modified to ensure success.
Results: A treatment rate of 2,000 patients/month was required from the beginning of the national program to achieve a 90% reduction in prevalence by the end of 2020, with equal treatment rates of PWID and the general population. From April 2015 to September 2017, 39,396 patients were treated, an average of ~1,300 per month; but the treatment rate has recently declined from a peak of 4,500/month in September 2016 to 2100/month in November-December 2016, and 1000/month in August–September 2017, with a sustained virological response rate (SVR) of 98% per-protocol or 78% intent to treat. The treatments achieved have, as of September 2017, reduced adult chronic prevalence by 21% (15–29%) to 4.0% (3.3–5.2%), reduced total incidence by 19% (13–27%), and prevented 1457 (802–2563) new infections and 80 (27–140) HCV-related deaths. If the treatment rate of 1000 patients initiated per month continues, prevalence will have halved by 2020, and reduce by 90% by 2028. In order to reach a 90% reduction by 2020, with the same SVR rate, the treatment rate must be quadrupled to about 4,000 per month (Figure).



Conclusion: The Georgia HCV elimination program has accomplished an impressive scale up of treatment, which has already had an impact on prevalence and incidence, and averted deaths due to HCV. However, treatment initiation has fallen short of the target and extensive scale up is needed to achieve a 90% reduction by 2020.

Email: fabienne.marcellin@inserm.fr

Background and Aims: Cannabis is frequently used by HIV-HCV co-infected individuals to relieve disease-related symptoms. Its use is associated with reduced risk of insulin resistance and steatosis, two conditions linked to increased mortality risk. We aimed to evaluate the impact of cannabis, coffee and other psychoactive substances (alcohol and tobacco) on HCV-related mortality, taking into account competing causes of death.
Method: ANRS CO13 HEPAVIH is a French nationwide prospective cohort of HIV-HCV co-infected patients collecting medical and psychosocial/behavioural data. We used Fine and Gray's competing-risk proportional sub-hazards model to estimate the effect of cannabis and of other psychoactive substances on HCV-related mortality, taking into account competing causes of death and adjusting for HIV/HCV clinical characteristics.

Table: Characteristics of the study population and factors independently associated with HCV-related mortality* (the ANRS CO13 HEPAVIH cohort, n = 1,028)

		%	No. of HCV deaths	aSHR	95% CI	p-value
Smoking status§	Current	71.8	59	1		
	Never/past	26.5	15	0.36	0.14–0.95	0.039
Coffee	≤1	51.3	24	1		
consumption§	2	22.1	6	0.83	0.33–2.10	0.698
(cups/day)	≥3	26.6	3	0.37	0.15–0.88	0.025
Cannabis	Never/sometimes	65.5	50	1		
consumption§	Regularly/daily	24.8	18	0.32	0.11–0.98	0.047

§measured at baseline
*The multivariate model is adjusted for gender, BMI, history of HCC/liver transplantation, previous indirect clinical signs of cirrhosis, CD4 cell count, HIV clinical stage.

Results: Over a median 5-year follow-up period, 77 deaths (including 33 HCV-related deaths) occurred among 1,028 eligible patients. In the multivariable analysis, regular/daily cannabis use, ≥3 cups of coffee/day and not smoking were independently associated with a 68%, 63%, and 64% reduction in HCV-related mortality (adjusted sub-hazard ratio (aSHR) [95%CI]: 0.32[0.11–0.98], 0.37[0.15–0.88], and 0.36[0.14–0.95]), respectively. Results were adjusted for gender, BMI and the following HCV-mortality risk factors: history of hepatocellular carcinoma (HCC)/liver transplantation, previous indirect clinical signs of cirrhosis, CD4 cell count, and HIV clinical stage. No significant association was found between alcohol consumption and HCV-mortality risk.
Conclusion: These results confirm the benefits of elevated coffee consumption and highlight the protective role of regular/daily cannabis use on HCV-mortality risk, despite the negative impact of smoking. Further research is needed to understand the causal mechanism involved.

Background and Aims: In the UK, prevalence of Hepatitis C Virus (HCV) is 50 times higher in the homeless population than the general population.[1] With availability of highly effective, well tolerated Direct Acting Antivirals (DAA), HCV is an easily curable disease as reflected in clinical trials and real world data. However, the homeless are likely to have high rate of multimorbidity, polypharmacy and less likely to engage with hospital services, where traditionally HCV treatment has been delivered from.
In Lothian, there has been an established HCV outreach service at a dedicated general practice for the homeless. This model utilizes a multidisciplinary team (MDT) of GP, support workers together with hepatology nurse practitioner from secondary care. With the advent of DAA, there was a role for a clinical pharmacist to ensure safe and effective use of medicines. HCV medicines were supplied via community pharmacy, often on a daily observed basis which allowed support and monitoring of adherence.
Method: From October "16 to November "17, DAA treatment was commenced. Treatment was led by hepatology nurse practitioner, with input from GP, practice based support workers and consultant hepatologist. The clinical pharmacist advised on Drug Drug Interactions (DDI) and liaised with community pharmacist for supply of medicines. Sustained Viral Response (SVR) was measured 12 weeks after cessation of treatment.
Results:

Total number of patients	31
Male	21 (67.7%)
Age (years)	41 (23–57)
F0–1	23 (74.2%)
F2-3	6 (19.4%)
F4	2 (6.5%)
Fibroscan® available	7 (22.6%)
Genotype 1	20 (64.5%)
Genotype 3	11 (35.5%)
Mean Viral Load (IU/ml)	1,543,345 (6809–8,870,263)
Treatment experienced	4 (12.9%)
Illicit drug use	Previous injectors: 25 Current injectors: 6
HCV treatment	Ombitasvir/Paritaprevir/ritonavir + Dasabuvir + ribavirin (RBV): 4 (12.9%) Elbasvir/Grazoprevir+/−RBV: 11 (35.5%) Ledipasvir/Sofosbuvir+/−RBV: 4 (12.9%) Sofosbuvir/Velpatasvir: 11 (35.5%) Sofosbuvir + Peg-Interferon + RBV: 1 (3.2%)
Average number of medicines per patient	3.4 (1–10)
Opioid substitution therapy (OST)	26 (83.8%)
Number medicines with DDI (n = 105)	11 (10.5%) All amber Treatment changes/Dose adjustments: 0
Dispensing frequency	Daily observed 26 (83.8%)* (*Sunday+/−evening doses unobserved)

To date, 91.7% (n = 24) patients completed >90% treatment. SVR 12 weeks has been achieved in 83% of patients (n = 12). Further data awaited.
Conclusion: This data demonstrates successful treatment of HCV can be delivered in an outreach setting convenient to patients with proactive support of MDT. Pharmacists can support treatment and adherence, particularly through linkage to supply of OST. Engaging with this cohort is key in contributing to goal of eradication of HCV and improving health outcomes in this population.

etiology. There is evidence that aging patients with chronic hepatitis B have a higher incidence of diabetes, hypertension and renal insufficiency. Similarly, clinical manifestations of late stage NAFLD and NASH have been associated with many aspects of metabolic dysfunction. This analysis, the first in an ongoing long-term retrospective analysis, aims to assess the burden of comorbidities in liver disease patients at a large urban liver clinic in Toronto, Canada.

Methods: 3,610 patient charts were retrospectively reviewed and was assigned to one of the following primary liver disease categories: chronic hepatitis B (HBV), chronic hepatitis C (HCV), NAFLD/NASH, autoimmune liver disease (AIH), alcoholic liver disease (ALD), and others. Patient age, sex, BMI, serial liver histology and serology were collected to look at the incidence of obesity (BMI > 29.9), hypertension (HTN), dyslipidemia, type II diabetes, gastroesophageal reflux disease (GERD), cardiovascular disease (CVD), thyroid disease, and various carcinomas.

Results: 3,610 patient charts reviewed: 56.2% males, 43.8% female; percent distribution of liver disease were as follows: NAFLD/NASH 47.7%, HCV only 16.1%, HBV only 16.2%, others 19.8%, with 52.9% ≥50 years of age at last visit. 58.9% of patients were reported to have only 1 liver disease; and 41.1% were reported to have 2 or more liver conditions. The most frequently reported comorbidities were HTN (26.8%), dyslipidemia (26.6%), diabetes (16.1%), thyroid disease (14.4%), and GERD (11.3%). HTN, dyslipidemia and diabetes occurred with greater frequency in the NAFLD/NASH patients compared to those with viral hepatitis (HBV and HCV). Cancer of any type was reported in 6.8% of patients (246/3610), with the following cancers found most frequently: liver/HCC (28.9%) breast (21.1%), and thyroid (8.1%). NAFLD /NASH contributed to 42.2% of overall cancer incidence, with higher number of breast and thyroid cancer reported in NAFLD/NASH patients. Further breakdown by disease etiology seen in Table.

Conclusion: The burden of comorbidities is high among a large sample of liver disease patients of diverse etiology, and is particularly pronounced in patients with NAFLD/NASH, with slightly higher percentage of certain cancers seen in NAFLD/NASH patients compared to other liver disease patients, although the incidence of cancer reported in this cohort was low. While these data are in agreement with much of the emerging data in patients with NAFLD/NASH, data collection for this study will continue with future analyses currently being planned.

Email: Jeffrey.Lazarus@isglobal.org

Background and Aims: Fifteen million people are infected with chronic viral hepatitis C in the WHO European Region, leading to 112,500 deaths per year. With the advent of direct-acting antiviral treatment regimens, eliminating hepatitis C by 2030 is feasible. The aim of this study was to examine patient group perspectives on whether European countries have national policies in place to support necessary scale-up of hepatitis C treatment.

Methods: The 2017 Hep-CORE study was carried out in 25 European countries with one patient group serving as the respondent for each country. It repeated 11 items from the 2016 survey, including questions about an approved national hepatitis C strategy, treatment in non-hospital settings and prisons, and restrictions on direct-acting antiviral access. Data were analysed descriptively and compared to 2016 findings.

Results: In 2017, an approved national hepatitis C strategy and/or action plan was reported in 12 countries (48%) (Table 1). The prior year, 11 countries (44%) reported having a strategy. In both years, respondents from five countries (20%) reported that hepatitis C

treatment was available in non-hospital settings. Treatment was reported to be available in prisons in 17 countries (68%) in 2016 and 18 countries (72%) in 2017. In 2016 and 2017 respectively, three countries (12%) and seven countries (28%) reported no restrictions on access to direct-acting antivirals (data not shown). The most frequently reported restrictions in both years were fibrosis level and current injecting drug use.

Table 1: Hepatitis C treatment policies reported by patient groups in 25 European countries, 2016–17

	Number of countries (%) 2016	2017
Written national strategy and/or action plan	11 (44%)	12 (48%)
Treatment in non-hospital settings	5 (20%)	5 (20%)
Treatment in prisons	17 (68%)	18 (72%)
Fibrosis level: restriction on access to direct-acting antivirals	18 (72%)	13 (52%)
Current injecting drug use: restriction on access to direct-acting antivirals	13 (52%)	8 (32%)

Conclusions: In 2017, patient groups reported that less than half of the 25 study countries had a hepatitis C strategy and/or action plan, despite this being an essential indicator of national readiness to address the disease. There were slight improvements in treatment policies from 2016 to 2017, most notably regarding restrictions on direct-acting antiviral access. In order to reach WHO hepatitis C elimination goals, many European Member States must still make key policy changes.

THU-052

Heterogeneity in hepatitis C virus treatment prescribing and uptake in Australia: a geospatial analysis of a year of unrestricted treatment access

N. Scott[1,2], S. Hainsworth[1], R. Sacks-Davis[1,2], A. Pedrana[1,2], J. Doyle[1,3], M. Hellard[1,2,3]. *[1]Burnet Institute, Disease Elimination, Melbourne, Australia; [2]Monash University, Department of Epidemiology and Preventive Medicine, Melbourne, Australia; [3]The Alfred and Monash University, Department of Infectious Diseases, Melbourne, Australia*
Email: Nick.Scott@burnet.edu.au

Background and Aims: Direct-acting antiviral (DAA) treatments became available for all people living with hepatitis C virus (PLHCV) in Australia in March 2016, with an estimated 20% of PLHCV treated in the first year. However, the geographical distribution of treatment uptake and the impact of non-specialists' ability to prescribe DAAs is not clear. We assess how treatment rates, the percentage of PLHCV treated and the proportion of treatments prescribed by specialists varies by geographical area.
Method: DAA treatment initiation data from the Australian Pharmaceutical Benefits Scheme were analysed for the period 1 March 2016 to 30 June 2017 across Australia's 338 Statistical Area 3 (SA3) geographical areas. Statistical regression models were used to test for correlations between the population demographics and healthcare service coverage of geographical areas and (a) their associated treatment rates; and (b) the proportion of prescriptions written by specialists compared to non-specialists.
Results: Five percent of SA3s (18/338) had no treatment initiations. Among those that did, there were a median of 76 (IQR 35–207; range 4–3834) treatment initiations per 100,000 population, corresponding to an estimated median of 7.9% (IQR 2.9–23.6%; range 0–100%) of PLHCV treated within each area. Major cities, areas of socio-economic advantage and areas with a lower proportion of the population born overseas had higher per-capita treatment rates with 54% (24059/44382) of treatment initiations prescribed by liver/HCV specialists. Prescribing patterns varied by geographical area and by prescriber type; of the 320 areas with any treatment initiations, 163 areas (51%) had prescription written by non-specialists only. For the 157 areas with some specialist prescribers, a median 60.0% (IQR 37.5–78.2%) of prescriptions were written by specialists. As areas became more regional, had a higher proportion of indigenous Australians or a higher proportion of people born overseas, non-specialist prescribing increased.

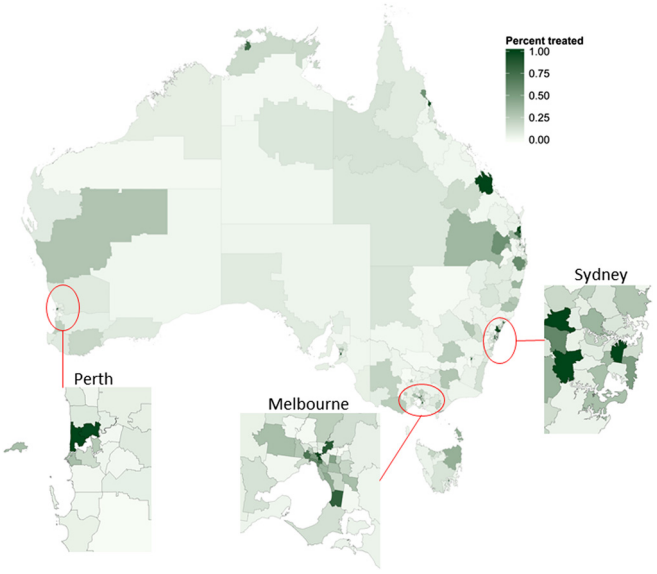

Figure: Percentage of people living with HCV who commenced DAA treatment from each of Australia's Statistical Area 3 geographical regions.
Conclusion: Despite national-level treatment uptake of 20% of PLHCV, more than half of SA3s may have treated less than 8% of PLHCV. Non-specialist prescribing appears to be significantly facilitating DAA uptake in non-metropolitan areas and among marginalised communities.

THU-053

Moderate and severe renal impairment in European CHB patients treated with TDF or ETV: a 7-year retrospective cohort study in 490 patients (on behalf of the ReCoRd investigators group)

P. Lampertico[1], J.F. Flaherty[2], M. Op Den Brouw[3], I.L. Rose[4], I. Faghmous[5], C. Phulpin[6], A. Van Troostenburg[7], H. Ramroth[5]. *[1]Fondazione IRCCS Ca Grande Ospedale Maggiore Policlinico, Unita Operativa Complessa, Milano, Italy; [2]Gilead Sciences, Clinical Research, Foster City, United States; [3]Gilead Sciences, Medical Affairs, Foster City, United States; [4]Gilead Sciences, Medical Safety Science, Foster City, United States; [5]Gilead Sciences, DSPH/Epidemiology, Uxbridge, United Kingdom; [6]Gilead Sciences, Clinical Operations, Uxbridge, United Kingdom; [7]Gilead Sciences, Exec Drug Safety, Great Abington, United Kingdom*
Email: Heribert.Ramroth@gilead.com

Background and Aims: There are limited data on the safety and efficacy of tenofovir disoproxil fumarate (TDF) and entecavir (ETV) in adult patients with moderate and severe renal impairment and dose adjustments of TDF and ETV are recommended in patients with decreasing creatinine clearance (eGFR < 50 ml/min) when the potential benefits of treatment are considered to outweigh the potential risks. We conducted a European retrospective, observational study of the safety, including renal safety, and effectiveness of TDF or ETV in chronic hepatitis B (CHB) patients with moderate or severe renal impairment.
Method: This study was conducted at 54 clinical sites in France, Germany, Italy, Spain and UK in CHB monoinfected patients 18 years and older who had experienced at least one occurrence of moderate or severe renal impairment with creatinine clearance (CrCL) (by Cockcroft Gault formula) of 20–60 mL/min, while concomitantly receiving treatment with either TDF or ETV at any time between April 2008 and December 2015. Adverse events (AEs) of special interest (AESI) included proximal tubulopathy (PRT) and/or renal tubular

dysfunction (RTD), renal AEs leading to withdrawal of treatment, renal serious AEs (SAEs), and decline in renal function if reported as a non-serious AE. An inverse probability treatment weighted (IPTW) approach was used to compare both study arms.

Results: 490 patients were enrolled in the study (67% TDF; 33% ETV) with a mean observation period of 3.3 years. Age and sex distributions were similar with 68% of patients being male. In the TDF and ETV groups, 30% and 58% of patients were treatment naïve, respectively. At the start of the observation period, 38% of TDF) and 23% of ETV patients reported clinical evidence of cirrhosis; evidence of decompensated liver disease was reported in 5% and 8% of patients, respectively; approximately 90% of patients were HBeAg negative, and renal impairment was present in 40% and 57% of TDF and ETV patients, respectively. Of patients receiving TDF, 48% had received a reduced dose at some point in the treatment course compared with 27% ETV-treated patients. AESIs were observed in 41 TDF patients (13%) compared with 11 (7%) ETV patients: Hazard ratio 1.8 (95% CI 0.9–3.6) (IPTW analyses). Only TDF were reported to have AESI of PRT or RTD (n = 11) and 26 TDF patients required treatment discontinuation. At study entry, 88% and 73% of TDF and ETV patients were virally suppressed (HBV DNA <69 IU/mL); there were no differences in the rates of virological suppression over time between both study arms.

Conclusion: In this retrospective cohort of patients with moderate to severe renal impairment only TDF patients were reported to have PRT or RTD or required treatment discontinuation. This data supports the need for newer treatments for CHB patients with renal impairment.

THU-054

The time trend of proportion and mortality rate of admissions associated with acute respiratory illness in cirrhotic patients with diverse ethnicity and socioeconomic status: an analysis on the U.S. National Inpatient Sample

B. Zou[1], Y.H. Yeo[1], D. Jeong[1], E. Sheen[1], H. Park[2], D.H. Lee[1], G. Garcia[1], M. Nguyen[1]. *[1]Stanford University Medical Centre, Division of Gastroenterology and Hepatology, Palo Alto, United States; [2]University of Florida College of Pharmacy, Pharmaceutical Outcomes & Policy, United States*

Email: mindiehn@stanford.edu

Background and Aims: Liver cirrhosis has become a major public health concern in the U.S. Cirrhotic patients might be more vulnerable to acute respiratory illness (ARI). The study aimed to explore the time trend of the prevalence and mortality rate of ARI-associated admissions in cirrhotic patients.

Method: A retrospective study was performed using the National Inpatient Sample database. We investigated the time trend of the proportion and mortality of ARI associated hospital admissions in patients with cirrhosis and compare the inpatient mortality rates for admissions with and without ARI from 2005 to 2011 in this population. We also performed subgroup analysis for the year 2011 by race and ethnicity, cause of cirrhosis and income levels.

Results: A total of 880,005 hospitalizations associated with cirrhosis were identified between 2005 and 2011. The total number of admissions associated with cirrhosis increased from 102,158 to 160,246 during 2005–2011. The proportion of ARI-related admissions witnessed an overall upward trend from 2005 (5.47%) to 2011 (7.09%). There was a decreasing trend for the mortality rates of both ARI-related and non-ARI-related admissions, but the mortality rate of ARI admissions was consistently higher than that of non-ARI (Figure). In 2011, the proportion of ARI-related admissions was significantly higher in Whites compared to Hispanics (7.48% vs. 5.36%, p < .0001). By aetiologies, the prevalence of ARI-related admissions was highest in non-alcoholic fatty liver disease (NAFLD) (8.16%) followed by hepatitis B virus (7.86%), hepatitis C virus (7.58%), other liver disease (7.41%) and alcoholic liver disease (ALD) (5.86%) (p < 0.0001). However, inpatient mortality rates for admissions associated with ARI was highest in ALD (11.94%) and lowest in NAFLD (4.62%) (p < 0.0001). Furthermore, the proportion of ARI-related hospitalizations was significantly higher in the lower quartile of the income levels (7.75% vs. 6.20%, p < 0.0001).

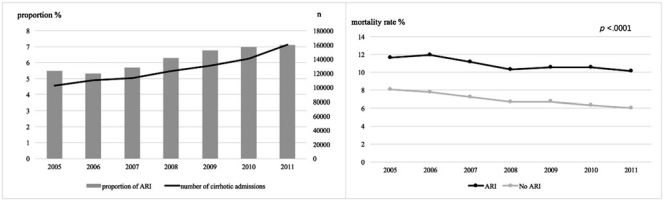

Figure: The time trend of number of admissions in patients with cirrhosis, proportion of ARI among these admissions and mortality rates for admitted cirrhotic patients with and without ARI from 2005 to 2011.

Conclusion: There was an increasing trend of proportion of ARI-related admissions between 2005 and 2011. In addition, higher mortality rates were observed in ARI-associated admissions compared to admissions without ARI. Physicians should consider preventive measures to curtail the disease burden of ARI in cirrhotic patients, especially in those with ALD, NAFLD and low-income.

THU-055

The cost-effectiveness of needle and syringe provision in preventing transmission of Hepatitis C virus in people who inject drugs

Z. Ward[1], S. Sweeney[2], L. Platt[2], L. Guinness[2], L. Maher[3], V. Hope[4], M. Hickman[1], J. Smith[5], R. Ayres[6], I. Hainey[7], T. Chamberlain[8], P. Vickerman[1]. *[1]University of Bristol; [2]London School of Hygiene & Tropical Medicine; [3]University of New South Wales, Kirby Institute; [4]Liverpool John Moores University; [5]Public Health Wales; [6]Bristol Drugs Project; [7]Cair Scotland; [8]Addaction*

Email: zoe.ward@bristol.ac.uk

Background and Aims: Over 80% of Hepatitis C virus (HCV) infections in the United Kingdom (UK) are acquired by people who inject drugs (PWID). Needle and syringe programmes (NSP) are a major component of most harm reduction strategies and a recent Cochrane systematic review has shown high coverage needle and syringe provision (HCNSP defined as obtaining more than one sterile needle and syringe per injection reported) can halve the risk of HCV acquisition amongst PWID. This study evaluated the impact and cost-effectiveness of current levels of NSPs in preventing HCV transmission in the UK and determined the cost-effectiveness of HCNSP when HCV treatment is scaled up to reach the World Health Organization (WHO) target of reducing HCV incidence by 90% by 2030.

Method: Three UK settings with different HCV antibody prevalence were described using a dynamic transmission model: Bristol (60%), Dundee (46%) and Walsall (32%). The model estimated the prevention benefits achieved by the status quo scenario (HCNSP coverage Bristol 56%, Walsall 28%, Dundee 49%) from 2016 compared to a counterfactual scenario where the effectiveness of HCNSP on HCV transmission risk was removed for 10 years. A healthcare perspective was taken with the health benefits measured in quality adjusted life years (QALY). Costs and QALY's were discounted at 3.5% over the 50-year time horizon. A willingness to pay (WTP) threshold of £20,000 per QALY was used for the incremental cost-effectiveness ratio (ICER) and a scenario analysis whereby direct acting antiviral HCV treatment numbers were increased to achieve the WHO elimination targets was carried out.

Results: Compared to removing NSP for 10 years, current HCNSP is associated with costs of £454,711 and 502 QALYs gained over 50 years in Bristol, cost savings of £972,074 and 195 QALYs in Dundee and costs of £398,592 and 192 QALYs in Walsall. The ICER was cost saving in Dundee and £906 and £2,076 per QALY in Bristol and Walsall respectively. Treatments per 1000 PWID need to be scaled up in

Bristol (from 9 to 43) and Walsall (from 2 to 18) to reach the WHO elimination targets with no treatment scale up needed in Dundee. Scaling up treatments resulted in NSP being cost saving in Bristol and remaining cost-effective in Walsall with an ICER of £9330 per QALY.
Conclusion: NSPs are highly likely to be cost-effective at the £20,000 per QALY threshold, and could be cost saving in many settings. As HCV treatment is scaled up NSPs remain cost-effective.

THU-056
Population health and economic impact of reaching the WHO 2030 targets in chronic hepatitis B diagnosis and treatment in the United States

M. Toy[1], D. Hutton[2], S. So[1]. [1]*Stanford University School of Medicine, Surgery, Palo Alto, United States;* [2]*University of Michigan School of Public Health, Health Management and Policy, Ann Arbor, United States*
Email: mtoy@stanford.edu

Background and Aims: In the U.S., an estimated 34% of the people living with chronic hepatitis B (CHB) were diagnosed and 45% were on treatment if medically indicated in 2015. The aim of this study is to assess the health and economic impact in achieving the WHO targets of 90% CHB diagnosed and 80% on treatment by 2030. We also evaluated the impact if the targets can be achieved by 2025.
Method: A Markov model was developed to simulate long-term outcomes of CHB (risks for cirrhosis, hepatocellular carcinoma (HCC), and CHB-related death) under three scenarios: current practice (34% diagnosed, 33% linked to care and 45% treated); a steady increased rate of screening, care and treatment to reach the WHO targets by 2030, and an accelerated pace to reach the targets by 2025. We used age-group and gender-specific disease progression estimates. We simulated an open cohort of foreign-born individuals including the population currently living in the U.S. as well as U.S. Census projected migration of people from high prevalence areas over a 50-year time period. We included screening costs, costs of linking patients to care, and costs of treatment to assess the investments required.
Results: Reaching the WHO target of 90% CHB diagnosed by 2030 will involve screening of 14.5 million foreign born individuals from endemic countries to diagnose 870,000 new CHB cases at the cost of $1.3 billion over a 15 year period. This effort will be cost-effective compared to current practice ($45,583 per QALY). Most of the total costs will be spent on treatment, as compared to screening and linkage to care. This approach will reduce 34% of HCC, 50% of decompensated cirrhosis, and 36% of CHB-related deaths. Annual screening costs could be substantial, peaking at $141 or $105 million, depending on the time line of 10 or 15 years. Once the peak is reached (2025 or 2030), the cost of screening will drop (Figure). Accelerating the pace of screening to achieve the WHO targets by 2025 would be even more cost-effective ($44,610 per QALY) and would result in more health gains (reduce HCC by 43%, decompensated cirrhosis by 63%, and CHB-related deaths by 47%).
Conclusion: Increasing CHB screening, care and treatment to reach the WHO targets by 2030 or at an accelerated pace by 2025 are both cost effective in the U.S. and would avert 36–47% of CHB-related deaths.

THU-057
Quantifying the impact of achieving the World Health Organization global health sector strategy goals for hepatitis C in the EURO region

S. Robbins, S. Blach, S. Brandon, C. Estes, I. Gamkrelidze, H. Nde, D. Razavi-Shearer-Spink, J. Schmelzer, H. Razavi. *Center for Disease Analysis Foundation, Polaris Observatory, Lafayette, United States*
Email: srobbins@cdafound.org

Background and Aims: The EURO region has one of the highest reported prevalence rates of Hepatitis C virus (HCV), with an estimated prevalence of 1.5%, or approximately 14 million infections in 2015. The development of direct acting anti-viral (DAA) therapy drastically shifted the current treatment paradigm for the Hepatitis C virus (HCV) from disease management to elimination. An understanding of disease burden is necessary to develop evidence-based public health strategies for elimination of HCV. We forecast the current and future disease burden of HCV in the European region and developed a strategy to achieve the World Health Organization (WHO) Global Health Sector Strategy (GHSS) Goals for Hepatitis by 2030.

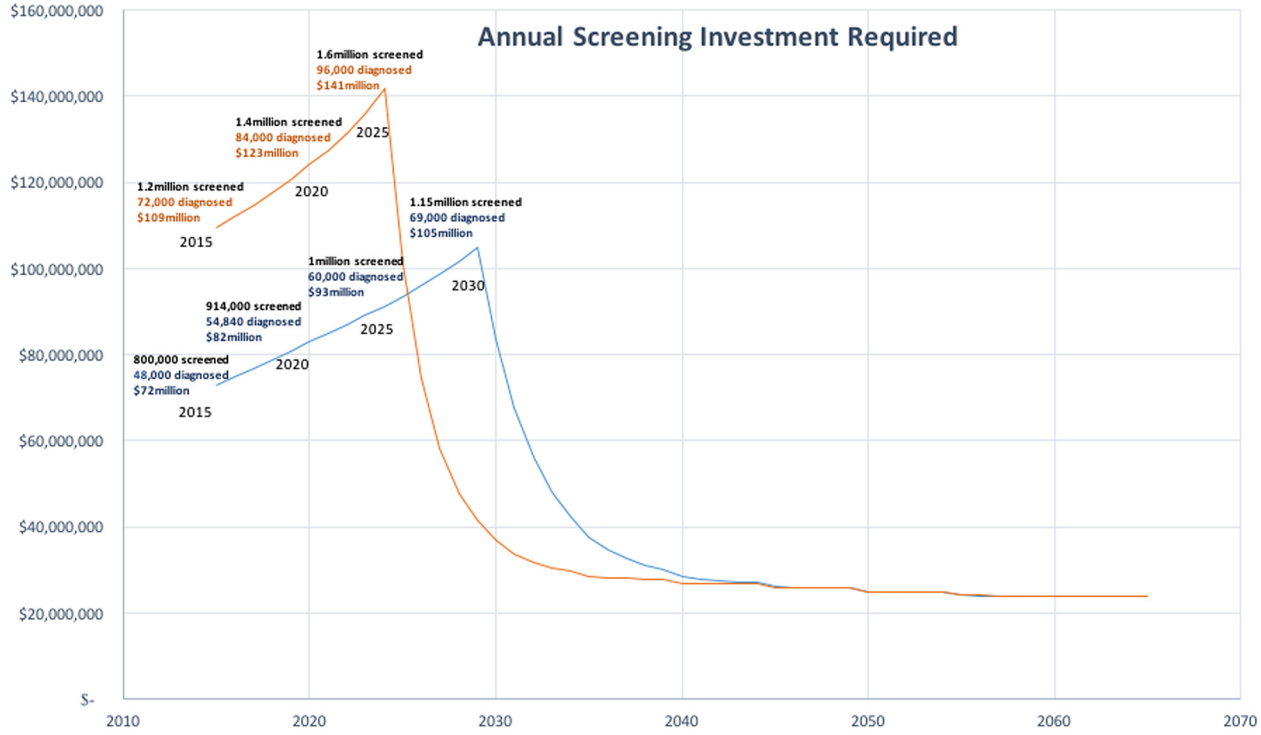

Figure: (abstract: THU_056)

Method: 53 EURO-country specific models were built and regional averages were applied to country populations when country-specific data was not available. Country estimates were then aggregated into a regional disease burden model. This disease progression model was used to quantify the size of the HCV-infected population by HCV-sequelae from 2016 through 2030.

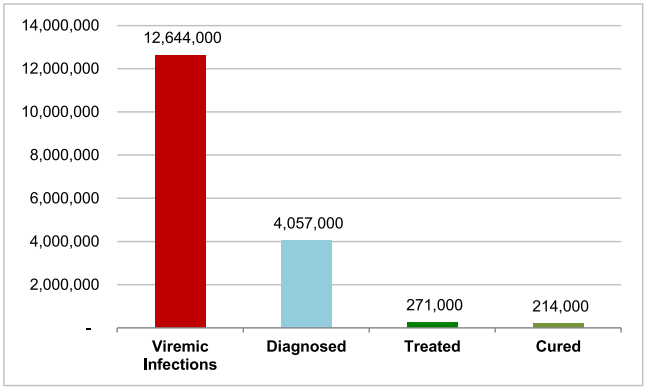

Figure 1: EURO Cascade of Care, 2016.

Results: In 2016, there were an estimated 12.6 million viremic infections in the EURO region, and 60% of all infections were found in those born between 1949 and 1989. Given the current standard of care over the next fifteen years, the total HCV-infected population in the EURO region is expected to increase by an estimated 1% by 2030. Liver related morbidity and mortality is forecasted to increase 40–45% by 2030. To achieve the GHSS goals, a significant increase in total number of patients screened and linked to care is necessary. The number of individuals diagnosed annually would need to increase to 800,000 by 2022 and the number of patients treated annually to 900,000 patients by 2025. Viremic infections are forecasted to decline by 75% by 2030; while decompensated cirrhosis cases, hepatocellular carcinoma cases, and liver related deaths will decline by 70–75% by the same year.

Conclusion: Total viremic infections are expected to increase by 1% in the EURO region over the next two decades. The WHO Goals can be achieved if drastic increases in the number of diagnosed and linked-to-care patients are met. Targeted screening strategies coupled with increased access to DAA therapy are needed to achieve these goals.

THU-058
Quantifying the impact of achieving the World Health Organization global health sector strategy goals for hepatitis C in the African Region

S. Robbins, S. Blach, S. Brandon, C. Estes, I. Gamkrelidze, H. Nde, D. Razavi-Shearer-Spink, J. Schmelzer, H. Razavi. *Center for Disease Analysis Foundation, Polaris Observatory, Lafayette, United States*
Email: srobbins@cdafound.org

Background and Aims: The development of direct acting anti-viral (DAA) therapy drastically shifted the current treatment paradigm for the Hepatitis C virus (HCV) from disease management to elimination. An understanding of disease burden is necessary in order to create evidence-based public health strategies for elimination of HCV. The AFRO region has one of the highest incidence rates of Hepatitis C worldwide. In 2015, approximately 136,000 deaths, or 10% of the total 399,000 reported deaths due to HCV that year, occurred in the AFRO region. We forecast the current and future disease burden of HCV in the African region and developed a strategy to achieve the World Health Organization (WHO) Global Health Sector Strategy (GHSS) Goals for Hepatitis by 2030.
Method: 35 AFRO-country specific models were built and regional averages were applied to country populations when country-specific data was not available. Country estimates were then aggregated into a regional disease burden model. This disease progression model was used to quantify the size of the HCV-infected population by HCV-sequelae from 2016 through 2030.
Results: In 2016, there were an estimated 11.6 million viremic infections in the AFRO region, and more than 65% of all infections were found in those born between 1953 and 1988. Relative to the current standard of care over the next fifteen years, the total HCV-infected population in the AFRO region is expected to decrease by less than 10% by 2030. Total cases of hepatocellular carcinoma (HCC) are

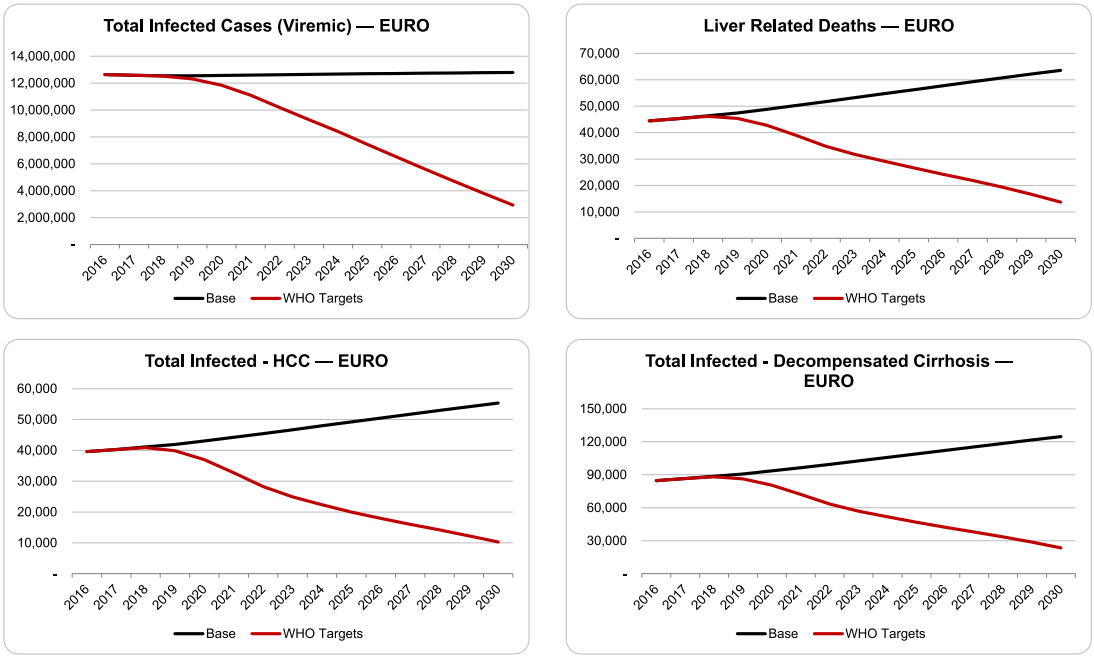

Figure 2: (abstract THU-057) Liver Related Morbidity and Mortality by Scenario, 2016–2030.

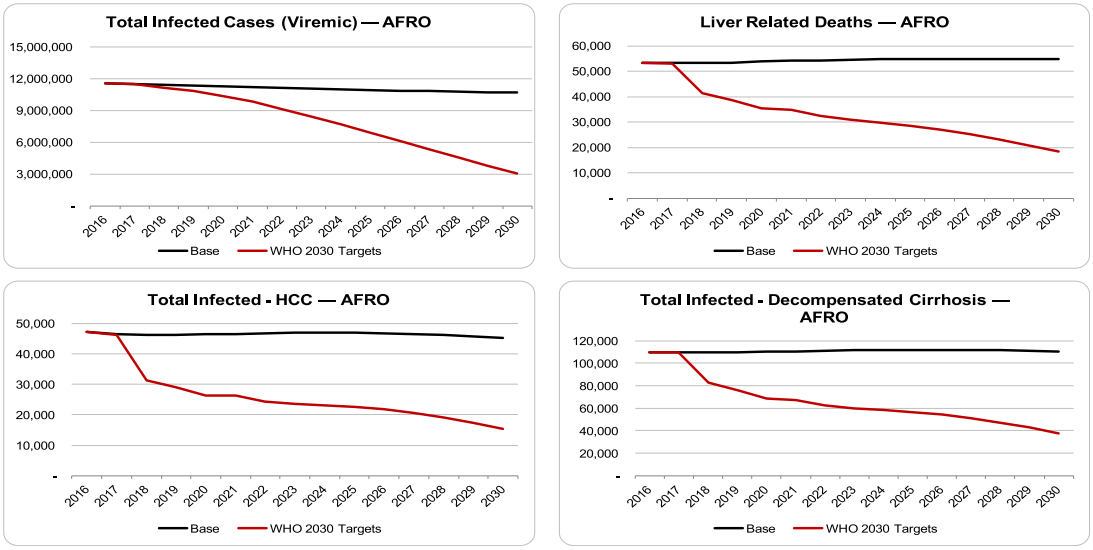

Figure 2: (abstract THU-058) Liver Related Morbidity and Mortality by Scenario, 2016–2030.

expected to decline by 5% over the next 15 years, while decompensated cirrhosis cases and liver related mortality will increase 1–2% by 2030.

To achieve the GHSS goals, a significant increase in total number of patients screened and linked to care is necessary. The number of individuals diagnosed annually would need to increase to 1.3 million by 2022 and the number of patients treated annually to 700,000 patients by the same year. Under this scenario, total viremic infections are forecasted to decline by 75% from 2015 to 2030; while decompensated cirrhosis, HCC, and liver related deaths will decline by 65% by the same year.

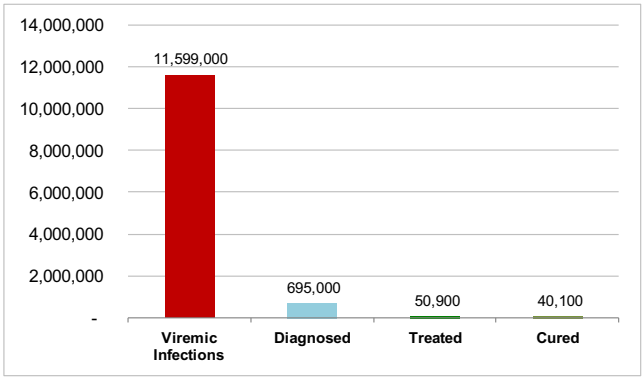

Figure 1: AFRO Cascade of Care, 2016.

Conclusion: Total viremic infections are expected to decline minimally in the African region over the next two decades. The WHO Goals can be achieved if drastic increases in the number of diagnosed and linked-to-care patients are met. Targeted screening strategies coupled with increased access to DAA therapy are needed to achieve these goals.

THU-059

Forecasting liver disease burden based on a real life cohort of the linked to care patients in Italy. Does the 'underwater portion of the iceberg' matter to reach the WHO HCV eliminating goals in the high HCV prevalent countries?

Email: sarah.robbins@centerforda.com

Background and Aims: Recent advances in direct acting antiviral treatment of Hepatitis C virus (HCV) has reinvigorated public health initiatives aimed at identifying affected individuals. We forecasted the impact of different disease management scenarios on viremic infections, liver related morbidity and mortality through 2030 in order to identify a potential scenario to achieve the World Health Organization (WHO) Targets.
Method: Using data from the Italy PITER cohort and from the Italian Medicines Agency Monitoring Registry, we modelled the impact on HCV disease burden according to different linkage to care scenarios.
Results: There were an estimated 849,000 viremic individuals in 2015 in Italy. Considering the 2016 standard of care, liver related mortality is expected to decline by 65%, achieving the WHO mortality target. Under the 40% linked to care scenario, the impact on disease burden would be significant; however eligible patients to be treated will be depleted by 2025, resulting in a treatment rate decline moving forward. A targeted screening strategy in 2020–2025 in those individuals born in the years 1948–1978 could aliment the pool of diagnosed and treated patients by finding approximately 80% of asymptomatic infected F0-F3 cases. Under the PITER 60% linked to care scenario, viremic infections will decline by 70% by 2030, but the patients eligible for treatment are expected to run out in 2028. If treatment is to be maintained at 33,700 through 2028, a screening strategy focusing on individuals born in the years 1958–1978 could be useful to capture 60% of eligible infected patients for treatment. Under the PITER 80% linked to care scenario, total viremic infections are forecasted to decline by 80%, by 2030. The pool of eligible patients to be treated is expected to be depleted by 2031 and screening limited to those born in the years 1968–1978, which would capture 25% of infected cases, would be sufficient to sustain treatment at levels required to achieve the WHO decreased prevalence target.

Conclusion: Due to DAA access policies, Italy is meeting the WHO target of a 65% reduction in HCV liver related mortality by 2030, without requiring further interventions. In the three PITER linkage to care scenarios, the eligible pool of patients to be treated will run out between 2025 and 2031, leaving a significant proportion of infected individuals undiagnosed and without access to care. Targeted screening strategies are required in order to achieve the overall WHO targets.

THU-060

Outcomes of delaying hepatitis C treatment in persons who inject drugs: Dynamic modeling of C-EDGE CO-STAR trial cohort

J. Chhatwal[1], S. Samur[1], K. Li[2], A. Spaulding[3], C. Nwankwo[4]. *[1]Harvard Medical School, Massachusetts General Hospital, Boston, United States; [2]The University of Texas Health Science Center at Houston, Houston, United States; [3]Rollins School of Public Health, Emory University, Atlanta, United States; [4]Merck & Co., Inc., United States*
Email: jagchhatwal@mgh.harvard.edu

Background and Aims: Hepatitis C virus (HCV) mortality, morbidity and incidence continue to increase globally among persons who inject drugs (PWIDs). Oral direct-acting antivirals (DAAs) have been shown to be highly effective for treating HCV in PWID. However, treatment rates remain low because of concerns about re-infection and unknown long-term benefits of treatment. Our objective was to evaluate outcomes of not treating HCV versus immediate treatment to PWID with potential re-infection.
Method: We used a dynamic agent-based model, *TapHCV* (*treatment as prevention of HCV*), that simulated the natural history of HCV progression and incorporated transmission among PWID, treatment with oral DAAs, and re-infection after treatment. The natural history of HCV in the model was validated with multiple observational studies. The baseline population in the model was based on C-EDGE CO-STAR clinical study, a multinational trial of HCV treatment of PWID. Sustained virologic response (SVR) rates and re-infection rates were extracted from the C-EDGE CO-STAR trial using 3-year follow-up data. We simulated two scenarios—no treatment and immediate treatment of PWID. Under "no treatment" scenario, patients' disease

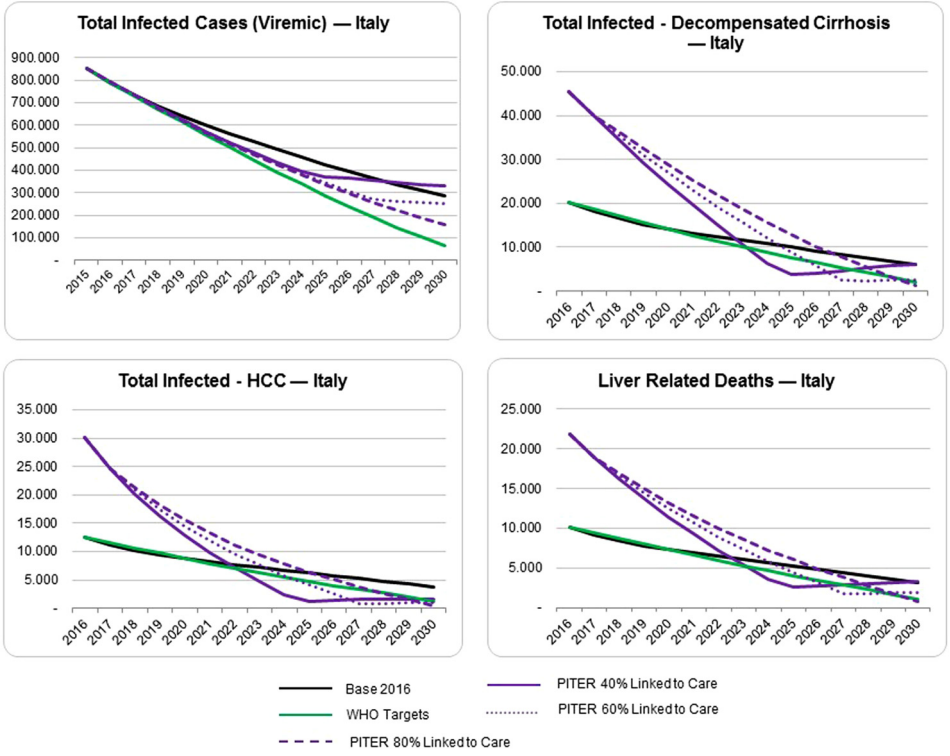

Figure: (abstract: THU_059)

continued to progress and HCV-positive PWID could infect non-HCV PWID. In "treatment" scenario, PWID could achieve SVR and get re-infected who could progress further to advanced stages of HCV. We ran our model for 6 years to compare the long-term outcomes.
Results: Among 10,000 treated PWID, it was estimated that 440 would get re-infected in 6 years. Despite this, compared with no treatment, treating 10,000 PWID with DAAs would prevent approximately 460 new infections in non-HCV PWIDs, 620 cases of decompensated cirrhosis, 580 hepatocellular carcinomas, 60 liver transplantations, and 590 liver-related deaths in 6 years.
Conclusion: Even after accounting for re-infections, immediate treatment of PWID offers substantial benefits between the time of treatment and re-infection. Providing HCV treatment with oral DAAs to PWID could reduce ongoing HCV transmission and HCV-associated diseases, both in treated PWID and non-HCV PWID. Such a strategy could also aid in HCV elimination efforts.

THU-061
Improved health outcomes from hepatitis C treatment scale-up in Spain's prisons: A cost-effectiveness study

J. Chhatwal[1], S. Samur[1], K. Li[2], T. He[3], S. Llerena[4], C. Cobo[5], T. Ayer[6], M. Roberts[7], A. Spaulding[8], J. Crespo[4]. *[1]Harvard Medical School, Massachusetts General Hospital, Boston, United States; [2]The University of Texas Health Science Center at Houston, Department of Biostatistics, Houston, United States; [3]Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing, Bejing, China; [4]Marques de Valdecilla University Hospital, Santander, Spain; [5]El Dueso Penitentiary Centre, Santoña, Spain; [6]Georgia Institute of Technology, Atlanta, United States; [7]University of Pittsburgh, United States; [8]Rollins School of Public Health, Emory University, Atlanta, United States*
Email: jagchhatwal@mgh.harvard.edu

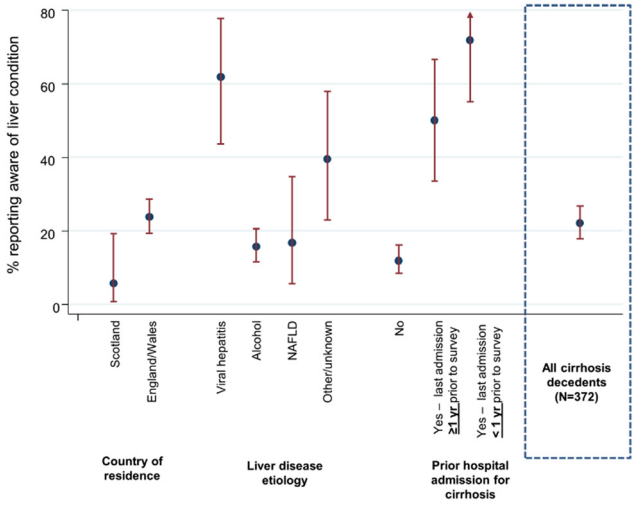
Background and Aims: Hepatitis C virus (HCV) infection is 15 times more prevalent among prison inmates in Spain compared with the general population. Direct-acting antivirals (DAAs) for HCV treatment can potentially reduce ongoing transmission, and eliminate HCV. Spain initiated an innovative pilot program, JAILFREE-C, to screen and treat HCV in prisons. Our aim was to identify a cost-effective strategy to scale-up HCV treatment to all Spain's prisons.
Method: We used a dynamic agent-based microsimulation model that considered HCV transmission, natural history of HCV progression, screening, treatment with oral DAAs, and simulation of prison and general population dynamics. The baseline population in the model represented Spain's population in the community and prisons in all regions stratified by age, prevalence of HCV, health states, HCV genotype, and injection drug use status. SVR rates and patient demographics in prisons were informed by published studies, including the JAILFREE-C study. Treatment capacity in prisons was assumed to be 2000/year. The long-term disease and cost outcomes of the following strategies in prisons were evaluated: (1) no treatment; (2) prioritize treatment of inmates by their health states (F4, F3, F2, F1, F0) irrespective of the prison/region; (3) prioritize inmates in prisons high HCV prevalence; and (4) prioritize inmates in prisons with high number of HCV-infected inmates.
Results: Under the current limited resources in prisons, scaling-up treatment by prioritizing patients based on their disease stage would yield the highest quality-adjusted life years (QALYs) – 7186 additional QALYs but cost €98.24 million more than that under no treatment. This strategy was also the most cost-effective strategy, yielding the incremental cost-effectiveness ratio of €5800/QALY when compared with the next effective strategy. Compared with no treatment, this strategy would prevent 70 new incident cases of HCV, 270 cases of decompensated cirrhosis, 450 cases of hepatocellular carcinoma and 670 HCV-related deaths in the next 25 years in Spain. The majority of these benefits would occur outside of prisons in the general community.
Conclusion: Scaling-up HCV treatment with DAAs to all prisons in Spain would reduce ongoing HCV transmission and HCV sequelae burden. Among the strategies considered, prioritizing patients with advanced disease stage in all prisons, irrespective of the region, HCV prevalence or size of the prison would be the most cost-effective strategy.

THU-062
Poor awareness of liver disease shortly before cirrhosis death: findings from a large community cohort in the UK

H. Innes[1], E. Aspinall[1], J. Morling[2], D. Goldberg[3], N. Guha[4,*], S. Hutchinson[1,*]. *[1]Glasgow Caledonian University, School of Health and Life Sciences, Glasgow, United Kingdom; [2]University of Nottingham, Division of epidemiology and public health, School of Medicine., Nottingham, United Kingdom; [3]Health Protection Scotland, Glasgow, United Kingdom; [4]NIHR Nottingham Digestive Diseases Biomedical Research Unit, Nottingham University Hospital NHS Trust and University of Nottingham., Nottingham, United Kingdom*
[*]Senior authors
Email: hamish.innes@gcu.ac.uk

Background and Aims: Death from liver cirrhosis typically occurs after decades of silent hepatitis and fibrogenesis triggered by a persisting liver insult. Early detection of progressive liver damage before serious complications emerge is critical to preventing cirrhosis mortality. In this study we investigated awareness of liver disease among cirrhosis decedents shortly before their death, using data from a large UK community sample.
Method: The study population comprised participants from the UK biobank cohort – a large community sample of middle aged men and women from UK, recruited in 2006–2010 – who died a cirrhosis-related death up to Nov 2016. Cirrhosis-related mortality was defined either as death: a) directly from liver cirrhosis (ICD 10: K70; K73; K74); or b) indirectly from cirrhosis via hepatocellular carcinoma (HCC), given that, by and large, cirrhosis is prerequisite for HCC in Western settings (ICD 10: C22.0). We inferred awareness of liver disease according to whether participants disclosed any liver-related condition when asked to report "serious medical conditions/disabilities" diagnosed by a doctor in their survey interview. We investigated determinants of liver disease awareness via univariate and multivariate logistic regression. Specifically, we assessed the association between awareness and the following patient factors: age, gender, deprivation score; country of birth; UK country of residence; year of interview; length of time between interview and death; type of cirrhosis death; previous hospitalisation for cirrhosis; comorbidity; abdominal pain in last month; and liver disease etiology.

Fig.1 Patient characteristics associated with awareness of liver disease at survey interview, shortly before cirrhosis death



Results: From 502,633 survey participants, there were 372 deaths from cirrhosis (the majority – 74% – due to alcohol etiology). The median time interval between survey interview and cirrhosis mortality was 4.2 years (IQR: 2.5–5.9). Of the 372 decedents, 82 (22.0%) reported awareness of a liver-related condition at baseline. Factors significantly associated with increased awareness in multivariate analysis were: viral hepatitis etiology; prior cirrhosis hospitalisation; and living in England/Wales (versus Scotland); see Fig. 1.
Conclusion: Less than a quarter of cirrhosis decedents reported awareness of liver disease 4.2 years (on average) prior to death. These data indicate suboptimal identification and/or communication of life-threatening liver disease among high risk individuals in the UK, and foreground the need for better diagnostic pathways in the community setting.

THU-063

Eradicate hepatitis C: A pilot of treatment as prevention in active drug users

J. Schulkind[1], F. Ahmad[2], B. Stephens[2], L. Johnston[2], M. Hickman[1], Z. Ward[1], J. Dillon[2]. [1]*University of Bristol, Population Health Sciences, Bristol, United Kingdom;* [2]*University of Dundee, Department of Molecular and Clinical Medicine, Dundee, United Kingdom*
Email: jasmine.schulkind@gmail.com

Background and Aims: To achieve WHO Hepatitis C virus (HCV) elimination targets by 2030, there needs to be significant scale-up of treatment among active injecting drug users – a concept known as "treatment as prevention" (TasP). Current EASL guidelines highlight active injectors as a priority group for HCV treatment. Our principal aim was to test whether active injectors can be recruited and treated successfully, and assess rates of re-infection.
Method: This prospective study recruited 104 HCV positive participants over 42 months from the largest Needle exchange (NE) centre in Tayside, Dundee. 94/104 individuals commenced treatment. Genotype 1 (G1) individuals (n = 37) were treated with peg-interferon + ribavirin+ Simepravir/Telaprevir. Genotype 2/3 (G2/3) (n = 57) received peg-interferon + ribavirin. Weekly study visits took place within the NE centre.
Results: Mean age of participants was 34.0 years (SD 6.9), 71.3% (61/94) were male. 1 in 5 (20/94) participants were homeless/living in unstable accommodation; 12.8% (12/94) were in prison at some point during the treatment period. Reported history anxiety/depression was high, 69.2% (65/94). Baseline data showed high rates of injecting: participants injected median 6.5 times/week, 54.3% (51/94) injected daily/more than once a day. In terms of clinical outcomes >80% treatment adherence was 71.3% (67/94). SVR12 data was available for 92/94 participants (Table 1). 2 participants died prior to 3-month follow-up. There was no difference in SVR12 rates between Genotype: 81.0% (30/37) for G1 and 85.5% (47/55) for G2/3. There was limited lost to follow-up at 6-months, 5.4% (5/92). Re-infection rates were 12.6/100 person-years (95% CI 5.3–30.4) (n = 5) at 6-months and 18.3/100 person-years (95% CI 11.1–30.4) (n = 15) at 18-months post-treatment.

Table 1: principal study outcomes

Study outcome	n = 92
SVR12, No. (%)	77 (83.7)
Lost to follow-up at 6-months, No. (%)	5 (5.4)
Died at 6-months, No. (%)	3 (3.2)
6-month reinfection rate, per 100-pyrs (95% CI	12.6 (5.3–30.4
18-month reinfection rate, per 100-pyrs (95% CI)	18.3 (11.1–30.4)

Conclusion: Active injectors were successfully recruited, treated and followed-up. However, we also report higher rates of re-infection than many other studies. These re-infection rates demonstrate this is a high-risk population, who should be considered a priority population for TasP. This pilot study provides a successful model for engaging active injectors in HCV treatment.

THU-064

HIV co-infection is associated with increased liver complications and reduced mental health among patients with chronic hepatitis B

M. Lu[1], N.P. Markowitz[2], Y. Zhou[1], K.-H. Wu[1], L.B. Rupp[3], S. Trudeau[1], J. Li[1], J.A. Boscarino[4], M.A. Schmidt[5], Y.G. Daida[6], S.C. Gordon[7]. [1]*Henry Ford Healthy System, Department of Public Health Sciences;* [2]*Henry Ford Healthy System, Department of Infectious Disease;* [3]*Henry Ford Healthy System, Center for Health Policy and Health Services Research;* [4]*Geisinger Clinic, Department of Epidemiology and Health Services Research;* [5]*Kaiser Permanente Northwest, Center for Health Research;* [6]*Kaiser Permanente Hawai'i, Center for Health Research;* [7]*Henry Ford Health System, Gastroenterology and Hepatology, Detroit, United States*
Email: mlu1@hfhs.org

Background and Aims: Most studies of hepatitis B (HBV) and HIV co-infection focus on HIV cohorts, and thus may not collect data regarding HBV-related treatment or outcomes. We used data from the Chronic Hepatitis Cohort Study (CHeCS)—a racially- and geographically-diverse sample from four large US health systems—to investigate the impact of HIV on the clinical characteristics and mental health of patients with chronic hepatitis B.

Table 1: HBV and HBV-HIV patients: demographics, current clinical status, and survey responses

Variable	Response	HBV (n = 4340)	HIV/HBV (n = 300)	p
Sex	Female	47%	9%	<0.001
	Male	53%	91%	
Age	<40	22%	14%	<0.001
	40 < 50	23%	29%	
	50 < 60	25%	37%	
	≥60	29%	20%	
Race	ASINPI	55%	9%	<0.001
	Black	13%	47%	
	White	23%	38%	
	Unknown	9%	6%	
Insurance	Medicaid	14%	26%	<0.001
	Medicare	20%	38%	
	Private	66%	36%	
Household Income	<$30 K	14%	36%	<0.001
	$30 < $50 K	41%	44%	
	≥$50 K	44%	19%	
Charlson-Deyo comorbidity score	0	69%	24%	<0.001
	1–2	17%	3%	
	≥3	14%	73%	
FIB4 Score		2.7 ± 11.7	4.1 ± 10.9	0.051
Antiviral med activity	Neither HIV nor HBV	70%	9%	<0.001
	HBV only	30%	6%	
	HIV only	0%	6%	
	Both HIV and HBV	0%	79%	
Cirrhosis	No	84%	77%	<0.001
	Yes	16%	23%	
Hepatocellular carcinoma	No	97%	98%	0.426
	Yes	3%	2%	
Deceased	No	88%	73%	<0.001
	Yes	12%	27%	
Survey response		n = 913	n = 67	
SF8 Mental health score		51.3 (8.8)	45.3 (12.3)	<0.001
SF8 Physical health score		50.6 (9.0)	47.4 (10.4)	0.007
High stress		14%	34%	<0.01
Any depression (PHQ9)		11%	37%	<0.01
Hx injection drug use		4%	13%	<0.001
Hx sex with multiple partners		43%	13%	0.019
Hx smoking		39%	64%	<0.01
Audit C: alcohol use		14%	25%	0.02
US or Canada born		35%	94%	<0.01
Married		13%	69%	<0.01

Method: Patient demographics and clinical status were collected from the electronic health record from date of diagnosis (HBV or HIV/

HBV co-infection) onward. A subgroup provided survey data regarding health-related behaviors and mental health. Chi-square tests and two-sample t-tests were used to compare categorical and continuous variables, respectively, between HBV mono-infected and HIV/HBV co-infected patients.
Results: Among a sample of 4640 HBV patients, 300 (6.5%) were HIV co-infected. HIV/HBV co-infected patients were significantly more likely to be male, African American or white, low-income, and publicly insured than HBV mono-infected patients. Despite high rates of antiviral treatment, co-infected patients also demonstrated increased comorbidities, fibrosis/ cirrhosis, and mortality. Among a subgroup of 980 survey respondents (913 HBV, 67 HIV/HBV), co-infected patients were significantly more likely to be depressed, to have lower mental health scores, and to report being "highly stressed".
Conclusion: HIV co-infection impacts a demographically distinct subset of HBV patients. Despite high rates of antiviral treatment, co-infected patients demonstrate increased rates of liver-related complications and report poor mental health outcomes.

THU-065
Australia on track to achieve WHO elimination targets following rapid initial DAA treatment uptake
J.A. Kwon[1], G. Dore[1], J. Grebely[1], B. Hajarizadeh[1], R. Guy[1], E.B. Cunningham[1], C. Estes[2], H. Razavi[2], R.T. Gray[1]. *[1]Kirby Institute, UNSW, Kensington, Australia; [2]Center for Disease Analysis (CDA), Lafayette, Colorado, United States*
Email: akwon@kirby.unsw.edu.au

Background and Aims: From March 2016, the Australian government made direct-acting antiviral (DAA) treatment available at a highly-subsidized cost to all adults living with chronic hepatitis C (HCV). An estimated 32,550 people initiated DAA treatment in 2016, equating to 14% of the 227,000 people living with chronic HCV. We estimated the initial and future impact of DAA treatment on prevalence, morbidity, and mortality of HCV to evaluate whether Australia can meet WHO HCV elimination targets by 2030.
Method: We used a mathematical model and assumed three different future treatment coverage scenarios over 2016–2030: optimistic, 32,550 people initiate DAA treatment each year 2016–2030; intermediate, treatment numbers drop moderately: 32,550 (2016), 27,900 (2017), 23,250 (2018), then 18,600 (2019–2030); and pessimistic, treatment drops markedly; 32,550 (2016), 18,600 (2017), 13,950 (2018), then 13,950 (2019–2030), with comparison to a status-quo scenario where treatment remains at 2015 levels (7,300 per annum). Treatment and testing rates were varied by disease stage, and reduced disease progression rates to decompensated (DC) and hepatocellular carcinoma (HCC) among the cured population. We assumed testing rates and current harm reduction programs remained in place from 2016 and only the impact of treatment uptake was analysed in this study.
Results: Under the intermediate DAA treatment scenario during 2016–2020, 28% (24–31%) of new HCV infections, 57% (46–67%) of DC, 59% (47–69%) of HCC, and 53% (42–63%) of liver-related deaths were averted. By 2030, the intermediate scenario would avert 57% (47–65%) of new HCV infections, 86% (70–91%) of DC, 89% (74–93%) of HCC, and 83% (64–88%) of liver-related deaths. The model estimates that under the intermediate scenario Australia will meet WHO targets of 80% reduction in HCV incidence in 2024, 80% eligible treated in 2025, and 65% reduction in liver-related mortality in 2020. The pessimistic scenario will delay meeting the targets by 3–5 years, and the optimistic scenario will bring it forward by 3–5 years.
Conclusion: Based on a realistic DAA treatment uptake scenario Australia should meet the WHO HCV elimination targets in 10–15 years even with moderate reductions in DAA treatment uptake from 2016 level. To achieve these targets requires a continuation of current harm reduction activities and HCV testing strategies to ensure anyone living with chronic HCV can receive treatment.

THU-066
Hepcare Europe: HepCheck; reaching vulnerable populations
J. Lambert[1], W. Cullen[2], C. Oprea[3,4], A. Story[5], J.M. Sanchez[6], J. Surey[7]. *[1]Mater Misericordiae University Hospital, Infectious Diseases Department, Dublin, Ireland; [2]University College Dublin, School of Medicine, Dublin, Ireland; [3]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [4]Victor Babes Clinical Hospital for Infectious and Tropical Diseases, Bucharest, Romania; [5]UCLH NHS Trust, London, United Kingdom; [6]Hospital Universitario de Valme, Infectious Diseases and Microbiology Unit, Seville, Spain; [7]University College London, Institute of Global Health, London, United Kingdom*
Email: alistairstory@gmail.com

Background and Aims: HepCare Europe is a three year EU funded project involving collaboration with four member states. The vision for the project is to create an innovative, integrated system for HCV testing & treatment among key "at-risk" groups, including PWID's and the homeless, through outreach to the community and integration of primary and secondary care services. With clinical sites in Dublin, London, Seville and Bucharest, and economic evaluation in Bristol UK, the consortium has developed a number of work packages focused on operationalizing the multiple components of testing, care and cure that are key components of the strategy to eradicate HCV in the European Union. Consortium members include UCD (Ireland) SAS (Spain) SVB (Romania) University of Bristol (UK) and University College London (UK).
Method: The HepCheck component of the project offered screening across the four clinical sites in Dublin, London, Seville and Bucharest. Point of care testing was offered to "at-risk" groups who are frequently marginalized with respect to health service engagement. Screening was conducted in prisons, opioid substitution treatment clinics and in homeless services.
Results: A total of 1,749 individuals were screened, 31.2% (n = 559) tested HCV antibody positive. To date 40% (n = 222) individuals have attended a specialist appointment for HCV treatment. In-depth analysis of the data is ongoing including identification of risk factors for HCV infection, levels of HCV related liver disease, prevalence of blood borne viruses and linkage to care.

	Dublin	London	Bucharest	Seville	Total
Screened	569	310	469	401	1749
Ab Positive	24%	41.8%	35%	34%	31.2%

Conclusion: In order to achieve WHO HCV elimination targets by 2030 we need to identify and successfully treat the most vulnerable HCV individuals in the community. Community based screening intervention can enhance HCV diagnosis for at risk populations but referrals to/ attendance at secondary care remains a challenge for this cohort. The HepCheck data highlights the potential for developing interventions to enhance engagement with HCV screening and entry to the cascade of care required to cure HCV.

THU-067
Achieving World Health Organization targets for hepatitis B by 2030: Results from 17 WHO AFRO Countries
H. Nde, S. Robbins, D. Razavi-Shearer-Spink, S. Brandon, I. Gamkrelidze, H. Razavi. *Polaris Observatory, Lafayette, United States*
Email: hnde@cdafound.org

Background and Aims: The AFRO region has a perilously high burden of hepatitis B (HBV) but data to guide management strategies are lacking. Progression to decompensated cirrhosis (DC), hepatocellular carcinoma (HCC), and liver related death (LRD) makes the virus a main driver of morbidity and mortality in the region with HBV accounting for almost 88,000 deaths annually.
Method: Excel-based disease progression models, built with verified, published and/or extrapolated data were used to assess 2016–2030 trends in morbidity and mortality in 17 World Health Organization

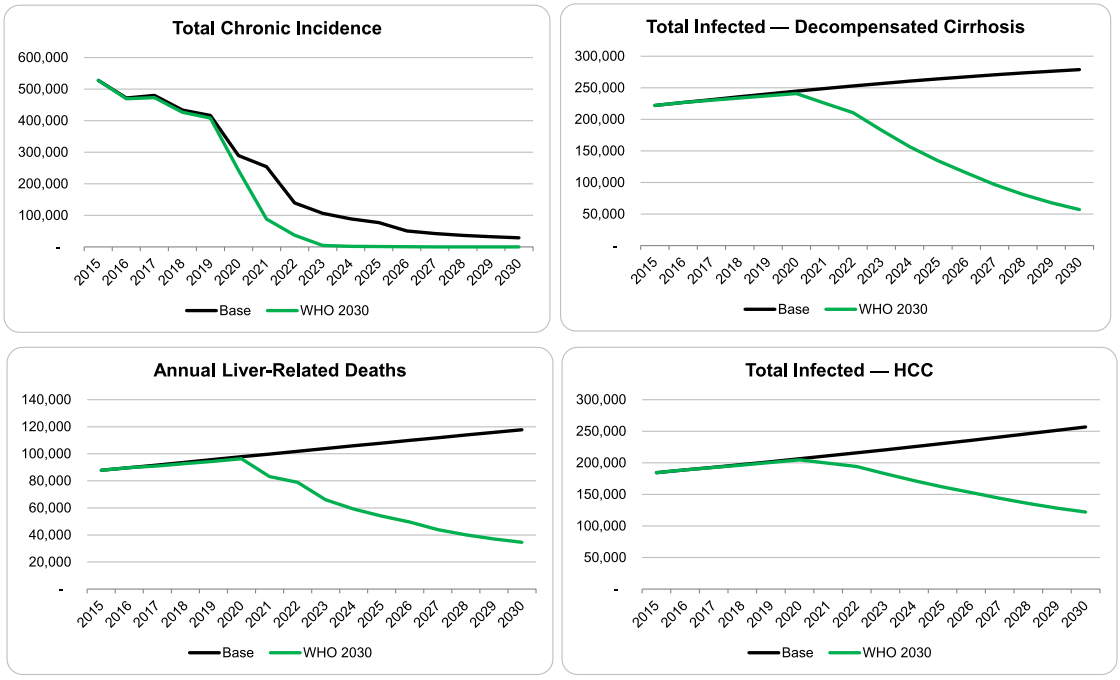


Figure: (abstract: THU_067)

(WHO) AFRO countries: Burkina Faso, Burundi, Cameroon, Central African Republic (CAR), Chad, Ethiopia, Gabon, Gambia, Kenya, Madagascar, Malawi, Nigeria, Rwanda, Senegal, Tanzania, Uganda, Zimbabwe. After 2017, interventions were introduced with the aim to achieve WHO 2030 hepatitis targets of 90% diagnosed and 80% treated with a 65% reduction in mortality by 2030.

Results: 2016 saw approximately 42 million chronic cases in all 17 modeled countries with Nigeria alone accounting for ~50% of all infections. Ten modeled countries had over a million cases each, five countries (Burundi, CAR, Kenya, Malawi, Rwanda) had 200,000–700,000 cases while two (Gabon and Gambia) had under 100,000 cases. 65% of cases were aged 15–49, with a male predominance. By 2030, cases decrease in all countries but Chad, Central African Republic and Nigeria where they increase 8–20%. However, prevalent DC, HCC and annual LRD increase 20–40% for all countries with Ethiopia, Gabon and Gambia showing >30% increases in HCC cases. Meeting WHO 2030 targets from this base requires 40 million total diagnosed cases and 9 million treated annually by 2025. This represents an exponential increase in diagnosis and treatment respectively from 2016, and it reduces DC by 75% and HCC by 35%. Mortality, however, could only be reduced by 61% in this time frame, contrary to the expected 65% to meet WHO 2030 targets.

Conclusion: HBV is a neglected disease in the AFRO region. Continuing current conditions will lead to increases in end-stage outcomes by 2030. In light of the sizeable disease burden in the young population of these countries, diagnostic and treatment efforts will have to be radically expanded in the next 10 years to meet WHO 2030 targets, although such an expansion will likely be insufficient to meet mortality targets. Countries thus need to review strategies on how to best control the expected increase in disease burden.

THU-068

Achieving World Health Organization targets for hepatitis B in infants and 5-year olds by 2030: Results from 17 WHO AFRO countries

H. Nde, S. Robbins, D. Razavi-Shearer-Spink, S. Brandon, I. Gamkrelidze, H. Razavi. *Polaris Observatory, Lafayette, United States*
Email: hnde@cdafound.org

Background and Aims: 90% of children infected via perinatal transmission of the hepatitis B virus (HBV) become chronic carriers, while childhood transmission poses a 20–50% risk. Chronic infection is linked to severe end-stage outcomes, and averting perinatal infections is crucial to elimination. Few countries in the WHO AFRO region, however, have all perinatal prophylaxes options available in existing frameworks, raising the question of if the WHO 2030 target of 0.1% prevalence in 5-year olds can be met otherwise.

Method: Excel-based disease progression models were built with verified, published and/or extrapolated epidemiological data from 17 countries in the WHO AFRO region: Burkina Faso, Burundi, Cameroon, Central African Republic (CAR), Chad, Ethiopia, Gabon, Gambia, Kenya, Madagascar, Malawi, Nigeria, Rwanda, Senegal, Tanzania, Uganda, Zimbabwe. 2016–2030 infection trends in the infant (<1 year old) and 5 year old population were analyzed, assuming the current immunization paradigm from 2014 remained constant. Interventions were introduced to the models after 2017 first by expanding coverage rates for the 3-dose vaccine, then treatment of high viral load mothers, birth-dose and HBIG with the aim to achieve the WHO targets for HBV in 5-year olds by 2030.

Results: By 2030, 16 of 17 analyzed countries saw decreased infant cases. CAR alone, with no birth-dose and under 50% 3-dose, saw a 13% increase in the number of infants cases by 2030. Similarly, cases in 5-year olds decreased 12–57% for all analyzed countries except for Burkina Faso and CAR which saw increases of 8% and 68% respectively. Sustaining 3-dose coverage rates from 2014 in Kenya, Malawi and Rwanda (all >80%) was sufficient to meet the WHO targets. CAR required increases to both 3-dose coverage and treatment of mothers (99% by 2025), as well as to birth-dose coverage (35% by 2025). The Gambia, with birth-dose and 3-dose coverage at 96% in 2014, required 99% coverage in both therapies as well as in treatment of mothers by 2025, to meet targets. Nigeria could meet targets by keeping the 2014 birth-dose rate of 54% while expanding 3-dose coverage and treatment of mothers to 99% by 2025. Alternately, increasing both immunization rates to 99% by 2025 and treating 85% of mothers by the same time would meet goals. In the remaining countries, increasing the 3-dose coverage to 99% by 2025 and treating 40% (Ethiopia) to 99% (Chad) of mothers by 2025 was sufficient.

Conclusion: Early infection with HBV poses a threat in the AFRO region. Current efforts go a long way towards reducing HBV disease burden as some countries could achieve WHO 2030 HBV targets for 5-year olds with the existing 3-dose coverage rates. Even more countries, however, will need to expand access to 3-dose and birth-dose coverage as well as treatment for infected mothers. Carefully designed strategies are thus necessary to maximize resources.

THU-069

Impact of the hepatitis B vaccine birth-dose on perinatal incidence between 2017–2050: Results from 17 WHO AFRO Countries

H. Nde, S. Robbins, D. Razavi-Shearer-Spink, S. Brandon, I. Gamkrelidze, H. Razavi. *Polaris Observatory, Lafayette, United States*
Email: hnde@cdafound.org

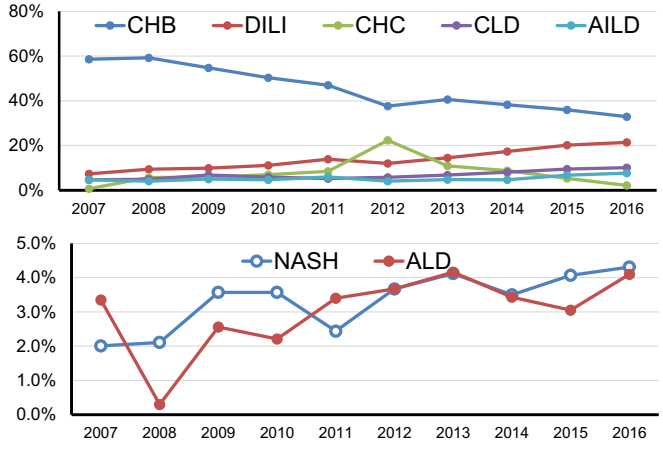
Background: Expanding access to the HBV vaccine birth-dose is recommended as an essential step towards preventing mother-to-child transmission of the virus as well as in elimination efforts. This is particularly the case in the WHO AFRO region where birth-dose coverage is still low. Few analyses exist, however, which investigate the impact of administering versus not administering birth-dose on future perinatal incidence.
Methods/Design: Excel-based disease progression models were seeded with verified, published and/or extrapolated epidemiological data from 17 countries in the WHO AFRO region (Burkina Faso, Burundi, Cameroon, Central African Republic, Chad, Ethiopia, Gabon, Gambia, Kenya, Madagascar, Malawi, Nigeria, Rwanda, Senegal, Tanzania, Uganda, Zimbabwe). The base model assumes no change in the country's current birth dose-coverage, with other parameters set to meet WHO 2030 targets for 5 year olds. The test model increased birth-dose coverage between 2017 and 2030 to match WHO target 3-dose coverage rates by 2030. The difference in perinatal incidence between 2017 and 2050 was then calculated.
Results: Expanding birth-dose to match 3-dose rates for WHO targets by 2030 in these 17 countries, results in ~200,000 total incident perinatal HBV cases prevented between 2017 and 2050. This ranged from 15 cases in The Gambia to ~44,000 cases in Ethiopia. Over 60% of all incident cases prevented occurred before 2030. Cameroon, Ethiopia, Nigeria, Tanzania and Uganda each prevented over 10,000 incident perinatal cases by 2030.
Conclusion: Expanding access to birth dose in the next 15 years will lead to reductions in incident perinatal HBV cases by 2050. This suggests that in the long term i.e., 2050 and beyond, the lack of a birth-dose might lead to more chronic cases and end stage outcomes, unless other measures are taken to manage disease burden.

THU-070

The 10-year chronic liver disease spectrum evolution in China: experience from the largest tartiary special hospital with 21382 liver biopsy cases

D. Ji[1,2], G. Chen[1,2], Y. Fu[1], C. Wang[3,4], J. Chen[3], Q. Shao[1,2], B. Li[1,2], F. Li[1,2], Z.B. Li[1], V. Wu[3], T. Wu[3], Y. Wang[3], G. Lau[2,5]. *[1]Beijing 302 Hospital, Second Liver Cirrhosis Diagnosis and Treatment Center, Beijing, China; [2]Beijing 302-Hong Kong Humanity and Health Hepatitis C Diagnosis and Treatment Centre, Beijing, China; [3]Humanity and Health Research Centre, Hong Kong, Hong Kong; [4]Nanfang Hospital, Southern Medical University, State Key Laboratory of Organ Failure Research, Guangdong Provincial Key Laboratory of Viral Hepatitis Research, Department of Infectious Diseases, Guangzhou, China; [5]Humanity & Health Medical Centre, Division of Gastroenterology & Hepatology, Hong Kong, Hong Kong*
Email: gkklau@netvigator.com

Background and Aims: Beijing 302 hospital is the largest tertiary special hospital for liver diseases, which receives patients from all over the China. The patients visited our hospital is representative and we aimed to assess the pattern and evolution of Chinese people liver disease spectrum using data from our patients to provide the evidence for developing population–based effective strategy of chronic liver disease management.



Method: The clinical data of executive patients who underwent liver biopsy by any reasons from 2007 to 2016 were retrospectively collected, and the disease spectrum and biochemical parameters of each patient were recorded, such as sex, age, outcome, etc. Liver biopsy were guided by ultrasound, and HE, Masson and reticular fiber staining were performed routinely in liver tissues,

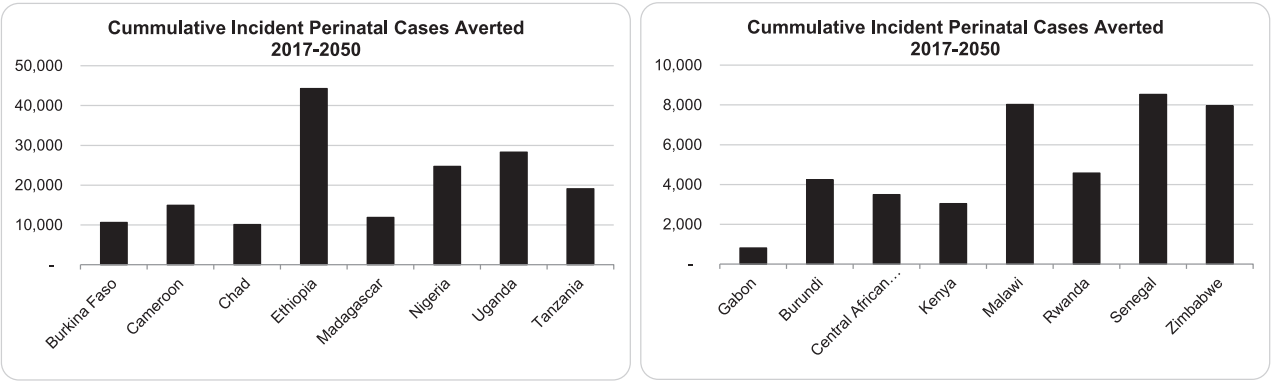


Figure: (abstract: THU_069)

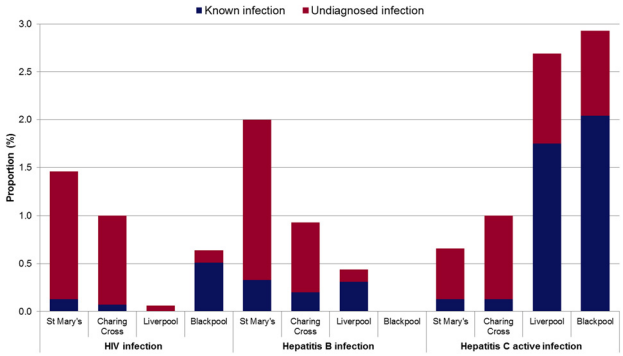
immunohistochemical staining and special staining, such as Congo red and PAS, were optional selected if necessary.
Results: In total, 21382 liver biopsy cases were enrolled and analyzed. The top 5 etiology were chronic hepatitis B (CHB) (44.1%), drug induced liver injury (DILI) (14.1%), chronic hepatitis C (CHC) (9.2%), cryptogenic liver disease (CLD) 6.9%, and autoimmune liver diseases (AILD) (5.2%). The rate of CHB patients decreased from 58.6% to 32.9%, DILI increased from 3.7% to 13.7%, CHC increased from 7% to 22.4%, and then decreased to 2.2%, CLD increased from 4.8% to 13.3%, and AILD increased from 6.3% to 13.3%. Besides, non-alcoholic steatohepatitis (NASH) increased from 4.1% to 11.4%.
Conclusion: Chronic liver disease spectrum in China has been changed, as the living standard of Chinese people rising recent decades. The incidences of DILI, CLD, NASH and AILD increased rapidly, while CHC decreased significantly, implying the DAAs therapy has achieved a great success.

THU-071

The ENABLE projects: Consistent high prevalence of undiagnosed active blood borne virus infection [HBV, HCV, HIV] across four urban emergency departments in England – Data for action?

M. Hopkins[1], S. Todd[2], M. Beadsworth[2], R. Vivancos[3], C. Anderson[4], D. Muir[5], Z. Mohamed[6], A. Brown[6], A. Guleri[7], R. Sharma[7], R. Palmer[7], D. Singleton[7], M. Ruf[8], A. Chawla[1]. *[1]Royal Liverpool University Hospital, Department of Clinical Virology, Liverpool, United Kingdom; [2]Royal Liverpool University Hospital, Tropical and Infectious Disease Unit, Liverpool, United Kingdom; [3]Public Health England, Field Service, National Infection Service, Liverpool, United Kingdom; [4]Public Health England, Field Service, National Infection Service, London, United Kingdom; [5]Northwest London Pathology, Infection & Immunity, London, United Kingdom; [6]Imperial College London, Hepatology, London, United Kingdom; [7]Blackpool Teaching Hospitals NHS Trust, Microbiology, Blackpool, United Kingdom; [8]Gilead Sciences, Medical Department, London, United Kingdom*
Email: hopkinsmj@gmail.com

Background and Aims: There is limited local epidemiological data on blood borne viruses [HBV, HCV, HIV] (BBV) infection in England. 18 million people attend emergency departments (EDs) in England each year, including marginalised groups at increased risk of BBV who may not regularly access healthcare. Routine BBV screening in EDs is uncommon. We estimated both diagnosed and undiagnosed active BBV prevalence in four busy urban EDs across England to inform BBV testing initiatives in this setting.
Method: Standardised triple blind unlinked anonymous BBV prevalence surveys using residual biochemistry blood samples of unselected ED attendees aged 16–65 years were undertaken at Liverpool (LP), Blackpool (BP) and two London hospitals (St Mary's and Charing Cross). Previously diagnosed BBV prevalence was estimated through interrogation of local hospital laboratory IT records. Samples were then irreversibly anonymised except for gender, age, and ethnicity; and screened for hepatitis B surface antigen (HBsAg), HCV antibody and HIV antigen/antibody. Positive results were confirmed using neutralisation, RNA and lineblot assays. Undiagnosed BBV was estimated by subtracting previously locally diagnosed from survey diagnosed prevalence.
Results: 5,383 samples collected from unique patients across the four sites between May and August 2017 were analysed. 53% were female. Pooled active BBV survey prevalence across sites was 3.33% (range 2.67–4.00%). Coinfection prevalence: 0.11%. Undiagnosed prevalence was estimated at 2.17% (range 1.02–3.53%).
Pooled survey prevalence stratified by virus was HCV-RNA: 1.69%, HBsAg: 0.95% and HIV: 0.80%. Undiagnosed prevalence for HCV-RNA: 0.80%, HBsAg: 0.71% and HIV: 0.67%.
HCV accounted for 82% and 84% of survey diagnosed local BBV infections in BP and LP, compared with 24% in the two London sites, although we found an HCV-RNA prevalence of 2.1% among 327 patients of black ethnicities in London. HBV and HIV prevalence were 1.47% & 1.23% in London, compared to 0.5% & 0.06% in LP and 0% & 0.64% in BP (Figure).



Conclusion: We demonstrated consistently high prevalence of active BBV infection in adults across four busy urban EDs; substantially higher than general population estimates. However, we also found marked geographical variation in BBV patterns. Our results suggest that targeted ED BBV testing initiatives, informed by local prevalence surveys, could provide a valuable contribution to improving diagnosis and linkage to care pathways for often marginalised populations.

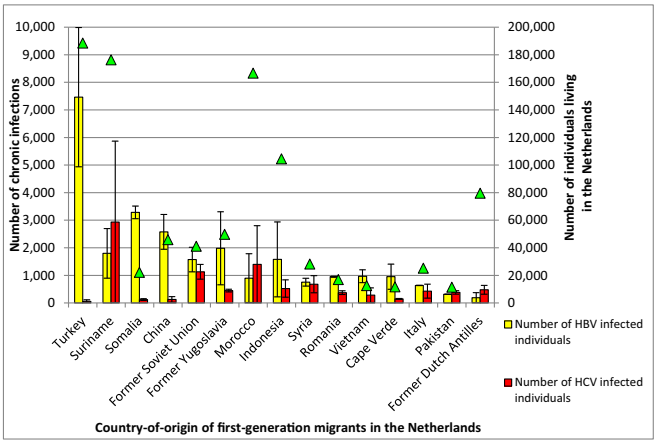
THU-072

Chronic hepatitis B and C infections in the Netherlands: estimated prevalence in risk groups and the general population

J. Koopsen[1,2], J. van Steenbergen[2], J.H. Richardus[3], M. Prins[4], E. Op de Coul[2], E. Croes[5], J. Heil[6], F. Zuure[4], I. Veldhuijzen[2]. *[1]Public Health Service of Amsterdam, Department of Infectious Diseases, Research and Prevention, Amsterdam, Netherlands; [2]National Institute for Public Health and the Environment, Center for Infectious Disease Control, Bilthoven, Netherlands; [3]Public Health Service of Rotterdam, Division of Infectious Disease Control, Rotterdam, Netherlands; [4]Public Health Service of Amsterdam, Department of Infectious Diseases, Research and Prevention, Amsterdam, Netherlands; [5]Netherlands Institute of Mental Health and Addiction (Trimbos Institute), Utrecht, Netherlands; [6]Public Health Service of South Limburg, Department of Sexual Health, Infectious Diseases and Environmental Health, Geleen, Netherlands*
Email: jkoopsen@gmail.com

Background and Aims: Worldwide, it is estimated that 248 million people are chronically infected with HBV and that 71 million are chronically infected with HCV. In the countries of the European Union (EU) and European Economic Area (EEA), approximately 4.7 million people live with chronic HBV and 5.6 million people are anti-HCV positive. Because chronic HBV and HCV infections are usually asymptomatic for decades, targeted screening is needed to diagnose infected individuals and prevent irreversible damage. Insight in the number of chronic HBV and HCV infections in the general population and in specific risk populations is needed to aid the design of screening programs.
Methods: Using a modified workbook method, originally designed for HIV estimations, the total number of ever chronically infected individuals in 2016 was determined for HBV and HCV. Population size and prevalence estimates were used, derived from studies in the general Dutch population and in populations at higher risk, including men who have sex with men (MSM), people who inject drugs (PWID), first-generation migrants from low-intermediate to high prevalence countries, sex workers and haemophilia patients. MSM and PWID were stratified by human immunodeficiency virus (HIV) status and first-generation migrants by country-of-origin.
Results: The estimated 2016 chronic HBV infection prevalence is 0.34% (low 0.22%, high 0.47%), corresponding to approximately 49,000 (low 31,000, high 66,000) HBV-infected individuals aged 15 years and older in the Netherlands. The estimated ever-chronic HCV

infection prevalence is 0.16% (low 0.06%, high 0.27%), corresponding to approximately 23,000 (low 8,000, high 38,000) ever HCV-infected individuals. First-generation migrants account for most infections with 81% and 60% of chronic HBV and HCV infections, respectively. The migrant groups that were estimated to harbor most chronic HBV infections in the Netherlands are migrants from Turkey, Somalia and China. The migrant groups that were estimated to harbor most chronic HCV infections in the Netherlands are migrants from Surinam, Morocco, and the former Soviet Union.



Conclusion: The prevalence of chronic HBV and HCV infections in the Netherlands is low. First-generation migrants are disproportionally affected, although about one fifth of HCV infections is found in the general population at low risk of infection. Targeted screening efforts are needed to diagnose and link infected persons to care. Our method could serve as an example of an accessible method to estimate risk group specific and overall HBV/HCV prevalences. Outcomes can be used to implement screening effectively and monitor progress towards elimination of chronic viral hepatitis.

THU-073

Transient elastography for screening of liver fibrosis in the population: A cost-effectiveness analysis using prospective databases from 6 countries in Europe and Asia

Email: pgines@clinic.cat

Background and Aims: The global epidemic of obesity and diabetes leads to an increased incidence of nonalcoholic fatty liver disease (NAFLD) posing a challenge to current hepatic clinical pathways in our healthcare systems. The aim of the present study is to explore the cost-effectiveness of transient elastography (TE) as screening method to detect advanced liver fibrosis in the general population.
Methods: Microdata from 7 independent prospective databases from 6 countries (5 in Europe and one in Asia) (n = 6,295), mean age = 54.7 (12.2), mean BMI = 27.0 (4.9) with mean liver stiffness measurement (LSM) value = 5.6 kPa (5.0) was merged and analyzed with data mining techniques (conditional inference trees, logistic regression and Heckman sample-selection models) to explore the relationship between socio-demographics, comorbidities, LSM, and hepatic fibrosis, as assessed by liver biopsy in 295 patients. The results were used in the parameter tuning of one cost-effectiveness model (Tanajewski L et al., BJM 2017) for a risk-based community stratification strategy in each of the populations.
Results: Heckman's inverse Mills ratio was −0.23, p = 0.343, indicating that the biopsied subsample of patients is consistent with no selection bias. A LSM cut-off of 9.1 kPa was found to provide the best discriminatory accuracy (DA) for advanced fibrosis (stages ≥ F2), AUC = 77.46% (95%CI 0.71–0.83). 343 (5.45%) patients of the whole sample presented LSM values above the selected threshold. The mean incremental cost-effectiveness ratios (ICER) of the risk-stratification strategy ranged from 4,034€ (95%CI 4,531–2,853€) per quality-adjusted life-year (QUALY) to 849€ (95%CI 1,533–603€) per QUALY depending upon the targeted population. For comparison we used the ICER of hepatocellular carcinoma screening published in 2016 that was found to be 39,825USD (Kuo et al., WJG 2016).
Conclusion: The evidence presented suggests that community risk factor-based TE screening pathways performed at primary care centres is a highly cost-effective intervention and potentially cost-saving for health systems in need for better resource allocation within their provision of care. Compared to previous published in hepatocellular carcinoma screening, our findings suggest that an earlier detection of fibrosis associated with NAFLD leads to a 10-fold improvement in cost-effectiveness estimates in European and Asian contexts.

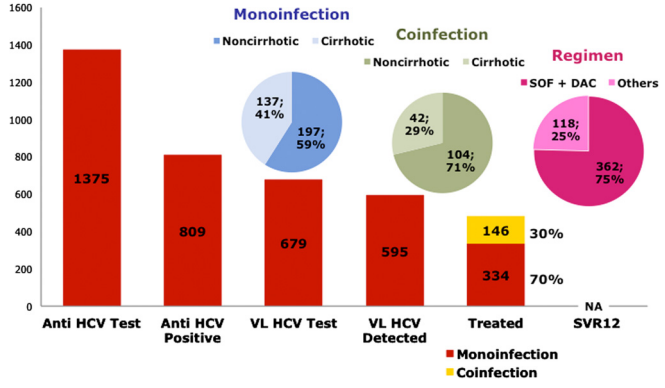
THU-074

Scale-up of the national HCV screening and treatment program in Indonesia: data from Jakarta, West Java and Central Java

A. Anartati[1], R. Kosasih[1], A. Budiman[1], J. Sacks[2], J. Tebor[2], C. Boeke[2], R. Sidjabat[3], S. Dwisangka[3]. *[1]Clinton Health Access Initiative, Jakarta, Indonesia; [2]Clinton Health Access Initiative, United States; [3]Indonesia Ministry of Health, Sub-directorate Hepatitis & Digestive Infection, Indonesia*
Email: aanartati@clintonhealthaccess.org

Background and Aims: HCV is a significant public health concern in Indonesia, with an estimated 1.28 million Indonesians living with chronic HCV. The government is committed to tackling the epidemic: a Ministerial Decree for hepatitis control was introduced in 2015, the 5 year Viral Hepatitis National Action Plan (2015–2019) was developed and the guidelines were updated to enable simplified diagnosis and treatment. The public program was launched in 2017, with the Government procuring diagnostics and DAAs (sofosbuvir/daclatasvir, sofosbuvir/simeprevir, and sofosbuvir/ribavirin) to treat up to 6,000 patients in 2017. Screening and treatment is currently

available across 7 provinces, with patients responsible for payment for visit fees and viral load consumables. Treatment is prescribed by specialists at hospitals, which are linked to primary health centers in the catchment area to expand access to screening. This analysis describes the initial scale-up in 3 provinces where the national program is most advanced.



Method: We conducted a retrospective analysis of routine programmatic data across 35 health facilities in Jakarta, West Java and Central Java for the first 1,375 patients who were screened. Screening targeted high risk groups, including people who inject drugs, people living with HIV, health care workers, and patients indicating they had been diagnosed previously. Data included analysis of serological markers, nucleic acid testing and assessment of fibrosis/cirrhosis through AST-to-platelet-ratio index (APRI).

Results: Out of 1,375 patients screened using anti-HCV rapid tests at 18 primary health centers and 17 hospitals, 809 (58.8%) were found to be positive. Of those who screened positive, 84% received a confirmatory HCV RNA test, of whom 88% were diagnosed with current HCV infection. 37% of all diagnosed were cirrhotic. As of October 2017, 81% of diagnosed patients had initiated treatment (n = 480), 30% of whom were HIV co-infected. The majority (362) of patients are being treated with SOF/DCV. Rates of treatment completion will be analyzed when data become available.

Conclusion: With strong political commitment and leadership, launching a public health HCV program in a high-burden middle-income country is feasible. Because direct patient payment is required, affordable diagnosis and treatment will be paramount to minimizing losses and achieving the public program's goal of diagnosis, treatment and cure for all Indonesians with chronic HCV.

THU-075

Hepatitis C screening within the national elimination program in the country of Georgia

A. Gamkrelidze[1], A. Turdziladze[2], V. Getia[3], M. Alkhazashvili[4], M. Tsereteli[1], A. Aslanikashvili[5], D. Baliashvili[6], P. Imnadze[1]. Email: mtsereteli2002@yahoo.com

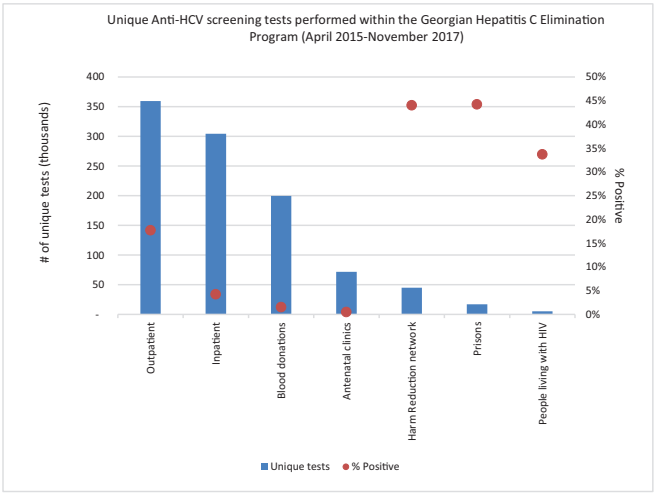
Background and Aims: Georgia is among the countries with high hepatitis C (HCV) prevalence. Based on the nationwide seroprevalence study conducted in 2015, 7.7% of the total population is hepatitis C antibody positive. In 2015, Georgia launched a large-scale public health program aiming to identify 90% of hepatitis C infected people, treat 95% of the identified individuals and achieve sustained virologic response in 95% of those treated. In order to achieve the set goals and eliminate hepatitis C by 2020, Georgia has significantly scaled up the screening activities during recent years.

Methods: Hepatitis C screening is provided free-of-charge by 602 testing centers across the country. Screening is performed according to the National Screening Protocol approved by the Georgian Government. The data are entered on-site into the electronic unified screening module, which is designed to capture results from all screening programs. Universal coverage with hepatitis C screening is ensured for certain population groups, such as pregnant women, blood donors and hospitalized patients. Screening-related data for these groups are entered in corresponding databases and imported into the module on a predefined regular manner.



Results: As of November 2017, 1,218,626 screening tests were registered in the electronic screening module, of which 9.3% were positive. 775,121 unique individuals were screened with 12.2% positive cases. The proportion of positive results were considerably higher in males compared to females with the positivity rates of 19.0% and 4.7%, respectively. Infection was mainly concentrated in 30–59 age group (79.0% of all screening positive cases) which reflects the 2015 seroprevalence study findings. The number of screening sessions and positivity rates among different population groups are shown in the figure.

Note: Figure shows only selected screening programs.

Conclusion: Georgia has markedly strengthened hepatitis C screening interventions and has already covered significant part of its population. Although, extending screening over the total population is still a challenge and requires a multi-sectoral approach.

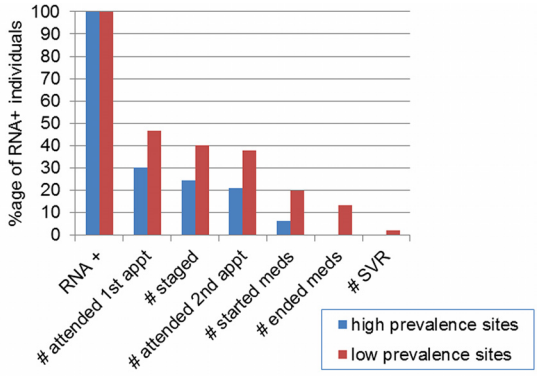
Email: lize.cuypers@kuleuven.be

Background and Aims: Despite treatment response rates of nearly 100% for the majority of hepatitis C virus (HCV) infected patients, the virus can only be eradicated on a global scale through the combined effort of preventing new infections and curing diagnosed cases. As HCV1a constitutes a large part of recent infections, investigating by which migration routes it spreads, is of public health relevance.
Method: HCV1a genetic data from two viral proteins, NS3 (n = 2514) and NS5A (n = 1957), was used to reconstruct the virus migration pathways through time and space on a global and European level. Data from thirteen European countries was available, including nine (Belgium, Germany, Ireland, Italy, Poland, Portugal, Russia, Spain and the United Kingdom) for which 1825 sequences were newly generated. These and publicly available spatiotemporally annotated virus genetic data were used to infer the migration rates between geographical locations with a fast and scalable Bayesian approach. To counter the impact of potential sampling biases on the phylogeographic reconstructions, the among-location exchange rate matrix was shared between the gene datasets.
Results: Inferring migration pathways for both genes reveals extensive movements on a supra-continental scale, showing a dominant role for the United States in seeding HCV1a into Europe (74.6% of all migration links), as well as considerable migration within Europe. As only a small minority of outgoing migration events from Europe is directed to the United States (<5%), this suggests a scenario of one-way traffic to Europe. Within Europe, the migration network becomes increasingly complex and diffuse over time. Preliminary analyses to identify source-sink relations within Europe suggest that Germany functions as a hub for the spread of HCV1a lineages in Europe, exporting mainly viral strains to France, Italy, the United Kingdom and Spain.
Conclusion: Molecular epidemiology of the European HCV1a epidemic illustrates complex patterns of human migrations that are increasing in complexity over time. The presence of a pan-European migration network impairs the efficacy of national-based intervention programs. In turn, this indicates that a supra-national coordinated approach is needed to more quickly and more efficiently curb the HCV1a epidemic. Furthermore, similar analyses for HCV3a and HCV4, both additional important sources of new infections, are needed to support evidence-based European prevention strategies.

THU-077
Outcomes of hepatitis C testing, linkage to care, and treatment in a community based program in high versus low prevalence sites

L. Magaldi, N. Brown, C. Coleman, M. Dorshimer, J. Kostman, D. Zaret, T.-W. Preston, M. Reddy, R. Rivera, S. Trooskin. *Philadelphia FIGHT, C a Difference, Philadelphia, United States*
Email: lmagaldi@fight.org

Background and Aims: In order to identify individuals with chronic hepatitis C virus (HCV) infection who are not engaged in medical care, HCV testing needs to be done in community settings. However, approaches to screening and linkage to care may be different depending on the type of community site. We describe the linkage to care rates in comprehensive drug treatment programs ("high prevalence sites") and those in other community testing sites ("low prevalence sites") receiving HCV testing through the C a Difference program.
Method: Participants presented for rapid HCV testing at various community settings in Philadelphia, Pennsylvania, between 10/2016 and 9/2017. Participants who tested positive for HCV antibody using the Oraquick HCV antibody test via fingerstick were immediately offered HCV confirmatory PCR testing via blood draw and linkage to subspecialty HCV care at a Federally Qualified Health Centre (FQHC) with experienced HCV treaters. We defined engagement in care as attending two visits at the FQHC. Comparisons of linkage rates and rates of treatment initiation were made between those tested in high prevalence sites and those tested in low prevalence sites using Chi Square tests.



HCV Care Continuum in High vs. Low Prevalence Community Based Sites

Results: During the study period 2244 adults 1523(68%) from low prevalence sites and 721(32%) from high prevalence sites presented for rapid HCV testing. Compared to those tested in low prevalence sites, those tested in high prevalence sites were more likely to be antibody positive (5.52% vs 45.9% p = 0.0001), and more likely to accept confirmatory testing (79.76% vs 91.84% p = 0.0144). Those tested in low prevalence sites were more likely than those tested in high prevalence sites to engage in subspecialty care after chronic infection was confirmed (37.78% vs 21.05% vs p = 0.0162) and were more likely to begin HCV treatment after engaging in care (20% vs 6.58% p = 0.0037).
Conclusion: Our study suggests that HCV community-based testing and screening programs are important for engaging those at risk for HCV. However, although the prevalence of chronic HCV infection is significantly higher incomprehensive drug treatment centres, the rates of care engagement and treatment initiation are significant lower when compared to individuals found to be HCV infected from low prevalence testing settings. In order to improve the HCV care cascade for individuals from high prevalence sites, on site treatment or models of intensive addiction-informed navigation are needed.

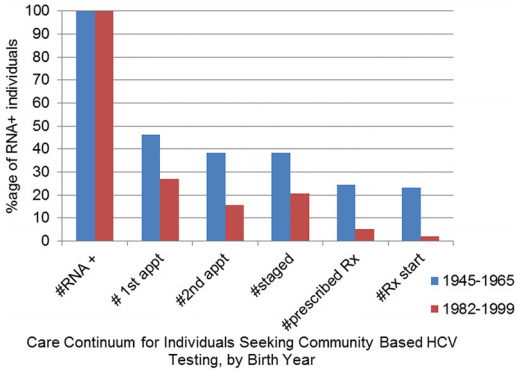
THU-078
Testing and linkage to care outcomes in baby boomers versus young adults tested in the community and linked to care at a Federally Qualified Health Center in the US

L. Magaldi, N. Brown, C. Coleman, M. Dorshimer, J. Kostman, D. Zaret, T.-W. Preston, M. Reddy, R. Rivera, S. Trooskin. *Philadelphia FIGHT, C a Difference, Philadelphia, United States*
Email: lmagaldi@fight.org

Background and Aims: While adults born between 1945–1965 (baby boomers) constitute the largest United States cohort with chronic hepatitis C infection (HCV) young adults born between 1982–1999, particularly those with a history of injection drug use, represent a growing population infected with HCV. Unfortunately, young adults often are not engaged in primary care and therefore are unlikely to be tested for HCV in this setting. Since community based testing can be used to identify members of these two cohorts with HCV infection,

we aimed to describe linkage to care rates of baby boomers versus young adults who were tested for HCV through C a difference, a community testing program.

Method: Participants include all adults born after 1945 presenting for point of care rapid HCV testing (Oraquick) at community settings in Philadelphia, Pennsylvania between 10/2016–9/2017. Participants testing positive for HCV antibody were immediately offered HCV confirmatory testing via phlebotomy and navigation to subspecialty HCV care in an FQHC setting. Care engagement was defined as attending at least two visits at the FQHC. We determined rates of antibody positivity, linkage to care, engagement in care and HCV treatment initiation and compared outcomes between baby boomers and young adults using Chi square tests.



Results: During the study period 1,349 adults, of whom 718 (53%) were baby boomers and 631 (47%) were young adults received community based HCV testing. Young adults were more likely to be antibody positive than baby boomers (23.3% vs 14.8% p = 0.0001), and more likely to accept immediate confirmatory testing (93.8% vs 85% p = 0.0341). However, young adults were less likely than baby boomers to engage in HCV care (19.1% vs 38.5% p = 0.0010) and baby boomers that engaged in care were more likely to begin HCV treatment (23.1% vs 4.8% p = 0.0001) (Figure).

Conclusion: Our results suggest that community-based programs are an important site for engaging and testing both baby boomers and young adults at risk for HCV and who may require assistance obtaining subspecialty care. Although young adults were more likely to be seropositive for HCV and to accept navigation services in an FQHC program, baby boomers were more likely to engage in care and start HCV treatment. Special care should be given to chronically infect young adults during the linkage process to be sure they enter and engage in subspecialty care and begin HCV treatment.

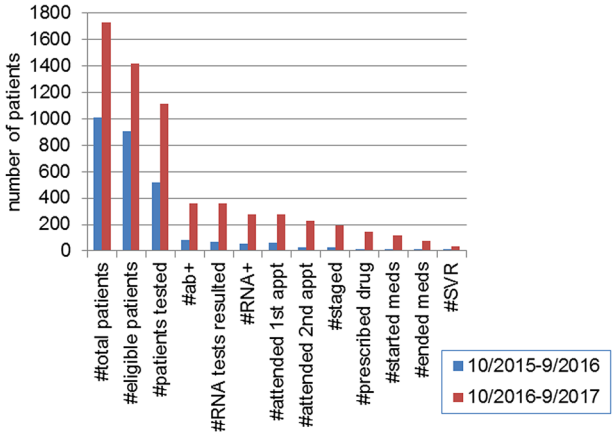
THU-079

The impact of EMR modification and a multi-disciplinary care team on the hepatitis C care cascade of a US Federally Qualified Health Center

L. Magaldi, N. Brown, C. Coleman, M. Dorshimer, J. Kostman, D. Zaret, T.-W. Preston, R. Rivera, M. Reddy, S. Trooskin. *Philadelphia FIGHT, C a Diffrence, Philadelphia, United States*
Email: lmagaldi@fight.org

Background and Aims: At least 50% of individuals infected with hepatitis C virus (HCV) are unaware of their status and 50% of individuals with a reactive antibody test never receive a confirmatory test; only a fraction of those engage in subspecialty care. Electronic Medical Record (EMR) lab order modifications for opt out HCV antibody testing with reflexive confirmatory PCR testing can increase rates of HCV testing and confirmatory testing. Implementing these EMR modifications in a Federally Qualified Healthcare (FQHC) setting where all providers also treat HCV and can be notified monthly of patients eligible for treatment may facilitate access to cure. We describe the impact of these EMR interventions on rates of HCV testing and treatment in a FQHC setting.

Method: Individuals seen between 10/2016 and 9/2017 with either no HCV testing recorded within one year or new FQHC patients had a lab order placed for automated HCV screening. Educational sessions were held for providers to reinforce implementation. Laboratory testing menus in the EMR were modified to include only HCV antibody tests with reflexive PCR testing on 7/12/2016. Data was collected through 5/11/2017. We compared points along the HCV care cascade with those at the same FQHC in the year prior (10/2015–9/2016). Since patients continue to progress through the care continuum, treatment and sustained virologic response (SVR) rates reflect interim outcomes.



Effect of EMR Modifications on the HCV Care continuum in an FQHC

Results: Prior to the EHR modifications, 57.3% (521 of 909) of eligible patients received antibody testing for HCV, and of those who were antibody positive (n = 81), 81% (n = 66) received confirmatory testing 45.5% of those (n = 25) received liver disease staging and 11 were treated for HCV. After EHR modifications, 78.4% (n = 1112) of eligible patients were tested, and of those who had a reactive antibody test, 99.7% (n = 358) had confirmatory reflexive testing. 98.6% of all RNA positive patients (n = 277) attended a subsequent HCV-specific provider visit; 68.6% (n = 190) received disease staging and 52.3% (n = 145) were prescribed HCV treatment. As of 4/11/2017, 42.6% (n = 118) began HCV treatment, 27.1% (n = 75) had completed treatment and 12% (n = 33) have achieved SVR.

Conclusion: Reflexive HCV testing via EMR modification resulted in significant increases in confirmatory testing rates. An FQHC setting where all providers are trained to treat HCV, results in improved treatment and SVR rates than reflected in the literature.

THU-080

Identifying patients with cirrhosis at high risk of readmission: a population-based data-linkage Australian study

P. Valery[1], L. Marquart[1], T. Rahman[2], P. Clark[3], S. Mcphail[4], R. Skoien[5], E. Powell[6]. *[1]QIMR Berghofer Medical Research Institute, Brisbane City, Australia; [2]The Prince Charles Hospital, Department of Gastroenterology and Hepatology; [3]Mater Hospital Brisbane, South Brisbane, Australia; [4]Queensland University of Technology, Institute of Health and Biomedical Innovation and School of Public Health & Social Work; [5]Royal Brisbane and Women's Hospital, Department of Gastroenterology and Hepatology; [6]Princess Alexandra Hospital, Department of Gastroenterology and Hepatology, Brisbane City, Australia*
Email: patricia.valery@qimrberghofer.edu.au

Background and Aims: While there are studies that have assessed predictors of readmission in decompensated cirrhosis, population-based Australian data are lacking. These data are essential to inform health work-force planning and strategies to reduce readmission. We describe the rates and associated risk factors of readmission within 1 year in patients with a first cirrhosis-related hospital admission.

Method: Hospital data on all patient admissions and deaths between Jul-2007 and Dec-2016 in the state of Queensland were obtained. Patient data were linked using deterministic and probabilistic methods. We identified index cirrhosis-related hospital admissions during 2012–2015 of patients ≥20 years of age, who did not have a liver transplant and were discharged alive. As ~50% of patients with decompensated cirrhosis die within 2 years, a look-back period of 4.5 years was used to identify the majority of *first* admissions with decompensation. We used Poisson regression to model the dichotomous outcome of readmission.
Results: Of 3,491 cases identified, most were male (66.7%), ≥50 years (77.2%), with the number of cases increasing by 38.4% between 2012 and 2015. The 1 year readmission rate was 32.7% (95%CI 31.1–34.2). Factors strongly associated with readmission included ascites (OR= 1.97, 95%CI 1.76–2.20; $p < 0.001$), hepatocellular carcinoma (OR = 1.58, 95%CI 1.11–2.60; $p = 0.012$), hepatorenal syndrome (OR = 1.57, 95%CI 1.00–2.45; $p = 0.049$), endoscopic banding procedure (OR = 1.52, 95%CI 1.34–1.74; $p < 0.001$) on the index admission, and history of alcohol consumption (OR = 1.22, 95%CI 1.08–1.37; $p = 0.002$). Having ≥2 cirrhosis-related complications (ascites, hepatic encephalopathy, gastroesophageal bleeding, jaundice, or hepatorenal syndrome), doubled the risk of readmission (OR = 1.95, 97%CI 1.56–2.44). Patients with one comorbidity vs. none were 1.79 (95%CI 1.60–2.00) times more likely to readmit, ≥2 comorbidities double the risk of readmission (OR = 2.02, 95%CI 1.63–2.52). A diagnosis of autoimmune liver disease was inversely associated with readmission (OR = 0.42 95%CI 0.23–0.76). Older age ($p = 0.019$) and male gender ($p = 0.048$) were weakly associated with readmission. No associations were seen with Indigenous status, rural residence, area-based socioeconomic status, year of admission, hospital sector, health insurance status, diagnosis of viral hepatitis (B/C) and/or NAFLD/NASH, and having gastroesophageal bleeding, hepatic encephalopathy, or jaundice on the index admission.
Conclusion: One-third of patients with cirrhosis are readmitted within 1 year. Opportunities exist to reduce readmissions via risk factor modification (e.g. alcohol consumption) and providing alternatives to re-hospitalization for management of ascites. The lack of association with Indigenous status, rural residence, and socioeconomic status needs further investigation.

THU-081

The role of a template-based assessment letter in the continuing education of general practitioners: a qualitative exploration of NAFLD educatioin

P. Valery[1], P. Patel[2], L. Horsfall[3], A. Russell[4], E. Powell[3], S. Williams[5].
[1]*QIMR Berghofer Medical Research Institute;* [2]*Princess Alexandra Hospital, Brisbane, Department of Gastroenterology and Hepatology;* [3]*Princess Alexandra Hospital, Department of Gastroenterology and Hepatology, Brisbane, Australia;* [4]*Princess Alexandra Hospital, Department of Diabetes and Endocrinology, Brisbane, Australia;* [5]*Inala Primary Care, Inala, Australia*
Email: patricia.valery@qimrberghofer.edu.au

Background and Aims: General practitioners (GPs) have a key role in identifying patients with non-alcoholic fatty liver disease (NAFLD) who are at risk of significant liver disease and may require specialist referral for further evaluation or management. However, many GPs under-recognize the clinical spectrum of NAFLD and how this is assessed.[1] On-line and other approaches have been used for providing continuing medical education for GPs across a range of diseases. Yet, acceptability and uptake has been limited, and research on learning opportunities about NAFLD by GPs is lacking. We aimed to investigate GPs' perspectives about the use of a template-based assessment letter ("template-letter") with educational content about NAFLD from hepatologists to referring GPs in routine care of patients with NAFLD.
Method: A qualitative study involving GPs from a primary care centre and specialists from an Endocrine clinic at a tertiary hospital in Queensland, Australia. Purposeful sampling was conducted to recruit GPs who took part in a focus group interview. Data were analyzed using a thematic analysis approach.
Results: GPs reported substantial benefits in the use of template-letters with educational content. Key themes that emerged for GPs included the consistency in the way patient information is presented in the template-letter (letters were "*accurate, concise, and consistent*"); information provided were practical and easy to follow ("*easy to understand, to the point*"), and the notes about the guidelines for management of NAFLD were "*very helpful*". While the GPs were unequivocal in their praise of the template-letters, suggestions to improve some dimensions of the template-letter were made e.g. having the key information about the patient upfront, i.e. patient follow up (what is expected from the GP vs. specialist follow up; long term plan for GP follow up, "*when to refer them* [patients] *back*") and no longer than 2 pages. Having a separate one-page document (and equivalent on-line version) with a simple algorithm for NALFD diagnosis, management and referral was seen as a helpful addition to the template-letter.
Conclusion: There is little published research into the influence of communication between primary and secondary care clinicians in the continuing education of GPs about NAFLD. A template-based assessment letter with an educational content generally had a positive impact on GP access to specialist expertise.

THU-082

The first large scale registry for non alcoholic fatty liver disease in Israel

I. Goldshtein[1], R. Oren[2], G. Chodik[1]. [1]*Maccabi Healthcaer Services, Epidemiology and Database Research, Research and Innovation Institute, Tel Aviv, Israel;* [2]*Institution of Gastrointestinal & Liver Diseases*
Email: goldst_in@mac.org.il

Background and Aims: Non-alcoholic fatty liver disease (NAFLD) is a growing public health concern worldwide, due to its rising prevalence, excess morbidity and mortality. Many patients are not recognized despite abnormal liver enzymes and/or NAFLD related findings on abdominal imaging tests. A previous EASL publication (M. Alexander, 2017) described the incidence and prevalence of recorded NAFLD in European databases, with 135,912 identified cases out of 21.9 million adults. Given the poor disease documentation, we aimed to establish a comprehensive NAFLD registry, combining structured as well as unstructured data to increase capture rate.
Method: The registry was built using the computerized database of Maccabi Healthcare Services, a nationally representative payer-provider health fund in Israel, currently covering 2 million members. Cases were included by either NAFLD/cirrhosis recorded diagnoses, or high NAFLD fibrosis scores (>0.67) or at least 2 elevated liver enzymes measurements, or imaging indication of fatty infiltration. The latter was facilitated by natural language processing of 1 million text reports of ultrasonography, computed tomography and magnetic resonance tests conducted in the years 2006–2017. The resulting coded presence and level of fatty infiltration were validated by a random sample of n = 800 manually annotated text reports, indicating 96% accuracy. Patients with other causes of fatty liver were excluded (viral hepatitis or excess alcohol intake as detected by diagnoses, laboratory and dispensed medications).
Results: A total of n = 217,154 NAFLD patients were identified, with approximately 18,000 incident cases each year, and a mean age of 50.7 (SD 17.5) at NAFLD onset. In January 2017 the registry included 9% of the general population or 21% of those aged 45 years old or above. Most cases were either overweight (36%) or obese (43%) and 29% had diabetes mellitus. Only 44% had NAFLD diagnoses coded in their health records.
Conclusion: To the best of our knowledge this is the first large-scale NAFLD registry relying on population-based data. This infrastructure will be further studied to characterize patients' comorbidities or health care utilization and will serve in the future as a valuable

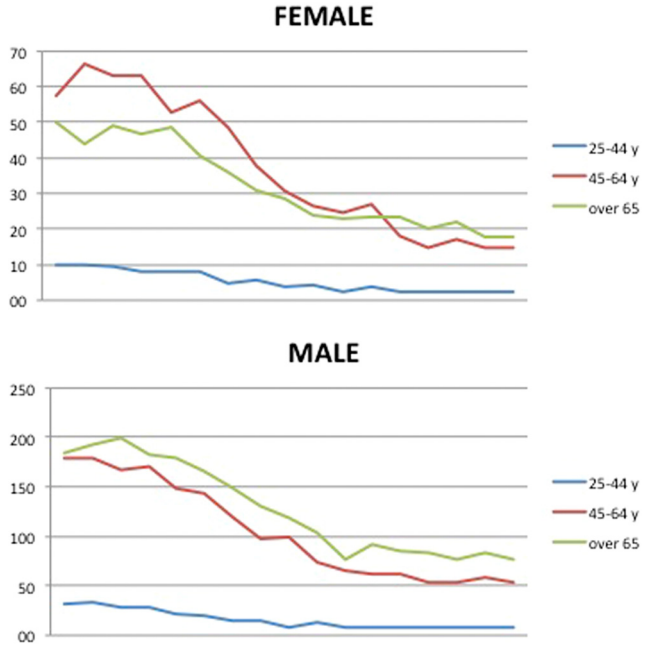
infrastructure to study real-world efficacy, safety and cost-effectiveness of evolving therapies.

THU-083

Hospitality discharge for alcohol related problems in north east Italy in a sixteen-years period: Influence of new population at risk

S. Vicario, M. Saia, D. Caroli, L. Scribano, F. de Lazzari, E. Rosa-Rizzotto, S. Lobello. *Gastroenterology*
Email: erik.rosarizzotto@aulss6.veneto.it

Background and Aims: WHO (2014) estimates a remarkable decline in per capita pure alcohol consumption in Italy, dropped from 18.1 to 7.1l in the period 1970–2013. Despite this, Italian Report on Alcohol 2016 showed an increase in drinking outside meals and a rise in consumption and binge drinking among young people (18–24, 14–17), particularly in males. The impact of these drinking styles on hospitalisation is still under-researched. This study aims to evaluate the trends of hospitality discharge for alcohol-related liver disease in the period 2000–2016 in Veneto Region in North Eastern Italy (4.8 million inhabitants).
Method: Retrospective cohort analysis based on Veneto Region anonymous computerised database of hospital discharges between 2000 and 2016. All Veneto residents discharge records with principal diagnosis of alcohol-related liver disease (cod. ICD9-CM: 571.0, 571.1, 571.2, 571.3) were included in the study. The principal diagnosis was chosen as it is considered the primary reason for hospital admission. Standardised Hospitalisation Ratio (SHR) per five-year age group (ref. pop. Veneto 2008) was calculated and expressed per 100.000 population.
Results: Over the period 2000–2016, 28.968 hospital admissions for alcohol-related diseases were recorded. Most part of subjects were males (74%) with a SHR more than double compared to females (53.3 vs. 18; OR:2.96; CI95%:2.89–3.04, $p < 0,05$). The longitudinal analysis of the hospitalisation trend shows a 7% increase on average age in both sexes (from 58.8 ± 9,2 to 62.6 ± 9,6) and a substantial decrease of 66% in SHR (X2 trend: 3933,326). In the last year of observation SHR tends to 19.5, and the greater risk for males is confirmed (30.2 vs. 8.8; OR:3.51; CI95%:3.05–4.10; $p < 0.05$). Considering the age groups, the highest decline in SHR can be found in the ranges 45–64 (from 69.2 to 34.1) and >65 (from 69.3 to 26.8). Interestingly, SHR shows a slightly rising trend in the group 25–44 between 2013 and 2016 ($p < 0.05$).



Conclusion: In Veneto Region, the reduction in alcohol intake over the last 30 years has lead to a marked decrease in hospitalisation for alcohol-related diseases. However, the changes in drinking styles occurred in the age range 25–44 may explain the upward SHR trend between 2013 and 2016. Thus, in the next few years it is likely to expect an increase in hospitalisation in this age group. Public Health strategies are needed to address the new styles of alcohol consumption, especially in young people.

THU-084

Is macro-elimination of HCV infection the right approach for Canada?

J. Holeksa, A. Alimohammadi, A. Bassi, A. Thiam, B. Conway. *Vancouver Infectious Diseases Centre*
Email: julie.holeksa@vidc.ca

Background and Aims: The World Health Organization has set a goal to eliminate HCV infection as a public health concern by 2030. Though some jurisdictions may implement country-wide macro-elimination strategies, this may not apply to many settings where health care delivery is a provincial/regional responsibility and where health care systems themselves are further divided to address the needs of local populations. A series of micro-elimination strategies may be more applicable in these circumstances. The inner city of Vancouver, British Columbia (BC) is home to a particularly vulnerable population with a 70% prevalence of HCV infection, and may be an ideal setting for the development of a pilot project for the control of HCV infection in the context of the development of a multidisciplinary model of care to address participants' needs, including optimized addiction care in the setting of the opioid crisis (3–4 opioid-related deaths/day in BC).
Method: We have developed a "four-legged chair" model to promote engagement with healthcare and social services. This model addresses the four main priorities of our population–medical, psychiatric, addictions, and social needs. This analysis was conducted to report on two principal outcomes: success of HCV therapy (SVR12), and opioid-related morbidity and mortality.
Results: Since 2014, 195 active/recent people who use drugs (PWUD) have received all-oral HCV treatment within this program. Key baseline characteristics were: median age 53 years; 78% male; 68/19% GT 1a/3; 20% F4; 68/59% using opiates/cocaine. Of patients with available SVR12 data, our overall success rate has been 140/149 (93%), with the remaining 7% experiencing a virologic relapse and requiring retreatment. Of the total cohort, 3% (n = 6) have been lost to follow up and will require novel strategies for reintegration in care. The remainder of the cohort is still in follow up and information will be updated appropriately. Over the past 2 years (almost 2,000 opioid-related deaths in BC), there have been only 22 medically significant overdose events and 2 opioid-related deaths within this cohort.
Conclusion: Given the broad range of health care delivery jurisdictions and target populations, a macro-elimination strategy for HCV infection in Canada will likely not be feasible. The model we have developed could be an ideal micro-elimination approach that will allow us to address both HCV infection as well as respond to the opioid crisis in a high-risk population. It is likely that Canada's optimal response to HCV infection will include a series of micro-elimination strategies, designed to optimize the social and healthcare needs of individual populations of interest.

THU-085

Low rates of prenatal testing for hepatitis B and C infections in Ontario, Canada

M. Biondi[1], A. Marchand-Austin[2], K. Sahdra[1], H. Janssen[1], T. Mazzulli[3], J. Feld[1]. [1]*Toronto General Hospital, Toronto Centre for Liver Disease, Toronto, Canada;* [2]*Public Health Ontario, Laboratory Surveillance and Data Management, Toronto, Canada;* [3]*Public Health Ontario, Toronto, Canada*

Email: mia.biondi@mail.mcgill.ca

Background and Aims: Prenatal testing is widely accepted for certain infections including syphilis, hepatitis B virus (HBV) and HIV, the latter of which has a testing uptake between 95% and 99% in Ontario. However, currently, universal prenatal testing for hepatitis C virus (HCV) is not recommended in most jurisdictions. The aim of our study was to examine HBV and HCV testing uptake, seroprevalence, and follow-up testing in women receiving prenatal care in Ontario, Canada, to identify potential gaps.

Methods: Anonymous, unlinked data from the provincial public health laboratory were collected to determine the number of women tested, and positive for HBsAg and anti-HCV from 2010–2017. As a result of unique identification numbers, we were able to link these individuals to results from subsequent tests completed for both HBeAg and HCV RNA. Data were compared by age and region.

Results: HBsAg prenatal testing occurred in 85% of live births with little year-to-year variation. Women ages 15–20 had the lowest prevalence at 0.1%, ages 21–25 at 0.5%, and those younger than 15, as well as ages 26–45 from 0.7–1%. Of the 2,326 women over 45 tested, 117 were positive, with a prevalence of 5%. From a regional perspective, the Greater Toronto Area had the highest rates ranging from 0.5% to 1.5%, whereas two regions in Northern Ontario had the lowest prevalence of 0.05%. Although HBeAg is a predictor of vertical transmission, only 8% of HBsAg-positive women received HBeAg testing within 259 days. With respect to HCV testing, 2% of all pregnant women from 2010 to 2017 were antibody tested using a prenatal requisition. Overall, 1.4% were HCV antibody positive, with the highest rates among pregnant women ages 21–25 at 2.5%. This is in comparison to younger (less than 21) at 2%, and older women (over 40) at 1.5%. Of women who tested HCV antibody positive, 56% had follow-up HCV RNA testing, with a positivity rate of 57%. HCV RNA was detected at the highest rates among those ages 21–30, at 61% of antibody positive individuals.

Conclusion: Our data demonstrate that HBsAg testing was frequent, but not universal, and that subsequent HBeAg testing was low; which may lead to missed opportunities for antiviral therapy. Acknowledging that some HCV screening may not be requested on a prenatal requisition, HCV testing uptake was also low, and only half of women received RNA follow-up testing. Knowing whether a woman is actively infected is essential to assess transmission risk and need for pediatric and maternal follow-up. These data point to the need for a streamlined approach to HBV and HCV prenatal screening and care.

THU-086

Scale up of hepatitis C virus treatment in the era of all-oral direct-acting antivirals: a 9-year Greek cohort study

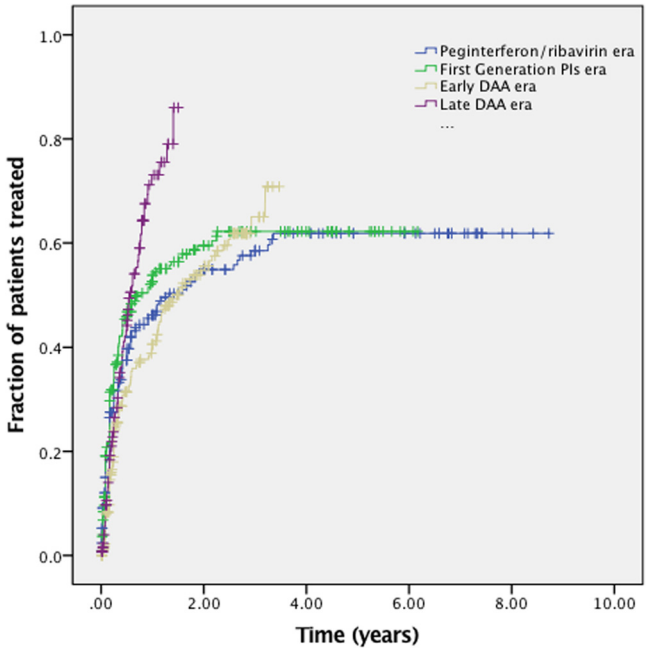
V. Papastergiou[1], M. Deutsch[1], M. Mela[2], C. Triantos[3], H. Kranidioti[1], C. Chatzievangelinou[2], K. Zisimopoulos[3], O. Anagnostou[4], G. Papatheodoridis[5], S. Manolakopoulos[6]. [1]*2nd Department of Internal Medicine, School of Medicine of National and Kapodistrian University of Athens, Athens, Greece;* [2]*Department of Gastroenterology, Evaggelismos General Hospital;* [3]*Department of Gastroenterology, University Hospital of Patras;* [4]*Greek Organisation Against Drugs (OKANA), Athens, Greece;* [5]*Academic Department of Gastroenterology, School of Medicine of National and Kapodistrian University of Athens;* [6]*2nd Department of Internal Medicine, School of Medicine of National and Kapodistrian University of Athens, Athens, Greece*

Email: vasi.pap@hotmail.com

Background and Aims: It is estimated that more than 80.000 people are living with hepatitis C virus (HCV) infection in Greece. A number of changes in direct-acting antivirals (DAA) reimbursement criteria have occurred during the last years, including prioritization of patients with ≥F2 fibrosis and those with hematological/kidney comorbidities since July 2017. However, the impact of these changes on HCV treatment initiation remains unknown. The aim of this study was to compare longitudinal HCV treatment initiation rates during 4 different periods: peginterferon/ribavirin (PR; January 2009–May 2011), first-generation protease inhibitors (PI; June 2011–December 2013), early DAA (January 2014–December 2015) and late DAA (January 2016–August 2017).

Method: Data were collected from 3 tertiary hospitals (5 physicians). A total of 832 HCV-viraemic adults were included (71.1% males, mean 46.5 ± 13.1 years, 56.3% intravenous drug users, 29.4% cirrhotics, 35.3% genotype-1, 74.9% treatment-naïve, PR/PI/early DAA/late DAA eras: 211/255/233/133), with at least one clinical visit between January 2009 and August 2017. Observation time was calculated from the day of first clinical visit to 31/10/17, initiation of antiviral treatment, last follow-up or death. Kaplan-Meier analyses were used to determine the cumulative incidence of start of antiviral therapy. Cox regression was used to estimate incidence rate ratios as relative risks (RR) with 95% confidence intervals (CI).

Results: Overall, 427 (51.3%) patients started treatment over a median (IQR) follow-up of 25.6 (8.6–73) weeks. The annual HCV treatment uptake remained stable from 2009 to 2013 fluctuating between 24.6%/year and 31.4%/year, dropped to 19.4%/year in 2014, and then raised again peaking to 32.7%/year in 2017. A steadily increasing trend was observed in the proportion of treated patients receiving all-oral DAAs, from 10.2% in 2014 to 89.9% in 2017. The overall cumulative probability of treatment across all periods was 50%, 64.3% and 66.3% at 1, 3 and 5 years respectively. Patients presenting in the late DAA era were significantly more likely to initiate therapy compared to those presenting in PR, PI, and early DAA eras (1-year cumulative treatment initiation: 73.1% vs 46.1%, 52.6% and 40.6% respectively; p = 0.006) (Figure). The probability of treatment was higher in the late (vs early) DAA period for non-cirrhotics (RR:2.43; 95%CI:1.51–3.90), treatment-naïve (RR:2.16; 95%CI:1.43–3.27), intravenous drug users (RR:3.05; 95%CI:1.92–4.82) and non-holders of public insurance (RR:4.87; 95% CI:2.63–8.70).



Conclusion: Our data show an increase in HCV treatment uptake after the introduction of new-generation DAAs and the expanded DAA

prioritization policies. However, as a substantial proportion of patients still remain untreated, more efforts are required in order to increase the HCV treatment uptake.

THU-087

Design and cost effectiveness of a hepatitis C virus elimination strategy based on an updated epidemiological study (ETHON cohort)

A. Cuadrado[1], C. Perello[2], S. Llerena[1], D. Escudero-García[3], M. Gómez[2], Á. Estébanez[1], L. Puchades[3], M. Serra[3], L. Rodríguez[2], J.C. Gonzalez[1], J.L.C. Panero[2], J. Crespo[1]. *[1]Marqués de Valdecilla University Hospital. IDIVAL. CIBERehd., Department of Gastroenterology and Hepatology; [2]Puerta de Hierro University Hospital, CIBERehd, Liver Unit; [3]University Hospital Clinic, Department of Medicine; University of Valencia, Service of Hepatology*
Email: acuadrado@humv.es

Background and Aims: Elimination of hepatitis C virus (HCV) is feasible in a country with universal access to direct acting antivirals, so hepatitis C screening in the general population is essential to achieve it. Our aim is to design a non-universal population screening strategy according to the results obtained in the ETHON study.
Method: Epidemiological, population and cross-sectional study carried out between July 2015 and March 2017 in three different communities of Spain (Madrid, Valencia and Cantabria). Two-stage cluster sampling was performed, with stratification by socio-economic status, rural/urban area and age. Anthropometric, demographic, analytical and serological data were collected. An analysis of the effectiveness of different HCV population screening settings was made. This analysis was carried out in 3 stages: Cost of the selection process, efficiency of the evaluation process and cost-effectiveness of the detection program + treatment.
Results: A total of 12,515 subjects were included (mean age 50.35 years, 41% men) (table). The prevalence of anti-HCV was 1.23%, and HCV-RNA were detectable in 0.32%. The prevalence was higher in males ($p < 0.001$), low educational level ($p < 0.001$) and with transmission risk factors ($p < 0.001$). 59% subjects knew the existence of the infection. The viremia positive was mainly between 45 and 59 years old (45–49: 0.30%, 50–54: 0.64%, 55–59: 0.46%), grouping more than 50% of cases. The strategy of HCV screening and its subsequent treatment has incremental cost-effectiveness ratios lower than 6,000 euros in any setting. The analysis by age cohorts shows that the screening strategy is cost-effective in any age cut, being especially effective between 45 and 49 years.
Conclusion: Our results show that a strategy of HCV screening and treatment aimed at subjects between 45 and 60 years old is highly cost-effective.

THU-088

Hepatitis C infection in the Pan American Health Organization Region: The current burden of disease and a road map for achieving the WHO Global Health Sector Strategy Goals

J. Schmelzer, S. Blach, S. Brandon, C. Estes, I. Gamkrelidze, H. Nde, D. Razavi-Shearer, S. Robbins, H. Razavi. *CDA Foundation, Polaris Observatory, Lafayette, United States*
Email: jonathan.schmelzer@centerforda.com

Background and Aims: The 69th World Health Assembly passed a resolution to eliminate viral hepatitis by 2030. Epidemiological assessment and predictive modeling are needed to develop strategies to achieve this goal. This study quantifies the current hepatitis C disease burden in the Pan American Health Organization (PAHO) and proposes a strategy for achieving the World Health Organization (WHO) Global Health Sector Strategy (GHSS) goals for Hepatitis by 2030.
Method: HCV disease burden models were developed for 24 countries and aggregated into a regional model which took into consideration new infections, disease progression, mortality and cured to estimate historic and future burden of disease. Regional averages were applied to country populations when country-specific data were not available. Intervention scenarios were developed within the regional model and projected outcomes related to the size of the HCV-infected population by disease stage were assessed from 2016 to 2030.

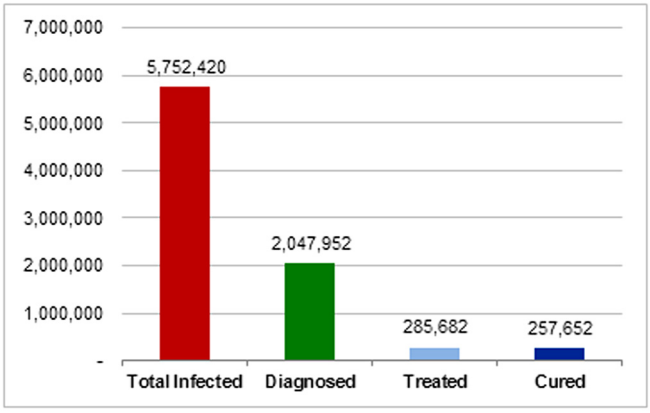


Figure 1: PAHO Cascade of Care, 2016.

Results: In 2016, there were an estimated 5.8 million viremic infections in the region, 36% of which had been previously diagnosed (163,000 newly diagnosed) and 286,000 of which had initiated treatment that year. Maintaining the current treatment and

Table: (abstract: THU-087)

TOTAL	12,515	154	1.23	40	0.32	92	30	56	34,438,585	384,744	105,882
						59,1%	26%	49%			

SNI, Statistics National Institute

diagnostic paradigm would result in an estimated 50% reduction in total HCV infections and 5% to 9% decrease in liver-related morbidity and mortality by 2030.
To achieve the GHSS goals of diagnosing 90% of total infections and reducing liver-related mortality by 65% by 2030, the region would need to treat an estimated 260,000 patients in 2017, gradually increasing to 280,000 in 2025, while gradually increasing the number diagnosed annually to 260,000 by 2025. Additional prevention efforts will need to be coordinated across the region in order to achieve the GHSS goal of a 90% reduction in new infections by 2030.

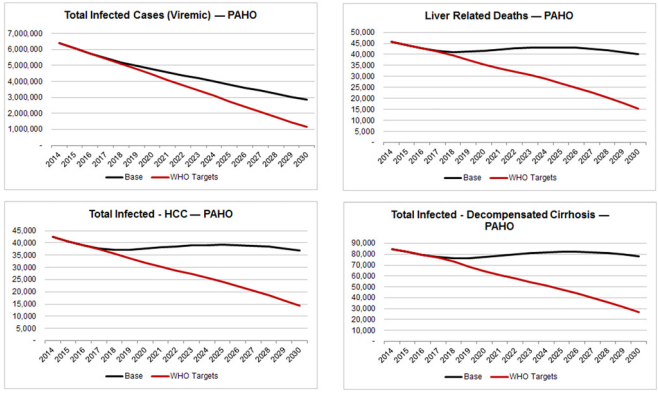

Figure 2: Liver Related Morbidity and Mortality by Scenario, 2016–2030.

Conclusion: Achieving the GHSS goals across the PAHO region is feasible with a slight increase in the number of annually diagnosed and treated cases. However, prevention efforts, easing age restrictions and the increased expansion of access to highly curative treatment will be necessary components.

THU-089
The current and future disease burden of hepatitis B in the general population and among five year olds in the Eastern Mediterranean Region

J. Schmelzer, D. Razavi-Shearer, S. Blach, S. Brandon, C. Estes, I. Gamkrelidze, H. Nde, S. Robbins, H. Razavi. *CDA Foundation, Polaris Observatory, Lafayette, United States*
Email: jonathan.schmelzer@centerforda.com

Background and Aims: Accurate national estimates of chronic hepatitis B (CHB) are needed to devise national and regional strategies. Previous studies have either provided prevalence estimates based on a literature review or have depended on regional models. This study quantifies the prevalence of CHB in the Eastern Mediterranean Region (EMRO) among the general population and five year olds from 2016 through 2030 using historical prevalence estimates combined with country level modeling.
Method: A literature review was conducted for hepatitis B surface antigen (HBsAg) prevalence among the general population (by age) and e-antigen prevalence among women of child bearing age. A dynamic country-level transmission and disease burden model was used to estimate the impact of vaccination, hepatitis B immune globulin, treatment of mothers, aging, disease progression and mortality in the infected population in each country. Regional averages were applied to populations of countries without available data and results were then aggregated to the region.
Results: HBsAg prevalence data were available and models were developed for 18 countries representing 92% of the region's population. In 2016, the regional CHB prevalence was estimated at 2.2% (CI:1.9–2.9%) corresponding to 14.9 million (CI:12.9–19.5 million) infections after the impact of perinatal prophylaxes was taken into consideration. There were an estimated 1.2 million total cases of cirrhosis, 111,000 cases of decompensated cirrhosis and 112,000 cases of hepatocellular carcinoma (HCC). Among five year olds, the regional prevalence was estimated to be 0.5% (CI:0.4–0.7%) corresponding to 76,100 infections (CI:67,300–110,000).
By 2030, total CHB infections in the EMRO region is projected to decline by 9% in the general population and 6% among five year olds. However, total cirrhosis, decompensated cirrhosis and HCC are expected to increase by 8%, 4% and 22% respectively.

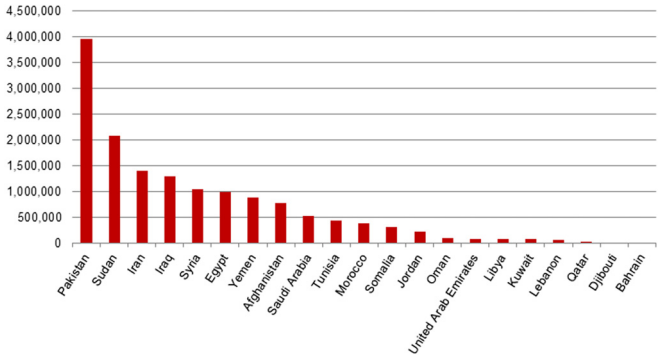

Figure 1: CHB Infections by EMRO Country, 2016.

Conclusion: While total CHB infections are expected to decline over the next 15 years in the EMRO region, advanced morbidity and mortality are projected to increase as the infected population ages. A CHB prevalence of 0.5% among five year olds and expected decline of only 6% suggests that higher perinatal prophylaxes coverage is needed to further reduce the prevalence among children.

THU-090
The covert "C"; prevalence: Risk factors and management of hepatitis C in psychiatric in-patients

J. Ramachandran[1], H. Slattery[2], S. Budd[2], T. Mohan[3], T. Cowain[4], A. Baas[5], L. Wigg[6], J. Alexander[6], K. Muller[1], B. Kaambwa[7], R. Woodman[8], A. Wigg[1]. *[1]Flinders Medical Centre, Flinders University, Department of Gastroenterology and Hepatology, Adelaide, Australia; [2]Flinders Medical Centre, Department of Psychiatry, Adelaide, Australia; [3]flinders medical Centre, Department of psychiatry, Adelaide, Australia; [4]the Jamie Iarcombe Centre, Glenside, veterans mental health, Adelaide, Australia; [5]Morier Ward, Noarlunga Hopsital, department of psychiatry, Adelaide, Australia; [6]gelnside campus, rural and remote mental health service, Adelaide, Australia; [7]flinders university, health economics unit, College of Medicine and Public health, Adelaide, Australia; [8]Flinders University, Flinders Centre for epidemiology and biostatistics, Adelaide, Australia*
Email: jeyamani.ramachandran@sa.gov.au

Background and Aims: Despite concerns about high prevalence of hepatitis C virus (HCV), psychiatry patients have been underserved due to neuropsychiatric adverse effects of interferon therapy. Directly acting antiviral (DAA) agents have made treatment of HCV in these patients feasible. In view of the paucity of information about prevalence of HCV in this group in Australia, and since an admission for mental illness may offer an opportunity for screening and treatment of HCV, this study was undertaken.
Aims of this study were to assess in patients admitted to hospital with mental illness: (1) HCV seroprevalence (2) prevalence of risk factors for HCV and (3) experience of treatment and follow-up.
Method: This was a point prevalence study including four inpatient psychiatric units. All inpatients from January 2017 to date were eligible to participate. After consent, HCV testing was performed and information about HCV risk factors obtained. Descriptive statistics for proportions were used to estimate HCV prevalence with 95% CI. Predictors of HCV prevalence were assessed using binomial logistic regression.

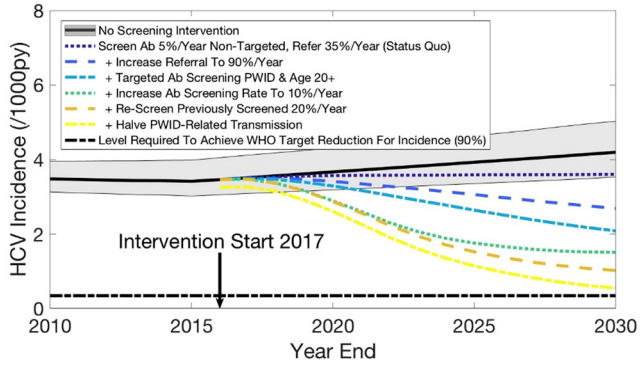
Results: 241 patients (70% male), median age 43 years (IQR 24) consented to the study, which was only 13% of patients admitted during the study period. Reasons for low recruitment included lack of interest, distrust and understanding by patients and busy schedule of medical staff.
Reasons for admission were major depression (26%), schizophrenia (17%), anxiety disorder (12%), bipolar affective disorder (10%), substance dependence (7%), personality disorder (3%) and other (14%). Prevalence of risk factors for HCV in the cohort were intravenous drug use (IVDU) (28%), exposure to custodial stay (20%), tattooing (63%), blood transfusion or organ transplantation (10%), sex workers (16%) and indigenous descent (8%). Period prevalence of HCV antibody was 10% (95%CI 7–15). Independent predictive factors for HCV seropositivity were IVDU (OR 15.60, 95%CI 4–61, $p < 0.001$) and custodial stay (OR 5.6, 95%CI 1.8–18, $p = 0.004$). HCV RNA was negative in 11/25 patients with positive antibody (prior treatment-5 and spontaneous clearance-6). Of the 14 patients with detectable HCV RNA, five were initiated on DAAs. Treatment was well tolerated, without significant non-adherence. One of them achieved viral clearance and results are awaited in the rest. The remaining 9 patients have proven difficult to engage with despite efforts by hospital and community care teams.
Conclusion: In view of high prevalence, psychiatric inpatients should be considered a high risk population for HCV and routine screening should be considered. Despite availability of well tolerated DAA therapy, engaging with this patient population remains a challenge. Non-traditional models of care involving community mental health teams, hepatitis nurses and primary care physicians require further investigation to improve treatment uptake.

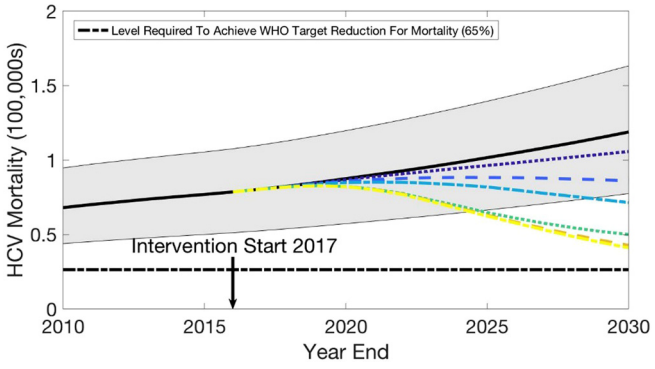
THU-091

Modelling the impact and efficiency of screening and treatment scale-up for hepatitis C virus in Pakistan: Working towards elimination

A.G. Lim[1], J. Walker[1], H. Qureshi[2], H. Mahmood[2,3], S.S. Hamid[4], F. Averhoff[5], P. Vickerman[1]. *[1]University of Bristol, Population Health Sciences, Bristol Medical School, Bristol, United Kingdom; [2]Pakistan Health Research Council (PHRC), Islamabad, Pakistan; [3]Centers for Disease Control and Prevention (CDC)/TEPHINET, Division of Viral Hepatitis, Atlanta, United States; [4]Aga Khan University, Karachi, Pakistan; [5]Centers for Disease Control and Prevention (CDC), Division of Viral Hepatitis, Atlanta, United States*
Email: aaron.lim@bristol.ac.uk

Background and Aims: Pakistan has the second-largest hepatitis C virus (HCV) burden worldwide. With increasing access to highly effective direct-acting antiviral (DAA) HCV treatment, Pakistan can now tackle the country's HCV epidemic and aim for the World Health Organization (WHO) HCV elimination targets. However, low levels of diagnosis and referral present challenges to treatment scale-up. We use modelling to project the impact of screening and treatment interventions in Pakistan to reduce HCV incidence by 90% and HCV-related mortality by 65% by 2030 compared with 2015.
Method: We developed a dynamic HCV transmission model for Pakistan incorporating screening and treatment, and calibrated to national HCV seroprevalence data from 2007 (4.8%), surveys among people who inject drugs (PWID, 56–69%), and HCV prevalence trends amongst blood-donors. Compared to a counterfactual of no treatment, we determine what screening coverage is needed from 2017 to sustain current treatment levels (150,000 annual treatments). We estimated the impact and costs of scaling-up screening, DAA treatment, and prevention interventions directed at achieving the WHO HCV-elimination targets.
Results: Current levels of treatment can be maintained by implementing general population screening with 5% of individuals screened annually (~10 million tested/year) and 35% of diagnosed individuals initiating treatment, resulting in 82 tests per treatment and 5 infections averted per 1000 antibody screenings (IA/1000Ab). However, incidence and mortality will rise by 6% and 38%, respectively, by 2030. Much greater impact is achieved by doubling annual screening to 10%, targeting adults (>20 years), increasing referral to 90%, and introducing re-screening every 5 years, with 56 tests per treatment, 10 IA/1000Ab, and the WHO mortality target reached by 2041. However, only with also halving HCV transmission risk in PWID will HCV incidence and mortality approach the WHO targets, now being reached by 2036. Preliminary costing estimates suggest that screening and treatment scale-up in Pakistan is likely to cost about USD$2,000 per cure, with the majority (70%) of costs coming from screening.





Conclusion: Substantial scale-up of screening and treatment interventions will be required to achieve the WHO HCV elimination targets. This can be optimised if referral rates are increased and screening is preferentially targeted toward priority groups with higher prevalence of HCV infection, but despite this, costs will be substantial.

THU-092

Characteristics and outcomes of patients with late presentation of hepatitis B among newly-diagnosed hepatocellular carcinoma: A national cohort study 2002–2013

D.H. Sinn[1], D. Kang[2], S.W. Paik[1], B.C. Yoo[3], J. Cho[2], G.-Y. Gwak[1]. *[1]Samsung Medical Center, Department of Medicine, Seoul, Korea, Rep. of South; [2]Samsung Medical Center, Department of Clinical Research Design and Evaluation, SAIHST, Seoul, Korea, Rep. of South; [3]Konkuk University Medical Center, Department of Medicine, Seoul, Korea, Rep. of South*
Email: sinndhn@hanmail.net

Background and Aims: Nowadays, effective and well tolerated treatments for hepatitis B virus (HBV) are available to treat and improve patient outcome, especially if diagnosed early. Consensus definition of late presentation of chronic viral hepatitis for medical

care has been recently suggested, yet, clinical implications on a population basis are lacking.
Method: We used a population-based, National Health Insurance Service-National Sample Cohort between January 1, 2002 and December 31, 2013 to assess presentation pattern among newly-diagnosed HBV-associated hepatocellular carcinoma (HCC) patients. Late presentation was defined when patients were diagnosed with HCC without prior clinic visit for HBV. For patients with prior clinic visit, they were categorized into "regular" or "irregular" visit based on the pattern of outpatient clinic visits before HCC diagnosis.
Results: Among 1,326 newly diagnosed HBV-related HCC patients, 424 (32.0%) cases were late presentation cases, while 557 (42.0%) and 345 (26.0%) patients belonged to the irregular and regular visit groups, respectively. Late presentation has declined from 45% in 2003 to 22% in 2013, while regular clinic visit has increased from 22% in 2003 to 35% in 2013, respectively. Lower economic status and young age were associated with late presentation. Late presentation was associated with higher mortality compared to regular visit group (multivariable-adjusted HR, 1.97; 95%CI, 1.59–2.44), as well as the irregular visit group (multivariable-adjusted HR: 1.42, 95%CI, 1.42–1.75).
Conclusion: Late presentation was associated with increased risk of mortality in HBV-related HCC patients, indicating that reducing late presentation is one of practical goals to decrease mortality for HBV-related HCC on a population level. Late presentation is a good surrogate to estimate clinical situation and monitor effectiveness of current health-care policy for hepatitis B and liver cancer on population level.

Evaluation of the Xpert fingerstick HCV viral load assay

F. Lamoury[1,2], S. Bajis[1], B. Hajarizadeh[1], A. Marshall[1], M. Martinello[1], E. Ivanova[2], B. Catlett[3], Y. Mowat[1], P. Marks[1], J. Amin[4], J. Smith[5], N. Ezard[6], V. Cock[7], J. Hayllar[8], D. Persing[9], M. Kleman[10], P. Cunningham[11], G. Dore[1], T. Applegate[1], J. Grebely[12]. *[1]UNSW Sydney, The Kirby Institute, Sydney, Australia; [2]Foundation for Innovative Diagnostics, Geneva, Switzerland; [3]St Vincent's Centre for Applied Medical Research, Sydney, Australia; [4]Macquarie University, Sydney, Australia; [5]Matthew Talbot Hostel, St Vincent de Paul Society NSW Support Services, Sydney, Australia; [6]St Vincent's Hospital, Alcohol and Drug Service, Sydney, Australia; [7]Drug and Alcohol Services of South Australia, Adelaide, Australia; [8]Metro North Mental Health, Metro North Hospital and Health Service, Alcohol and Drug Service, Brisbane, Australia; [9]Cepheid, Sunnyvale, United States; [10]Cepheid AB, Solna, Sweden; [11]St Vincent's Centre for Applied Medical Research, Sydney, Australia; [12]UNSW Sydney, The Kirby Institute, Australia*
Email: jgrebely@kirby.unsw.edu.au

Background and Aims: Point-of-care hepatitis C virus (HCV) RNA testing is advantageous over antibody testing (which only indicates previous exposure), enabling diagnosis of active infection in a single visit. The aim of this study was to evaluate the performance of the Xpert® HCV Viral Load Fingerstick assay (Xpert HCV VL FS) from samples collected by finger-stick capillary whole-blood and the Xpert® HCV Viral Load Assay from plasma samples collected by venepuncture.
Method: Plasma and finger-stick capillary whole-blood samples were collected from participants in an observational cohort enrolled at four sites in Australia (three drug treatment clinics and one homelessness service). This study evaluated the sensitivity and specificity of the Xpert® HCV VL FS assay for HCV RNA detection (finger-stick) and the Xpert® HCV Viral Load Assay (plasma) compared with the Abbott RealTime HCV Viral Load assay by venepuncture (reference standard).
Results: Of 223 participants enrolled, 181 had HCV RNA testing results for the three assays tested. Participants receiving HCV therapy were excluded from analyses (n = 16). HCV RNA was detected in 36% ([95%CI 29–44], 60 of 165). Sensitivity of the Xpert® HCV Viral Load Assay for HCV RNA quantification in plasma collected by venepuncture was 100.0% (95%CI 93.9–100.0) and specificity was 100.0% (95%CI 96.5–100.0). Sensitivity of the Xpert® HCV VL FS assay for HCV RNA quantification in samples collected by finger-stick was 100.0% (95%CI 93.9–100.0) and specificity was 100.0% (95%CI 96.5–100.0).
Conclusion: The Xpert® HCV VL FS test can accurately detect active infection from a finger-stick sample in one hour allowing single-visit HCV diagnosis, representing an advance over current diagnostic algorithms which involve sequential antibody and RNA testing. This advance offers an opportunity to move towards a single-visit HCV diagnosis.

THU-094

Sero-prevalence of Hepatitis B surface antigen among 5–7 years old children and their mothers in Cambodia by nationwide multi-stage stratified random sampling strategy

J. Tanaka[1], J.V. Woodring[2], V. Ork[3], M. Bunsoth[4], S. Nagashima[1], C. Yamamoto[1], C. Chuon[1], K. Ko[1], S. Hossain[5]. *[1]Hiroshima University, Epidemiology Infectious Disease Control and Prevention, Hiroshima, Japan; [2]WPRO, Expanded Programme on Immunization, Manilla, Philippines; [3]Ministry of Health Cambodia, National Immunization Program, Phnom Penh, Cambodia; [4]University of Health Science, Phnom Penh, Cambodia; [5]WHO Country Office in Cambodia, Expanded Programme on Immunization, Phnom Penh, Cambodia*
Email: jun-tanaka@hiroshima-u.ac.jp

Background and Aims: HBV is highly endemic in Cambodia with an estimated HBsAg prevalence of 9%. Since 2005, HB vaccine has been launched as NIP at birth and then the regional goal of <1% HBsAg prevalence among >5 years old children was set to attain in 2017. The primary aim was to assess the impact of NIP by estimating HBsAg prevalence among children who were born after 2005. Additionally, this study determined the effectiveness of dried blood spots (DBS) sample in field settings.
Method: Nationwide cross-sectional sero-prevalence study among 5–7 years old children and their mother was conducted by collaboration among Hiroshima Univ, WPRO, WHO-Cambodia, US-CDC, NIP and UHS. Multistage stratified random sampling was used in which four villages were selected from each commune among total 70 communes in three strata. Thereafter, nine pairs of targeted children and their mothers were selected from each village. Demographic data and written or oral vaccination history were collected by questionnaires. The total of 2514 children and 2021 mothers were participated and tested for HBsAg by rapid testing and then additional blood samples were taken by DBS. Among them, total of 520 children and 408 mothers were undergone venepuncture for further investigation of HBV serological markers including anti-HBs, anti HBc as well as HBV DNA by Nested-PCR.
Results: The average age of mother was 32.5 ± 6.1 years. The prevalence of HBsAg among children was 0.6% [95%CI: 0.3–0.8%] by rapid test, 0.5% [0.2–0.8%] by DBS and 0.8% [0–1.5%] by venepuncture while 4.4%, 4.7% and 5.4% in mother respectively. By questionnaires, 1145(45.5%) children received birth-dose HB vaccine within 24 hours after birth, 791(31.4%) children received after 24 hours and 581 (23.1%) children did not. Among 95 HBsAg positive mothers, 9(9.5%) children become HBsAg positive in which 3(33.3%) children have already received HB birth-dose vaccine. Among 1,926 HBsAg negative mothers, 2(0.1%) children became HBsAg positive in which 1(50%) child has received HB birth-dose vaccine.
Conclusion: Since 9.5% of children born to positive mother were positive for HBsAg, it is indicated that mother-to-child transmission is not under control. Finally, <1% seroprevalence among children indicates that Cambodia has met the 2017 regional target. By this study, DBS with resultant sensitivity of 92% (24/26) and specificity of 100% (895/895) compared by venepuncture suggested that it is as useful in field setting.

Burden of comorbidity in patients with advanced NASH-a retrospective analysis using a large US insurance claims database

T.D. Kou[1], L. Burns[2], Y. Qiu[3], T. Kansal[4], N. Ray[5]. [1]*Bristol-Myers Squibb, Global Pharmacovigilance and Epidemiology, Pennington, United States;* [2]*Bristol-Myers Squibb, CORDS, Hopewell, United States;* [3]*Bristol-Myers Squibb, Worldwide Health Economic and Outcome Research, Hopewell, United States;* [4]*Mu-sigma, Pennington, United States;* [5]*Mu-sigma, Hopewell, United States*
Email: tzuyung.kou@bms.com

Background and Aims: Patients diagnosed with nonalcoholic steatohepatitis (NASH) have a higher risk of cirrhosis, end stage liver disease, and liver transplantation. The presence of advanced fibrosis has been associated with increased mortality and liver-related events in NASH patients. Most NASH natural history studies relied upon relatively small cohorts of patients chosen from clinical practice. Elucidating which patient characteristics are associated with NASH, and with advanced fibrosis in a large, real-world setting, is critical for a more complete understanding of the natural history of NASH.

Method: Using the Optum insurance claims database, patients with relevant diagnosis code(s), with available liver enzyme test results, and with coverage enrollment between 2002 and 2015 were included in the analysis. FIB-4 score at time of index date was calculated. Burden of comorbid conditions based on diagnosis codes at baseline was described using the modified Charlson Comorbidity Index. Clinical and demographic characteristics of NASH patients with FIB-4 score ≥2.67 (indicative of advanced fibrosis) and no evidence of decompensation were compared to patients with FIB-4 score <2.67. Relevant statistical methods were used to test for significant difference ($p < 0.05$). Potential association was further evaluated using a multivariate logistic regression.

Results: NASH patients with available estimated FIB-4 score (n = 112,183) were included in the analysis. 5,964 or 5.3% had a FIB-4 score ≥2.67. Overall, NASH patients had higher a prevalence of pulmonary disease (28.5%), type 2 diabetes (T2DM) (37.6%), cardiovascular risk factors (8.2%), rheumatologic disease (6.8%), and other chronic disease compared to general population. Compared to NASH patients with FIB-4 score <2.67, NASH patients with FIB-4 score ≥2.67 were older (mean age 65.6 vs. 52.8), more frequently male (49.8 vs. 43.5%), and had a higher burden of comorbidities (Charlson comorbidity index score of 2.2 vs. 1.3). NASH patients with FIB-4 score ≥2.67 also had a higher prevalence of T2DM (49.2 vs. 37.0%), renal disease (14.9 vs. 7.0%), congestive heart failure (16.0 vs. 7.7%), and higher prevalence of malignancy (17.7 vs. 10.8%). Multivariate logistic regression controlling for potential confounders further confirmed these associations.

Conclusion: The overall NASH patient population has a higher comorbidity burden compared to the general population. NASH patients with advanced fibrosis (FIB-4 score ≥ 2.67) but without decompensation are more likely to have various comorbid conditions such as T2DM, renal disease, congestive heart failure, and malignancy compared to NASH patients without advanced fibrosis. Findings suggest that NASH patients with advanced fibrosis represent a unique subset of all NASH patients with a distinct natural history requiring different treatment considerations.

Khat chewing increases the risk for developing chronic liver disease: A hospital-based case-control study

S. Orlien[1], I. Sandven[2], N. Berhe[3], N.Y. Ismael[4], T.A. Ahmed[4], K. Stene-Johansen[5], S.G. Gundersen[6,7], M. Morgan[8], A. Johannessen[1]. [1]*Oslo University Hospital Ullevål, Regional Centre for Imported and Tropical Diseases, Oslo, Norway;* [2]*Oslo University Hospital, Oslo Centre of Biostatistics and Epidemiology, Oslo, Norway;* [3]*Addis Ababa University, Aklilu Lemma Institute of Pathobiology, Addis Ababa, Ethiopia;* [4]*Haramaya University, College of Health and Medical Sciences, Harar, Ethiopia;* [5]*Norwegian Institute of Public Health, Department of Molecular Biology, Oslo, Norway;* [6]*University of Agder, Department of Global Development and Planning, Kristiansand S, Norway;* [7]*Sørlandet Hospital HF, Research Unit, Kristiansand S, Norway;* [8]*University College London, UCL Institute for Liver & Digestive Health, London, United Kingdom*
Email: stian@orlien.no

Background and Aims: The chewing of the leaves of *Catha edulis* (khat) is widespread at the Horn of Africa and Arabian Peninsula; the habit is perpetuated or even adopted by immigrant communities worldwide. Case reports from Europe, USA, Africa and Australia implicate khat in the development of liver disease but no controlled observations have been undertaken. The aim of the present study was to determine whether chewing khat is associated with the development of chronic liver disease (CLD).

Method: A case-control study was conducted at two public hospitals in Harar, Ethiopia, between April 2015 and April 2016. The cases comprised of 150 adult hospital attendees with evidence of CLD were included as cases. The controls comprised of 300 adult hospital attendees without clinical or laboratory evidence of CLD. Information on risk factors for liver disease was collected from cases and controls. Khat consumption was quantified in khat years; one khat year was defined as daily use of 200 grams of fresh khat for one year. A logistic regression model was used to control for confounders; interaction was pinpointed by stratification analysis.

Results: There was a significant association between chewing khat and the risk for developing CLD (crude odds ratio [OR] 2.64; 95% CI 1.56–4.58). After adjusting for age, alcohol consumption and viral hepatitis, the effect was strong in men (adjusted odds ratio [AOR] 5.67; 95% CI 1.85–17.37; p = 0.002), but not evident in women (AOR 1.04; 95% CI 0.49–2.19; p = 0.922). In men, a dose-response relationship was observed (Table). The findings were robust in a post hoc sensitivity analysis in which cases and controls with identifiable risk factors for CLD were excluded.

Table: Gradient effect of khat use on chronic liver disease, stratified by sex

	Men[1] (n = 280)			Women[1] (n = 170)		
Khat years (quartiles):	Cases (n = 108)	Controls (n = 172)	OR (95% CI)	Cases (n = 42)	Controls (n = 128)	OR (95% CI)
0	4	40	1	19	61	1
0.1–5.0	21	40	3.88 (1.11–13.56)	11	37	1.24 (0.48–3.17)
5.1–40.0	34	51	5.84 (1.73–19.65)	7	22	0.99 (0.32–3.12)
40.1–250.0	49	41	13.62 (3.71–50.05)	5	8	1.75 (0.38–8.16)
Test for trend:	p = 0.0007			p = 0.8805		

CI, confidence interval; OR, odds ratio.
[1]Adjusted for age, alcohol and viral hepatitis.

Conclusion: A significant association was observed between chewing khat and the risk for developing CLD. In men, the association was strong and dose-dependent, suggesting a causal relationship. These findings have significant public health implications given the widespread use of khat worldwide.

THU-097

The global prevalence of HBsAg by age in 2016 and the case for universal treatment in low and middle income countries

D. Razavi-Shearer, I. Gamkrelidze, S. Blach, S. Brandon, C. Estes, H. Nde, S. Robbins, J. Schmelzer, H. Razavi. *The Polaris Observatory, Lafayette, United States*
Email: hrazavi@cdafound.org

Background and Aims: For over thirty years, vaccination to protect against hepatitis B virus (HBV) has been available. The impact of rigorous vaccination programs have resulted in major reductions in the incidence of HBV and the prevalence in vaccinated cohorts. However, there are many countries that have yet to introduce birth dose, and HBV remains a major problem. Quantifying the age of the infected population is imperative, as it is evidence of the importance of vaccination, but also a harbinger for the coming burden of the later stages of the disease that will impact health systems globally.
Method: 120 country level PRoGReSs models were built based on literature review and consultation with country experts. The transmission and disease progression model was utilized use historical prevalence estimates to quantify the prevalence of HBsAg by age in 2016 after taking into account the impact of perinatal prophylaxes measures. Global age specific prevalence was estimated by extrapolating data from countries in each Global Burden of Disease Regions to countries without data and summing across all countries.
Results: In 2016, there were an estimated 284 (UI: 246–339) million individuals chronically infected with HBV. While the impact of vaccination can be seen in the 25–29 year cohort, it is the <25 year cohorts in which this impact is most visible (Figure). Unfortunately, even with availability of vaccines, there are an estimated 49 million under the age of 20 who are infected due to low or no birth or 3 dose vaccination. Although HBsAg prevalence stays relatively constant after age 25, the total number of infections declined as shown below due to mortality and declining population. Almost 70% of all infections (200 million) are found between the ages of 15 and 54 and this cohort has by and large yet to progress to the later and more expensive stages of the disease. Without treatment, many will progress to end stage liver disease as they age.

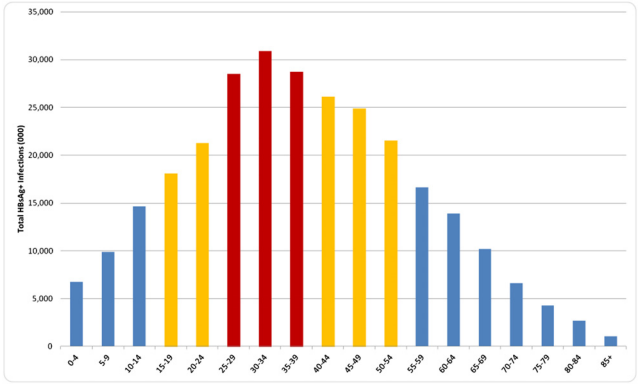

Figure 1: Global Distribution of HBsAg by Age, 2016.

Conclusion: Due to vaccination, the future prevalence of hepatitis B will be lower in the younger age cohorts. However, HBV related disease burden will continue to increase as the infected population ages. With limited availability and the cost of annual diagnostics and follow-ups in lower and middle income countries, universal treatment of all infected can aid in stopping transmission and disease progression. The low cost of antiviral treatments allows for a test and treat strategy in these countries.

Influence of geographical origin on access to therapy and therapy outcomes in hepatitis C virus-infected persons: the Swiss Hepatitis C Cohort Study

M. Brezzi[1], B. Bertisch[1], D. Moradpour[2], A. Cerny[3], J.-F. Dufour[4,5], M. Heim[6], B. Müllhaupt[7], D. Semela[8], F. Negro[9], O. Keiser[1]. *[1]Institut of Global Health, University of Geneva, Geneva, Switzerland; [2]Division of Gastroenterology and Hepatology, University Hospital Lausanne, Lausanne, Switzerland; [3]Epatocentro Ticino, Lugano, Switzerland; [4]Hepatology, Department of Clinical Research, University of Bern, Berne, Switzerland; [5]University Clinic of Visceral Surgery and Medicine, Inselspital Bern, Berne, Switzerland; [6]Gastroenterologie & Hepatologie, Universitätsspital Basel, Basel, Switzerland; [7]Gastroenterology and Hepatology, University Hospital Zurich, Zurich, Switzerland; [8]Division of Gastroenterology and Hepatology, Kantonspital St.Gallen, St.Gallen, Switzerland; [9]Divisions of Gastroenterology and Hepatology and of Clinical Pathology, University Hospitals Geneva, Geneva, Switzerland*
Email: matteo.brezzi@gmail.com

Background and Aims: Hepatitis C (HCV) is an important health threat, and late diagnosis, limited access to care and poor adherence to treatment may increase morbidity and mortality. We explored whether their origin is associated with access to therapy and therapy outcomes in HCV-infected persons in the Swiss Hepatitis C Cohort Study (SCCS).
Method: We included all persons enrolled in the SCCS and analyzed the association between their origin and the following outcomes by univariable and multivariable logistic and Cox regressions: (a) antiviral treatment status (ATS), (b) sustained virologic response (SVR), (c) cirrhosis at enrolment, (d) incident cirrhosis during follow-up, (e) loss to follow-up (LTFU), and (f) mortality. Analyses were adjusted for the following baseline characteristics: gender, age, education, source of income, alcohol consumption, injection drug use (IDU), HCV genotype, HIV and/or HBV co-infection, duration of HCV infection, cirrhosis and center of enrolment.
Results: Among 5,356 persons of known origin, 1,752 (32.7%) were foreign-born. IDU was more frequent among Swiss (65.5%) compared to non-Swiss (37.7%). Figure 1 shows both crude and adjusted results. In adjusted analyses, persons of foreign origin were more likely to have cirrhosis at enrolment (odds ratio OR 1.29, 95%CI 1.06–1.56) and to be LTFU (hazard ratio HR 1.37, 95%CI 1.20–1.58). Mortality was lower in foreign-born persons (HR 0.69, 95%CI 0.54–0.87). There was no association for treatment status, sustained virologic response and incident cirrhosis. Part of the differences between persons of Swiss and foreign origin were attributable to particular countries. For example, LTFU was more frequent in persons from Germany, Eastern and Southern Europe as well as America; while baseline cirrhosis was more frequent in Italians.
Conclusion: There were substantial differences in access to therapy and therapy outcomes depending on the country of origin of the study participants, and the type of the outcome studied. The heterogeneity was only slightly reduced in the adjusted analyses, which suggests that additional unmeasured lifestyle factors associated with drug use, genetic factors, and physician-related factors may explain most of the difference.

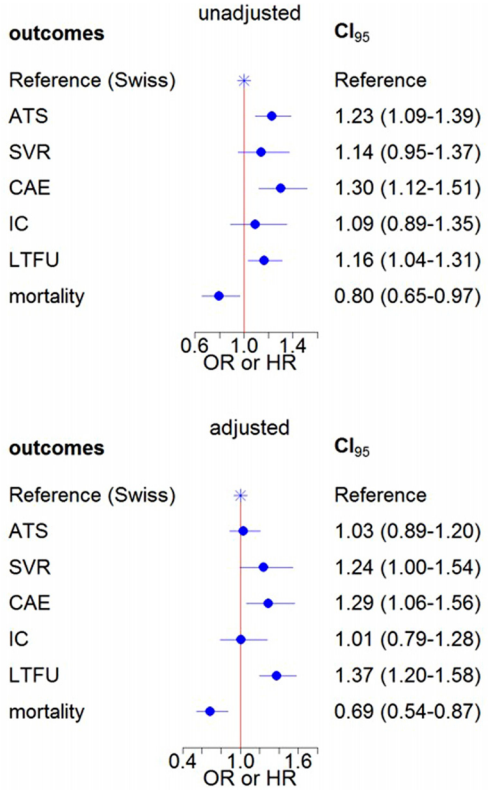

Figure 1: Univariable and multivariable logistic and Cox regression analyses for different outcomes by origin (Swiss versus foreign-born). Odds ratios (OR, with 95% confidence intervals) are shown for antiviral treatment status (ATS), sustained virologic response (SVR) and cirrhosis at enrolment (CAE). Hazard ratios (HR) are shown for incident cirrhosis (IC), loss to follow-up (LTFU) and mortality.

THU-099

Lowering the upper limit of serum alanine aminotransferase levels may detect significant liver disease in the elderly

H. Schmilovitz-Weiss[1,2], R. Gingold-Belfer[3], A. Gossman[4], N. Issa[2], D. Boltin[4], Y. Beloosesky[4], N. Koren-Morag[5], J. Meyerovitch[6], A. Weiss[4].
[1]Rabin Medical Center Golda Hasharon Campus, Gastroenterology, Petah Tikva, Israel; [2]Rabin Medical Center Golda Hasharon Campus, Petach Tikva, Israel; [3]Rabin Medical Center Beilinson, Gastroenterology, Petah Tikva, Israel; [4]Rabin Medical Center Beilinson, Petah Tikva, Israel; [5]Tel Aviv University, Sackler Faculty of Medicine, Tel Aviv, Israel; [6]Schneider Children 's Medical Center, Petah Tikva, Israel
Email: hemdaw1@017.net.il

Background and Aims: Serum alanine aminotransferase (ALT) levels above normal range are markers of liver injury. Studies recently suggested lowering the upper limit of normal (ULN) of ALT. This study aimed to investigate the prevalence of significant liver disease in elderly patients in whom ALT levels fall within the difference between the previous ULN the newly suggested ULN ("delta range").
Method: The database of a large HMO was searched for all individuals aged ≥ 65 years who underwent at least one measurement of ALT in 2002 and were followed until 2012 (n = 49,634). Fibrosis scores in the two groups were calculated with the FIB-4, AAR, and APRI. Prevalence rates of chronic liver disease (CLD) and particularly liver cirrhosis (fibrosis score ≥ 2) were compared between those with ALT levels in the delta range (42–45 IU/l for men, 26–34 IU/l for women) and those with ALT levels in the newly suggested normal range (15–42 IU/L for men, 10–26 IU/L for women).
Results: CLD was diagnosed in 2022 subjects (41% male, mean age 83 ± 6 years), and cirrhosis, in 366. Compared to subjects with ALT values in the newly suggested range, subjects with "delta-range" values had higher rates of CLD (men, 15.3% vs. 4.9%; women, 7.8% vs. 3.3%) and cirrhosis (men, 4.2% vs. 0.9%; women, 1.5% vs. 0.4%) and significantly higher mean fibrosis scores.
Conclusion: Lowering the current ULN of serum ALT may help to identify significant liver disease in the elderly.

Hepatitis C patients with HIV co-infection demonstrate unique liver-related complications and health behaviors compared to HCV mono-infected patients

M. Lu[1], N.P. Markowitz[2], Y. Zhou[1], K.-H. Wu[1], L.B. Rupp[3], S. Trudeau[1], J.A. Boscarino[4], M.A. Schmidt[5], Y.G. Daida[6], S.C. Gordon[7]. *[1]Henry Ford Healthy System, Department of Public Health Sciences; [2]Henry Ford Healthy System, Department of Infectious Disease; [3]Henry Ford Healthy System, Center for Health Policy and Health Services Research; [4]Geisinger Clinic, Department of Epidemiology and Health Services Research; [5]Kaiser Permanente Northwest, Center for Health Research; [6]Kaiser Permanente Hawai'i, Center for Health Research; [7]Henry Ford Healthy System, Department of Gastroenterology and Hepatology*
Email: mlu1@hfhs.org

Background: Most studies of hepatitis C (HCV) and HIV co-infection focus on HIV cohorts, and may not collect data regarding liver-related outcomes. We used data from the Chronic Hepatitis Cohort Study to investigate the impact of HIV on clinical characteristics and mental health in HCV patients.
Methods: Patient demographics and clinical status were collected from the electronic health record from date of diagnosis (HCV or HIV/HCV co-infection) onward. A subgroup provided survey data regarding health-related behaviors and mental health. Chi-square tests and two-sample t-tests were used to compare categorical and continuous variables, respectively, between mono- and co-infected patients.
Results: Among 14545 patients, 584 (4.0%) were HIV co-infected. Compared to mono-infected patients, co-infected patients were significantly younger and more likely to be male, African American, low-income, and publicly insured; less likely to see a liver specialist or receive HCV treatment; and demonstrated increased comorbidities, fibrosis/ cirrhosis, hepatocellular carcinoma, and mortality. Among 5008 survey respondents (4885 HCV; 123 HIV/HCV), co-infected patients were significantly more likely to report drug/ alcohol use and sex with multiple partners.
Conclusion: HIV co-infection impacts a demographically distinct subset of HCV patients. Despite high rates of HIV treatment, co-infected patients were less likely to see a liver specialist or receive HCV-specific treatment than HCV mono-infected patients. Co-infected patients also demonstrated increased rates of liver complications and mortality, as well as high-risk behaviors.

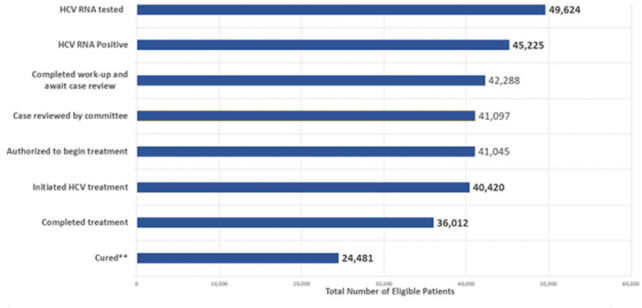
Email: mtsereteli2002@yahoo.com

Background and Aims: The country of Georgia has high burden of hepatitis C virus (HCV) infection. The nationwide seroprevalence survey conducted in 2015, indicated 5.4% of adults (approximately 150,000 persons) with active HCV infection (RNA positive). In April 2015, the Georgian government, in collaboration with CDC and other partners embarked on a national program to eliminate HCV by 2020, defined as decreasing prevalence of active infection by 90%; a key strategy is scaling up HCV treatment by ensuring access to free of charge treatment for all infected persons.
Method: Data from all screening and treatment sites are collected and analysed by the Georgia National Center for Disease Control and Public Health and Ministry officials. All data from treatment providers are entered into a web-based database. A unified electronic screening registry captures data from all national and local HCV screening programs throughout Georgia. Data from the screening and treatment programs are linked by a unique identification number; these data were analysed to describe the national cascade of care.
Results: From April 28, 2015 through October 31, 2017, more than 1.2 million people were screened for HCV, and 45,225 HCV infected (RNA positive) individuals were registered for the treatment program. Among those who registered, 40,420 (89.4%) individuals initiated treatment, approximately 27% of the estimated 150,000 persons living with HCV in the country. Of those who initiated treatment, 36,012 (81%) completed treatment. Among individuals with available data on sustained virologic response (SVR) i.e., cure (n = 32,835), the overall SVR was 98.2%.



** of **32,835** patients eligible for SVR assessment, **24,930–**were tested, 24,481 **(98.2%)** achieved SVR, 7.905 (24%) missing data

Conclusion: In the first 30 months of the HCV Elimination Program, Georgia has scaled up the screening and treatment services achieving impressive cure rates. These activities represent a key step towards reaching the established national HCV elimination goals.

THU-102

High prevalence of hepatitis delta virus in specimens from Cameroon

E. Butler[1], M. Rodgers[1], K. Coller[1], D. Barnaby[2], E. Krilich[2], A. Olivo[1], M. Cassidy[1], D. Mbanya[3], L. Kaptue[4], N. Ndembi[5], G. Cloherty[1]. [1]*Abbott Laboratories, Infectious Disease Research, Abbott Park, United States;* [2]*Franciscan University of Steubenville, Franciscan Institute for Science and Health, Steubenville, United States;* [3]*Université de Yaoundé I, Yaoundé, Cameroon;* [4]*Université des Montagnes, Bangangté, Cameroon;* [5]*Institute of Human Virology, Abuja, Nigeria*
Email: mary.rodgers@abbott.com

Background and Aims: Hepatitis Delta virus (HDV), an RNA satellite virus of Hepatitis B virus (HBV), infects an estimated 15–20 million people worldwide and confers a greater risk for accelerated progression to liver disease and death. However, limited HDV surveillance data are available in sub-Saharan Africa where HDV diversity is high. To determine the prevalence and diversity of HDV in Cameroon, serological and molecular characterization was performed on 1928 HBV surface antigen (HBsAg) positive specimens.
Method: HBsAg positive plasma specimens were selected from retrospective HIV and HBV viral surveillance studies conducted in Cameroon from 2010–2016. Samples were screened for HDV IgG antibodies on the Abbott ARCHITECT instrument and HDV RNA on the Abbott m2000 instrument by prototype research assays. HDV positive specimens with sufficient viral load were selected for sequencing of overlapping regions covering the 1.7 kb HDV genome.
Results: The seroprevalence of HDV in HBsAg positive samples from Cameroon was 46.73% [95%CI; 44.51–48.96%], with prevalence of active HDV infection being 34.2% [95%CI; 32.09–36.41%]. HDV antibodies were detected in 98.6% of HDV RNA positive samples. Within the HIV positive cohort (48.86% of all samples), HDV seroprevalence was 43.29%. HDV sequences were obtained from n = 211 specimens, including n = 145 complete or near complete genomes with HDV genotypes 1, 6, 7 and 8 and several subgenotype branches within 1 and 7 clades identified.

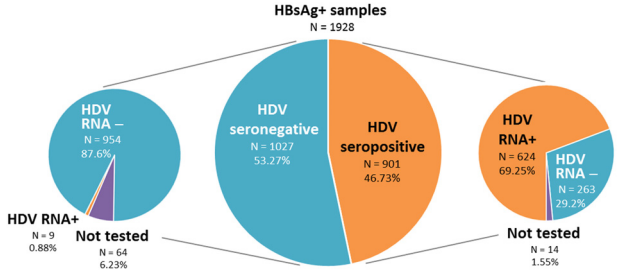


Figure: Pie charts summarizing results of serological testing (center) and RNA testing for HDV seropositive (left) and seronegative (right) for all HBsAg+ samples in the study.

Conclusion: HDV prevalence is high within the study cohort, indicating that a large portion of HBV infected individuals in Cameroon are at elevated risk for severe hepatitis and death. Collectively, these results emphasize the need for preventative measures like HBV vaccination and regular HDV testing of HBsAg positive patients in Cameroon.

THU-103

Achieving the World Hepatitis Organization global health sector strategies goals for hepatitis in the WHO Western Pacific Region: A modeling study

S. Brandon, C. Estes, H. Nde, J. Schmelzer, H. Razavi. *Center for Disease Analysis, Lafayette, United States*
Email: sbrandon@cdafound.org

Background and Aims: The Western Pacific Region (WPRO) region accounts for 20% of the burden of hepatitis C (HCV) globally, but data to guide management strategies are lacking. Progression to decompensated cirrhosis (DC), hepatocellular carcinoma (HCC), and liver related death (LRD) makes the virus a main driver of morbidity in the region. This study sought to quantify the burden of HCV in WPRO and identify a strategy to achieve the Global Health Sector Strategy Goals (GHSS) for Viral Hepatitis Elimination by 2030.
Method: Excel-based disease progression models, built with published data and/or expert consensus were used to assess 2016–2030 trends in HCV infection and morbidity in 16 WHO WPRO countries and Taiwan (Australia, Cambodia, China, Fiji, Hong Kong, Japan, Laos, Malaysia, Mongolia, New Zealand, Papua New Guinea, Philippines, Samoa, Singapore, South Korea, Vietnam).
Results: In 2016, there were an estimated 13.7 million viremic HCV infections, 21% have been diagnosed. Under today's treatment paradigm (300,000 treated annually), this is expected to decrease by 30%, to 10 million, by 2030. Liver related mortality is expected to increase 20%, from 102,000 deaths in 2016 to 124,000 in 2030. The number of patients with end-stage liver disease is also expected to increase 20%.

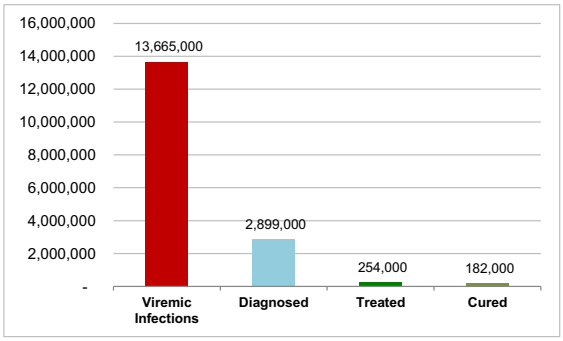

Figure 1: WPRO Cascade of Care, 2016

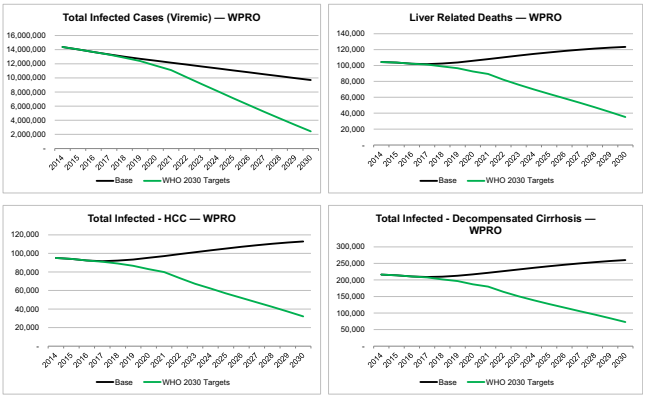

Figure 2: Liver Related Morbidity and Mortality by Scenario, 2016–2030.

In order to achieve GHSS goals of diagnosing 90% of the infected population and reducing liver related mortality by 65%, treatment in the region must be increased to 900,000 patients annually by 2030. Similarly, the annual number of newly diagnosed patients will need to increase to 750,000 by 2019 (from 350,000 in 2016). These actions will reduce total HCV infections by 90% and liver related morbidity and mortality by 70%. After 2031, the number of infections will decline and the number of treated patients can be scaled back accordingly.
Conclusion: Under the status quo, HCV prevalence in WPRO countries will decrease by 2030, but cases of advanced liver disease and liver-related deaths will continue at a high level. Increasing diagnosis and treatment can lead to significant reductions in total infections, mortality, and morbidity.

THU-104

The first result from the general population hepatitis screening in Mongolia: 38% of 40–65 year olds screened and anti-HCV prevence of 15.6% among 40–65 year olds

B. Dashtseren[1,2], U. Baatarsuren[2], T. Dagvadorj[3], A. Bungert[4], Z. Genden[4], D. Yagaanbuyant[2,3,4], N. Dashdorj[2,4], N. Dashdorj[2]. [1]*Liver Center, Mongolia;* [2]*Onom Foundation;* [3]*Mongolian National University of Medical Sciences, Department of Infecious Diseases;* [4]*Liver Center*
Email: d.bekhbold@onomfoundation.org

Background and Aims: Recent estimates show an HCV infection rate of 8.5% among Mongolian adults. As part of the Hepatitis Prevention, Control, and Elimination Program (HPCE) in Mongolia – Элэг бүтэн Монгол хөтөлбөр with the mission to eliminate HCV in Mongolia by 2020, all adult Mongolians are to be screened for HCV by 2018. The first stage, starting from June 2017 targets the age group of 40–65 years of age. As of October 1, 2017, 287,000 out of 741,000 (total Mongolian population in this age group) were tested for anti-HCV.
Method: The data presented is based on the official data from the Ministry of Health of Mongolia. Screening was conducted at primary health care centers through the country. On-site rapid diagnostic tests for anti-HCV from different manufacturers were used for screening. The data is compared to a recent prevalence study that we conducted in 2013 and published recently (*J Viral Hepat*. V. 24, Issue 9; 2017 pp: 759–767).
Results: In total, 26,200 participants were detected to be anti-HCV positive out of 287,000 people who were screened. HCV prevalence is higher in older age groups and these results are reflected to a high degree in the 2013 estimate. 116,092 or 15.6% of all Mongolians 40–65 are anti-HCV positive.

Age groups	Screened population in 2017 (Absolute number)	Anti-HCV(+) percentage 2017	Anti-HCV(+) percentage 2013 estimate	Total population in 2016 (Absolute number)	Total anti-HCV(+) population (Absolute number)
40–44	59,910	9.93%	8.5%	210,897	20,942
45–49	59,335	13.06%	6.5%	179,429	23,433
50–54	60,830	16.62%	16.9%	157,548	26,184
55–59	59,882	21.04%	22.4%	119,171	25,073
60–64	46,941	27.65%	30.4%	73,995	20,460
40–65	286,898	15.6%		741,040	116,092

Conclusion: These results show the progress of the General Population Hepatitis Screening, which has reached 38% of the target population in 4 months. Given the high outreach of the screening, the total number of 116,092 or 15.6% anti-HCV positives in this age group is a highly accurate estimate.

Diagnosis of hepatitis C virus infection in Spain. On the correct side of the road?

F.G. Garcia[1,2], A.J.B. Bravo[3], P. Lazaro[3], A. Aguilera[4,5], F.J.G.-S. Rey[6], J.M. Eiros[7], J.L.C. Panero[8,9], J. Crespo[10]. [1]*Instituto Investigación Biosanitaria Ibs. Granada;* [2]*Servicio de Aparato Digestivo. Hosital Universitario San Cecilio, Granada., Granada, Spain;* [3]*Independent Health Services Researcher. Madrid., Madrid, Spain;* [4]*Servicio de Microbiología, Complejo Hospitalario Universitario de Santiago de Compostela, A Coruña;* [5]*Departamento de Microbiología, Universidad de Santiago de Compostela, A Coruña., Spain;* [6]*Hospital Universitario La Paz, CIBERehd, Madrid, Spain;* [7]*Servicio de Microbiología, Hospital Universitario Río Hortega, Valladolid., Valladolid, Spain;* [8]*Servicio de Aparato Digestivo, Hospital Universitario Puerta de Hierro, Majadahonda, Madrid;* [9]*CIBERehd, Universidad Autónoma de Madrid;* [10]*Servicio de Aparato Digestivo. Hospital Universitario Marqués de Valdecilla, Santander, Spain*
Email: plazaro@gmx.es

Background and Aims: Reflex testing of antibodies and viral load in the same sample for diagnosing active hepatitis C virus (HCV) infection, together with appropriate communication strategies, have shown to improve linkage to care and access to treatment. However, how HCV diagnostics is done in Spain is still unknown. The aim of the study is to describe resources and procedures for the diagnosis of HCV infection in Spanish hospitals.
Method: Cross-sectional study with data collection through a survey addressed to hospitals of the Hospitals National Catalogue with the following inclusion criteria: (1) general hospital (monographic, e.g., psychiatric hospitals are excluded); (2) with at least 200 beds; and (3) public, or teaching hospital if private. A questionnaire with the variables of interest, designed by a scientific committee composed of hepatologists and microbiologists, was sent to the selected hospitals. The field work was carried out in September and October 2017.
Results: Of the 160 hospitals that met inclusion criteria, 90 centers from 14/17 autonomous communities (regions) answered the survey (response rate: 56.3%). Two hospitals (2.2%) have no diagnostic resources, 15 (16.7%) can only test for anti-HCV (Ab), 9 (10.0%) for Ab and viral load (VL), 47 (52.2%) for Ab, VL and genotype (GT), 2 (2.2%) for Ab, VL and core antigen (Ag), and 15 (16.7%) can perform Ab, Ag, VL and GT tests. General practitioners (GP) can request VL testing to 35 (38.9%) hospitals, and GT to 24 (26.7%) hospitals. When an Ab test is positive, 34 (37.8%) hospitals perform reflex testing, being VL + GT (17 hospitals) the most frequent additional testing. When active infection is diagnosed, some communication strategy is used in 62 (68.9%) hospitals: the most frequent are a direct contact with the solicitor (in 39 hospitals) and an alert in the report (in 32). Thirty eight of 86 (44.2%) respondents believe that all determinations needed to reach a diagnosis should be done in a single blood sample, and 76 (88.4%) that some type of alert should be used when active infection is diagnosed.
Conclusion: Although 81% of Spanish hospitals have the resources to perform reflex testing, it is only done in 38%, and less than a half of respondents believe that the diagnosis should be done in a single sample. Nine out of 10 respondents believe that some kind of alert should exist when an active infection is detected, but almost a third of hospitals do not have any communication strategy. Educational programs are needed in Spain to implement reflex testing across the country and increase linkage to care.

THU-106

HepCARE: A tool enabling the identification, assessment and management of viral hepatitis. An integrated approach to the patient journey

B. Anthony[1], L. Smith[1], K. Childs[1], P. Troke[2], F. Sinan[1], K. Agarwal[1], G. Dusheiko[1], M.D. Cannon[1]. [1]*King's College Hospital NHS Foundation Trust, United Kingdom;* [2]*Gilead Sciences*
Email: benanthony@nhs.net

Background and Aims: HepCARE is an end to end viral hepatitis (HBV and HCV) patient management tool. HepCARE enables simple, automated, rapid identification and analysis of patient cohorts and provides a single system for management of patients during clinic visits. Funding for HepCARE at our centre was provided by a service to medicine grant from Gilead Sciences. HepCARE can also assist in the provision of an outreach service for the treatment of HCV and HBV, through the analysis of geographical and liver health data.
Method: All patients with a positive marker of HBV and/or HCV were identified through read code searches to create the database. All relevant lab test results were then extracted and uploaded to HepCARE. New patient diagnoses of HBV and/or HCV are instantaneously transmitted to HepCARE through the hospitals electronic patient records. In parallel, transient elastography (Fibroscan), CAP score and clinically relevant laboratory results are also transfer electronically to HepCARE. APRI and FIB-4 scores are automatically calculated.
Results: HepCARE has collated data on 9,816 patients with viral hepatitis attending Liver Services at our centre (HBV: 6524; HCV: 3292).

To date, 891 HCV treatment outcomes following direct-acting antiviral therapy have been identified by HepCARE. This includes 319 patients who have cirrhosis who have been identified for ongoing HCC surveillance and follow-up.
A further 1,506 individuals with untreated HCV infection have been identified, of these, 1,094 were previously known to the service but have not attended their clinic appointments in the past 18 months. Of these, 294 have cirrhosis based on FIB-4 and/or Fibroscan data. 26.9% are thought to be cirrhotic.
Of those with HBV, 3,375 are currently engaged with our viral hepatitis service, and 481 are cirrhotic.
Analysis of the geographic distribution of patients with HCV who are awaiting treatment is ongoing. Extraction of patients' geographic and liver health data is enabling service redesign to ensure the provision of HBV/ HCV treatment services are directed towards high prevalence areas. Data will be presented on the impact of HepCARE on the redesign of HCV outreach services.
Conclusion: The use of HepCARE has reformed local clinical management, and will enable large-scale patient reengagement with our service. It also facilitates in-depth analysis of the patient cohort attending the viral hepatitis service at our centre. Future strategies include linking raw patient data from primary care to assist with case finding, and mapping of geographic inequalities in diagnoses and treatment, to ensure equity in access to care.

THU-107
A tool to measure the impact of inaction towards elimination of hepatitis C virus: A case study in Germany

M. Cornberg[1], Y. Sanchez[2], A. Pangerl[2], H. Razavi[3]. *[1]Department of Gastroenterology, Hepatology and Endocrinology, Hannover Medical School, Hannover, Germany; [2]AbbVie Inc., North Chicago, United States; [3]Center for Disease Analysis, Lafayette, United States*
Email: yuri.sanchezgonzalez@abbvie.com

Background and Aims: Chronic infection with hepatitis C virus (HCV) and its sequelae presents a significant source of economic and societal burden. Introduction of highly effective curative therapies has made elimination of HCV attainable. Our study aimed to develop a predictive model scalable at national, regional or local level to assess the clinical and economic impact of implementing screening and treatment policies towards HCV elimination, using Germany as a case study.
Method: A Markov disease progression model of HCV infection was developed to analyse the clinical and economic impact of delaying diagnosis and treatment of HCV using modules that quantified the disease burden and medical costs associated with CHC (chronic hepatitis C) and its sequelae. The model was built using national-level inputs, but the modelled population was scalable to support decision-making on a regional or treatment-facility level as well. In this analysis, the model compared the clinical outcomes of the national status quo in Germany of 13,125 treatments and 4,371 newly diagnosed HCV-infected cases annually, starting in 2017 to (1) a scenario that met WHO's diagnosis, incidence, and mortality targets for elimination of HCV by 2030, and (2) a scenario of delaying these interventions by two years. Modelled historical incidence of HCV was calibrated to match the reported prevalence of antibodies against HCV (0.5% in 2012) by sex and age group. Elimination scenario required 17,983 treatments and 9,811 newly diagnosed cases annually, starting in 2018, to reach the 2030 targets.
Results: Compared to base case, elimination would avert 9,995 incident cases of HCV, 1,219 cases of decompensated cirrhosis (DCC), 1,587 cases of hepatocellular carcinoma (HCC), 289 liver transplantations (LTs), and 1,329 liver-related deaths (LRDs) over the 2017–2030 period. Delaying treatment and diagnosis interventions for elimination until 2020 would avert 6,418 incident cases, 925 cases of DCC, 1,190 cases of HCC, 224 LTs, and 1,004 LRDs versus base case.
Conclusion: The Markov model is a tool to visualize the impact of screening and treatment interventions and track their progress towards WHO targets. In this example for Germany, HCV elimination would avert a significant portion of incident cases, as well as new cases of end-stage liver disease (ESLD) and LRDs due to HCV. Postponing this intervention by just two years would fail to avert over 3,500 new HCV infections, nearly 700 cases of ESLD, 65 liver transplantations, and 325 LRDs by 2030.

Scenario	Base case	Elimination	Delay of elimination
	Total new cases, 2017–2030		
Incident cases of HCV	54,911	44,916	48,493
New cases of DCC	2,200	981	1,276
New cases of HCC	3,008	1,421	1,818
Liver transplantations	479	190	254
Liver-related deaths	2,479	1,150	1,475

HCV—hepatitis C virus; DCC—decompensated cirrhosis; HCC—hepatocellular carcinoma.

THU-108
Linkage to HCV care and reincarceration following release from New York City jails

M. Akiyama[1], R. Macdonald[2], A. Jordan[2], D. Columbus[3], J. Schwartz[4], A. Litwin[1], B. Eckhardt[3], E. Carmody[3]. *[1]Montefiore Medical Center/ Albert Einstein College of Medicine; [2]New York City Health and Hospitals, Correctional Health Services; [3]New York University School of Medicine; [4]New York City Department of Health and Mental Hygiene, United States*
Email: makiyama@montefiore.org

Background and Aims: Hepatitis C virus (HCV) is an international public health problem in correctional settings. HCV treatment is often not possible in US jails due to short lengths of stay. Linkage to care (LTC) is crucial in these settings, but competing priorities complicate post-release LTC. Reincarceration is also a common outcome following release; however, its impact on LTC for HCV is lesser known. We present rates of linkage, reincarceration, and other barriers to HCV care associated with a care coordination program (CCP) for patients with HCV following release from New York City jails.
Method: We conducted a one-armed clinical trial to assess rates of linkage associated with the CCP. The CCP consists of a needs assessment, discharge planning by jail-based transitional care coordinators, HCV education, appointment scheduling, reminder calls, and appointment accompaniment by a community patient navigator after reentry. Enrolment in the CCP began 5/16/15, was complete 4/14/2017, and follow-up is ongoing. We determined predictors of linkage using the Addiction Severity Index at enrolment. Statistical significance was determined using Fisher's exact tests. We used the EventFlow data visualization tool to visually inspect the data and identify relevant temporal event sequences.
Results: Among 100 eligible participants, the mean age was 45 (SD 13); 59 were male, 52 were Hispanic, 23 were non-Hispanic (NH) white, 19 were NH black, 6 were other. In terms of disposition, 88 have been released to the community, 4 initiated HCV treatment prior to release, 1 is pending release, 7 are in state prison. Of those released, 35 (40%) were reincarcerated ≥1 time within 1 year of release. Reincarceration was the initial event for 31 (36%) within a median of 109 days. 26 (30%) participants have linked to HCV care within a median of 25 days, 16 (18%) of whom have initiated HCV treatment, and 35 (38%) have been lost to follow up. Having an existing primary care provider ($p = 0.05$), being on methadone ($p = 0.01$), and feeling supported socially (0.03) prior to incarceration were all associated with LTC.
Conclusion: These data provide preliminary evidence that an integrated community-based CCP with jail-based transitional care coordinators may be effective in improving timely LTC. Despite encouraging linkage rates, additional multicomponent interventions aimed at intervening on cycles of reincarceration and increasing

social support, linkage to primary care, and opioid agonist therapy could lead to improvement in linkage to HCV care.

THU-109

Impact of elevated coffee intake on the risk of advanced liver fibrosis in HIV-HCV co-infected patients of the French ANRS CO13 HEPAVIH cohort: a sex-based analysis

I. Yaya[1], C. Protopopescu[1], F. Marcellin[1], L. Esterle[2], L. Wittkop[2], C. Duvivier[3], L. Piroth[4], P. Sogni[5], D. Salmon-Ceron[6], M.P. Carrieri[7].
[1]SESSTIM ORS-PACA, INSERM, IRD, SESSTIM, Marseille, France; [2]Univ. Bordeaux, ISPED, Inserm, Bordeaux Population Health Research Center, Bordeaux, France; [3]AP-HP-Necker Hospital, Infectious Diseases Department, Paris, France; [4]CHU de Dijon, Infectiologie, Dijon, France; [5]Assistance Publique des Hôpitaux de Paris, Hôpital Cochin, Service d'Hépatologie, Paris, France, Paris, France; [6]AP-HP, Hôpital Cochin, Service Maladies infectieuses et tropicales, Paris, France; [7]Aix Marseille Univ, INSERM, IRD, SESSTIM, Marseille, France
Email: issifou.yaya@inserm.fr

Background and Aims: Hepatic fibrosis remains one of the most common manifestations of the HIV-HCV co-infection. Several studies reported that coffee consumption is inversely associated with the progression of liver disease, including hepatic fibrosis. The aim of this longitudinal study was to analyze the sex-specific effect of elevated coffee consumption on advanced liver fibrosis in HIV-HCV co-infected patient.
Method: A longitudinal analysis was performed using 5-year follow-up data from patients included in the French national cohort ANRS CO13-HEPAVIH. Data from annual biological/clinical records and socio-behavioral characteristics were used. The outcome, advanced liver fibrosis, was defined as a FIB-4 index >3.25. We used mixed logistic regression models to examine the association between elevated coffee consumption (≥3 cups/day) and advanced liver fibrosis, after adjustment for other correlates.
Results: Overall 1019 HIV-HCV co-infected patients were included in the study. At the last visit available, 27.4% of them reported elevated coffee consumption during the previous six months and 15.2% had an advanced liver fibrosis. In the multivariable analysis, adjusted for significant clinical (CD4 count, HCV clearance, BMI), socio-demographic (age) and behavioral factors (alcohol consumption, IV drug use), men with elevated coffee intake were 64% less likely to have an advanced liver fibrosis; while elevated coffee intake was not significantly associated with advanced liver fibrosis in women (table).
Conclusions: In the ANRS CO13-HEPAVIH cohort, elevated coffee consumption was not associated with advanced liver fibrosis in HIV-HCV co-infected women.

THU-110

High agreement with HCV RNA in screening and DAA treatment monitoring indicates that cost-effective HCV core Ag test can also be enlisted in the fight to eliminate hepatitis C

N. Chitadze[1], M. Alkhazashvili[2], G. Chanturia[3], A. Gamkrelidze[4], B. Skaggs[5], J. Drobeniuc[6], G. Cloherty[7], G. Kamkamidze[8], R. Sukhiashvili[1], F. Averhoff[9]. *[1]National Center for Disease Control and Public Health of Georgia, Department of Virology, Molecular Biology and Genome Research, Tbilisi, Georgia; [2]National Center for Disease Control and Public Health of Georgia, Manager Lugar Center, Tbilisi, Georgia; [3]National Center for Disease Control and Public Health of Georgia, Head of Department of Virology, Molecular Biology and Genome Research, Tbilisi, Georgia; [4]National Center for Disease Control and Public Health of Georgia, Director General, Tbilisi, Georgia; [5]Division of Global Health Protection, Centers for Disease Control and Prevention, Country Director, Tbilisi, Georgia; [6]Division of Viral Hepatitis, Centers for Disease Control and Prevention, United States; [7]Abbott Diagnostics, Abbott Park, United States; [8]Clinic NeoLab, Tbilisi, Georgia; [9]Division of Global Health Protection, Centers for Disease Control and Prevention, United States*
Email: chitadzenuki@gmail.com

Background and Aims: HCV core antigen (HCVcAg) is a serologic marker of HCV infection highly concordant with HCV RNA testing-the current standard of care. The aim of this study was to assess feasibility of the HCVcAg test as a high throughput and cost-effective alternative to HCV NAT to determine active HCV infection in screening and DAA treatment monitoring program.
Method: The study consisted of two arms: 1) Evaluation of a new HCV screening algorithm that will include reflex HCVcAg testing for confirmation of active infection in anti-HCV-positive participants; and 2) Feasibility of HCVcAg test for monitoring patients on DAA therapy.
The first arm included 4,235 samples obtained from regular screening sites of the hepatitis C elimination program in Georgia- Blood Banks, Harm Reduction Networks (HRN), Provider Clinics, Screening centers, and from the National Seroprevalence Survey (NSS).

Table 1: (abstract: THU-109): Effect of elevated coffee intake on risk of advanced liver fibrosis in HIV-HCV co-infected patients (ANRS CO13 HEPAVIH cohort)

**khi-2.
[1]Multivariable model adjusted for age, CD4, HCV clearance, BMI, alcohol consumption and IV drug use.

In the second arm a total of 976 samples were collected at Baseline, Week 4, End of Treatment (EOT), and 12 weeks post treatment, submitted by three provider clinics in Georgia. HCV RNA and genotype testing was conducted at the clinics using standard of care Nucleic Acid Test (NAT).
Specimens were tested with the ARCHITECT HCVcAg assay at the Georgia NCDC R. Lugar Center for Public Health Research. Percent agreement between HCVcAg and HCV RNA results was calculated based on qualitative results.
Results: Overall agreement between HCVcAg and HCV RNA among participants subjected to HCV screening was 97.14% (1258/1294) which concordance in samples with quantifiable viral load >3,000 IU/mL (estimated LOD for HCVcAg) excluding HCVcAg grey zone not-repeated (n-=10) was 99.68% (1258/1,262).
The agreement between HCVcAg and HCV RNA in the Pre-Treatment specimens was 98.3% (414/421), and in specimens from the 4 week monitoring point was 96.5% (334/346). At EOT and 12 weeks post treatment, the agreement between HCVcAg and HCV RNA was 98.9% (186/188) and 100% (21/21), respectively.
Conclusions: The observed percent agreement between HCV RNA and HCVcAg in the new HCV screening algorithm, and among patients who underwent Pre-Treatment testing selected for DAA therapy, were similar – 98.3% and 97.14% respectively. Among patients who received DAA therapy, the agreement between HCVcAg and HCV RNA exceeded 98% at the EOT, and reached 100% at the 12 week post treatment. These data suggest that the HCVcAg can be used as an alternative to HCV RNA to determine active infection in anti-HCV screening positive population, and for the DAA treatment monitoring.

THU-111

Elimination of hepatitis C in two different Swiss regions – A model-based microelimination scenario

U. Rusch[1], S. Robbins[2], S. Blach[2], H. Razavi[2], P. Vernazza[3], F. Negro[4], D. Semela[1]. *[1]Cantonal Hospital St. Gallen, Division of Gastroenterology and Hepatology, St. Gallen, Switzerland; [2]Center for Disease Analysis, Louisville, United States; [3]Cantonal Hospital St. Gallen, Division of Infectious Diseases, St. Gallen, Switzerland; [4]University Hospital Geneva, Divisions of Gastroenterology and Hepatology and of Clinical Pathology, Geneva, Switzerland*
Email: ursrusch88@hotmail.com

Background and Aims: The high effectiveness of direct-acting antivirals (DAAs) make global elimination of hepatitis C virus (HCV) possible. In Switzerland, only a minority of HCV patients has been cured this far and estimated >50% of the Swiss HCV population has not been diagnosed yet. Since 10/2017, all HCV patients in Switzerland have access to DAAs. According to the WHO goals, the Swiss hepatitis strategy aims to reduce morbidity and mortality caused by HCV and eliminate it by 2030. Our aim is to model micro-elimination scenarios for two distinct regions.
Method: A previously described HCV disease burden model (*Razavi H et al. 2014*) was used to develop two elimination scenarios to achieve the Swiss hepatitis strategy goals in Eastern Switzerland and Geneva. Hospital-based data gathered from retrospective analysis of electronic medical records and current reported data from the federal office of public health (FOPH) with proportional adjustments were used as input data for the model. Two scenarios were developed. The "Base 2016" scenario continues the current standard of care (before general DAA access with limitation to fibrosis stage 2) in the individual cantons through 2030 while the "Swiss Hepatitis Strategy" scenario increases diagnosis and treatment, in order to achieve a 30% reduction in new infections, total viremic infections, liver transplants, and HCC cases by 2020 and a further 90% reduction by 2030.
Results: *2016 Scenario:* The Eastern Switzerland model shows a reduction of liver related death by 55%, while liver cancer due to HCV was reduced by 60% in 2030. The model shows also a reduction of chronic infections by 55% in 2030. By retaining a rate of 95 new diagnosed patients per year, 85% of all infected patients could be detected in 2030. In Geneva, the model estimates similar declines in liver related morbidity and mortality. The model estimates a reduction of liver related death and liver cancer due to HCV by 80% in 2030. There is also forecasted a reduction of chronic infections by 65% in 2030. By retaining a rate of 140 new diagnosed patients per year, 48% of all infected patients could be detected in 2030.
Swiss Hepatitis Strategy: To achieve these goals in Eastern Switzerland treatment had to be expanded to a maximum of 430 patients in 2020 and 195 treated patients per year during the following ten years. In Geneva, with 450 treated patients per year starting in 2018 all the goals can be achieved.
Conclusion: Elimination of chronic HCV infection in Eastern Switzerland and Geneva by 2030 is possible, but higher treatment and diagnosis rates are necessary to meet the 90% elimination goal.

THU-112

Role of physician specialties to close gaps in the care cascade of hepatitis C: Evidence from paid claims in the United States from 2010 to 2016

D. Mehta[1,2], J. Mccombs[1], Y. Sanchez[2], S. Marx[2], S. Sammy[3]. *[1]University of Southern California, Schaeffer Centre for Health Policy and Economics, Los Angeles, United States; [2]AbbVie Inc., Health Economics and Outcomes Research, Mettawa, United States; [3]University of California, Los Angeles, David Geffen School of Medicine, Los Angeles, United States*
Email: darshanm@usc.edu

Background and Aims: US estimates report that 50% of people with chronic hepatitis C virus (HCV) infection have been screened, and 16% have been linked to care. The role of physician specialty to close such gaps in the care cascade from screening to treatment is not well understood. This study assesses antibody (AB) screening rates and AB+ detection rates by physician specialty, and evaluates the impact of physician specialty on linking infected patients to care.
Method: Claims data from Optum Clinformatics® Data Mart, a de-identified claims database from the US, were analyzed for 2010–2016. HCV screening was identified by paid claims for Current Procedural Terminology (CPT) codes 86803, 86804, or G0742. Physician specialty was determined based on the physician's order or bill for the index AB test. Screened patients who were AB+ were identified and their linkage to care was assessed. Descriptive statistics were generated for screening rates, AB+ detection rates and treatment rates by physician specialty. Logistic regressions were used to estimate the effect of physician specialty and time trend on the likelihood of testing positive and being linked to care, controlling for patient characteristics.
Results: Among the 1,058,207 total patients tested, most HCV AB tests were ordered by primary care physicians (PCPs; 29.7%), obstetricians/gynecologists (OB/GYNs; 19.1%) and nurses/physician assistants (PAs; 5.3%). The mean AB+ detection rate across all studied specialties was 3% of screened patients, higher than the national AB+ prevalence of 1.7%. While gastroenterologists, oncologists, and infectious disease specialists did not screen more than 3% of total sample, their tests resulted in the highest observed rate of AB+ results (3.9–5.3%). Linkage to care was low for AB+ patients at 13.8% overall, and hospitalist and gastroenterologists had the highest linkage rates (19.9–25.0%). Among the top three specialties ordering AB screening, OB/GYN had the lowest linkage to care rate at 4.7%. Logistic regressions showed that being screened by gastroenterologists (56.7%) significantly increased treatment rate compared to PCPs. The availability of curative therapies increased the treatment rate for AB+ patients by 25.6%.
Conclusion: PCPs and OB/GYNs emerged as the gatekeepers for AB screening accounting for nearly half of total tests. In spite of high AB+ detection rates across specialties, increased efforts are needed to improve linkage to care, especially in PCP and OB/GYN settings.

THU-113

Effectiveness of hepatitis C virus screening laws in United States: Evidence from paid claims data from 2010 to 2016

D. Mehta[1,2], J. Mccombs[1], Y. Sanchez[2], S. Marx[2], S. Sammy[3]. [1]*University of Southern California, Schaeffer Centre for Health Policy and Economics, Los Angeles, United States;* [2]*AbbVie Inc., Health Economics and Outcomes Research, Mettawa, United States;* [3]*UCLA, David Geffen School of Medicine, Los Angeles, United States*
Email: darshanm@usc.edu

Background and Aims: The World Health Organization [WHO] has set a goal of having 90% of the world's population screened for chronic hepatitis C (HCV) infection by 2030. Starting from 2014 in the United States (US) 5 states (NY, CA, CT, MA, CO) implemented new HCV screening policies. This study assesses the effectiveness of these screening laws and projects states' progress toward the WHO target.
Method: Claims data for 2010–2016 from Optum Clinformatics® Data Mart, a de-identified claims database from the US were analyzed. HCV screening was identified by paid claims for CPT codes 86803, 86804, or G0742. Logistic regression models of the likelihood of a patient being screened were estimated, controlling for patient demographic and clinical characteristics. Three time periods [2010; 2011–13 and 2014–16] were used to measure the effect on screening of the availability of the newer curative agents. Variables identifying states with screening policies were entered as interaction terms with the post-2014 time period to test if new screening policies enhanced screening rates, independent of the availability effect of the newer agents. Further, the proportion of the population screened in each state was extrapolated to 2050 using each state's 2014–16 screening rates applied to an assumed baseline diagnosis rate of 50%.
Results: Relative to the annual screening rate in 2010, annual screening rates were increased by 19.9% post 2014. In the states that passed screening laws, the annual post 2014 screening rates were increased by an additional 6.4%. Among the states that passed screening laws, MA and CT increased annual screening rates but policies in NY, CA and CO had no significant effect. Other factors that increased the likelihood of a patient being screened were female gender, Medicare enrollment and presence of comorbidities like chronic kidney disease, mixed cryoglobulinemia, fatigue and coinfection with HIV and/or HBV. Projections of screening rates suggest that NY and 4 other states without screening laws were on track to reach the WHO target by 2030 with 8 additional states attaining WHO target by 2040. 29 states would not attain this target by 2050.

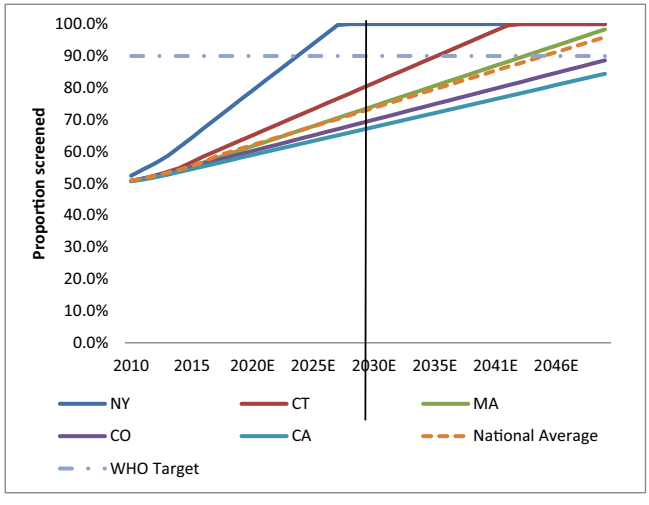

Figure 1: Projected screening rates in US states implementing HCV screening policies: 2010–2050.

Conclusion: The availability of curative therapies has increased the likelihood of screening for HCV. While current efforts to increase annual HCV screening have had positive impact, over 90% of states in the US are still not on track to reach WHO target by 2030.

THU-114

Development of a clinical prediction score for targeted hepatitis C screening in a low-risk HIV cohort in Cambodia

A. De Weggheleire[1], J. Buyze[1], S. An[2], S. Thai[2], J. van Griensven[1], S. Francque[3], L. Lynen[1]. [1]*Institute of Tropical Medicine Antwerp, Clinical Sciences;* [2]*Sihanouk Hospital Center of Hope, Infectious Diseases, Phnom Penh, Cambodia;* [3]*UZA, Gastroenterology Hepatology, Edegem, Belgium*
Email: adeweggheleire@itg.be

Background and Aims: WHO guidelines recommend screening all people living with HIV for hepatitis C virus (HCV). Considering the limited resources for health in Cambodia, and data indicative of low-to-intermediate HCV/HIV coinfection rates (3.5%), targeted HCV screening is potentially more feasible and cost-effective in the current phase of initial HCV care scale-up. We developed a clinical prediction score (CPS) for targeted screening combining age and factors linked to liver disease severity.
Method: We analyzed data of a cross-sectional HCV diagnostic study in the HIV cohort of Sihanouk Hospital Center of Hope in Phnom Penh, Cambodia (clinical trials.gov NCT02361541). Score development relied on the Spiegelhalter and Knill-Jones method. Predictors independently associated with current HCV infection (HCV RNA detected) with likelihood ratio ≥1.5 or ≤0.67 were retained, and transformed to their natural logarithm and rounded to the nearest integer to calculate the score. CPS performance was evaluated by the area-under-the-ROC curve (AUROC) with 95% confidence intervals (CI), and diagnostic accuracy at the different cut-offs of the score. As clinically useful threshold-to-screen, we considered a 1% probability of having a current HCV/HIV coinfection.
Results: Data of 3045 HIV patients of whom 106 with current HCV infection were available for analysis. The predictors identified for the CPS were: age 50 or above (+1 point), diabetes mellitus (+1), partner or household member with liver disease (+1), generalized pruritus (+1), platelet count $<200 \times 10^9$/l (+1), aspartate aminotransferase (AST) <30 IU/l (−1), AST-to-platelet ratio index (APRI) ≥0.45 (+1), and APRI <0.45 (−1). The CPS yielded an AUROC of 0.84 (95% CI: 0.80–0.89), indicating good discrimination between HCV/HIV coinfection and HIV mono-infection. A score ≥0 fitted best as threshold-to-screen with a negative predictive value (NPV) of 99.2% (95%CI: 98.8–99.6). Applying this cut-off (≥0), 30% (n = 926) would have needed screening, and 16 coinfections been missed, but none with advanced fibrosis (details in Tables 1 and 2).

Table 1: HCV coinfection rate by score

Score	HCV coinfection rate n/N (%)
−2	7/1174 (0.60)
−1	9/945 (0.95)
0	11/256 (4.30)
1	16/345 (4.64)
2	28/222 (12.61)
3	24/85 (28.24)
4	8/14 (57.14)
5	3/4 (75.00)

Table 2: Diagnostic accuracy of the prediction score at different cut-offs

Cut-off	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)
≥−1	93.4	39.7	5.3	99.4
≥0	84.9	71.6	9.7	99.2
≥1	74.5	79.9	11.8	98.9
≥2	59.4	91.1	19.4	98.4
≥3	33.0	97.7	34.0	97.6
≥4	10.4	99.8	61.1	96.9
≥5	2.8	99.97	75.0	96.6

Conclusion: The CPS for targeted HCV screening performed well in the derivation cohort and bears potential to identify most patients with active HCV/HIV coinfection in contexts of low-to-intermediate prevalence whilst substantially decreasing the number to test. The score requires further validation before it can be recommended for wider use.

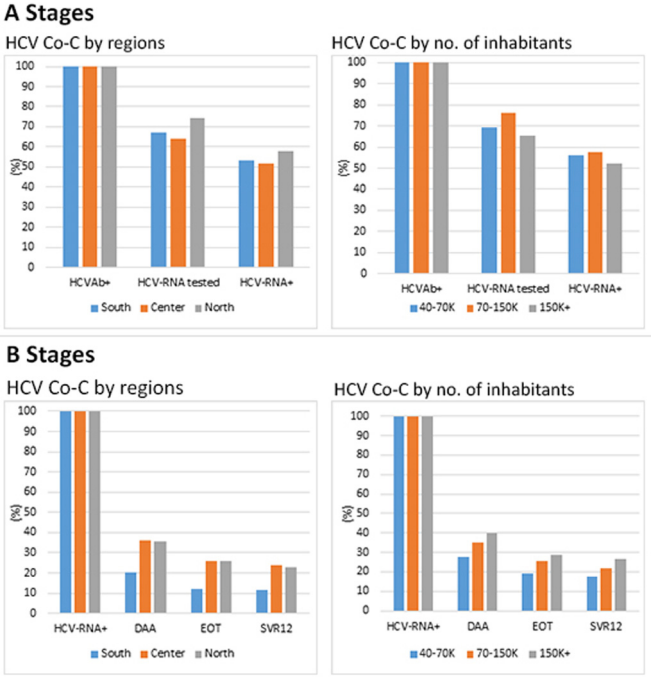
The hepatitis C continuum of care among HIV infected individuals in the Icona study network

E. Girardi[1], M. Puoti[2], C. Mussini[3], A. Tavelli[4], I. Mastrorosa[1], F.C. Silberstein[5], G. Madeddu[6], C. Molteni[7], P. Nasta[8], A. Antinori[1], A.D'arminio Monforte[9], A. Cozzi-Lepri[10]. *[1]National Istitute for Infectious Diseases "Lazzaro Spallanzani" IRCCS, Rome, Italy; [2]Infectious Diseases Unit, ASST Grande Ospedale Metropolitano Niguarda, Milan, Italy; [3]Infectious Disease Clinic, Modena University Hospital, University of Modena and Reggio Emilia, Department of Medical and Surgical Sciences for Children & Adults, Modena, Italy; [4]Icona Foundation, Milan, Italy; [5]University of Rome Tor Vergata, Department of Experimental Medicine and Surgery, Rome, Italy; [6]University of Sassari, Infectious diseases Department, Sassari, Italy; [7]ASST Lecco, A Manzoni Hospital, Department of Infectious and Tropical Diseases, Lecco, Italy; [8]University of Brescia and Brescia Spedali Civili General Hospital, University Department of Infectious and Tropical Diseases, Brescia, Italy; [9]Clinic of Infectious and Tropical Diseases, ASST Santi Paolo and Carlo, University of Milan, Department of Health Sciences, Milan, Italy; [10]Institute for Global Health, University College London, Centre for Clinical Research, Epidemiology, Modelling and Evaluation (CREME), London, United Kingdom*
Email: a.cozzi-lepri@ucl.ac.uk

Background and Aims: It is estimated that there are currently 20,000 HIV/HCV+ persons in Italy. WHO has the goal of eliminating viral hepatitis by 2030. We aimed to develop and evaluate a HCV continuum of care (CoC) in HIV/HCV+ individuals across Italy and to describe differences by region and population density.

Method: We included HIV/HCV+ individuals in the Icona cohort under active follow-up at January 2015. This population was used to describe the first stages of CoC: A1 = "tested for HCV-RNA" and A2="HCVAb+ with HCV-RNA+". People in Icona who were ever HCV-RNA+ and those in HepaIcona (with HCV-RNA+ and DAA-naïve) were used to describe the subsequent stages: B1= "started IFN-free DAA"; B2 = "with available HCV-RNA after end of treatment (EOT)"; B3 = "achieved sustained virologic response (SVR)". Stage B1 was stratified by level of Fib4 ($\leq$3.25 vs. >3.25). CoC stages were described by region of Italy (North, Center, South) and density of population in surrounding urban area (SUA, 40k–70k, 70k–150k, >150k inhabitants). Predictors of HCV-RNA testing in HCVAb+ (stage A1) were identified by means of multivariable logistic regression.

Results: We included 1,212 HIV/HCV+, the majority were PWID (62%) and 34% sexual contacts (17% MSM), 25% females. Median age was 50 (IQR:43–54) years, CD4 count 632 (445–885)cells/mm^3, 83% with a HIV-RNA $\leq$50 copies/ml. 853 (70%) had a HCV-RNA test result available and 671 (55% of total and 76% of HCV-RNA tested) were HCV-RNA +. Overall, there were significant differences by regions ($p = 0.0006$) and population density ($p < 0.0001$) across A stages (Figure A Stages). For B stages we included 3,241 subjects (1,108 Icona and 2,133 HepaIcona). 1,109 of these (34%) started DAA. This percentage was 33% (888/720) in those with Fib4 $\leq$ 3.25 and 42% (221/521) in those with Fib4 > 3.25. Overall, 788 (24% of total and 71% of those who started DAA) had a HCV-RNA available 12 weeks after EOT and 707 (22% of total and 90% of those evaluable) achieved SVR. There were significant differences by regions ($p < 0.0001$) and by population density ($p < 0.0001$) across B stages (Figure B Stages). Large SUA cities (OR = 0.47 vs. intermediate, $p = 0.0001$), younger age (OR = 0.70, $p < 0.0001$), higher current HIV-RNA (OR = 0.72, $p < 0.0001$) and heterosexual HIV transmission (OR = 0.57 vs. PWID, $p = 0.003$) were all associated with a reduced chance of HCV-RNA testing.



Conclusion: Currently only 22% of our HIV/HCV-RNA+ population is cured. Although DAA access/SVR rates were higher in large SUA cities, the opposite was seen for HCV-RNA testing. It is crucial to identify and address leaks in the CoC to ensure individuals' transition through all stages.

THU-116

One-step diagnostic strategy of viremic hepatitis C virus infection from dried-blood spots: feasibility and usefulness in people who inject drugs

V. Saludes[1,2], C. Folch[2,3], A.A. Torres[1], N. Ibáñez[4], V. Monotya[5], R. Harrigan[5], J. Colom[4], J. Casabona[2,3], E. Martró[1,2]. *[1]Germans Trias i Pujol University Hospital and Research Institute (IGTP), Microbiology Service, Badalona (Barcelona), Spain; [2]Biomedical Research Networking Centre in Epidemiology and Public Health (CIBERESP), Instituto de Salud Carlos III, Madrid, Spain; [3]Centre for Epidemiological Studies on Sexually Transmitted Infections and HIV/AIDS of Catalonia (CEEISCAT), Catalonia Public Health Agency (ASPCAT), Badalona (Barcelona), Spain; [4]Catalonia Public Health Agency (ASPCAT), Program on Substance Abuse, Barcelona, Spain; [5]BC Centre for Excellence in HIV, Vancouver, Canada*
Email: emartro@igtp.cat

Background and Aims: Simplified strategies are needed to improve the diagnosis of active HCV infection in people who inject drugs (PWID). For the first time in Spain, we aimed to: (i) assess the feasibility and usefulness of an alternative one-step screening and confirmatory assay based on HCV-RNA detection in dried-blood spots (DBS), (ii) estimate the prevalence of active HCV infection and its determinants, (iii) epidemiologically characterize the infections, and (iv) assess self-knowledge of HCV infection and linkage-to-care among PWID attending harm-reduction centers (HRC).

Methods: A cross-sectional study of current injectors attending four HRC in Barcelona was conducted (n = 410). Epidemiological and behavioral data were compiled, rapid HCV antibody (Ab) testing was performed, and fingerprick DBS were collected. DBS were shipped to the laboratory at room temperature and HCV-RNA was assessed using a previously developed in-house RT-PCR assay (LOD, 541 IU/ml of blood). Plasma was collected in one center (n = 300) for viral load quantification (Abbott), and for next-generation sequencing and phylogenetic analysis to evaluate HCV intra and inter-host variability.

Results: DBS testing was easily implemented at HRC. Participants were mostly male (85.4%) of Spanish origin (70.5%), with an average age of 40.5 years and 17.7 years of injection, 19.0% being recent injectors (<5 years). HCV seroprevalence was 79.8%, and the prevalence of active infection was 58.5%. Among the latter, 14.0% were not aware of their disease (38.2% in recent injectors), and 24.3% were co-infected with HIV. Of those with a viremic infection and previously diagnosed, 31.9% were linked to care, and 18.6% reported having received therapy. Having shared injection equipment (OR, 2.7; 95%CI: 1.4–5.1) and the injection of cocaine (4.6; 95%CI: 1.6–13.0) were associated with HCV infection. The DBS assay was 95% sensitive and 100% specific in comparison with the conventional two-step algorithm (rapid Ab test followed by viral load if positive; Figure). Circulating genotypes, transmission networks and recent infections were virologically identified.

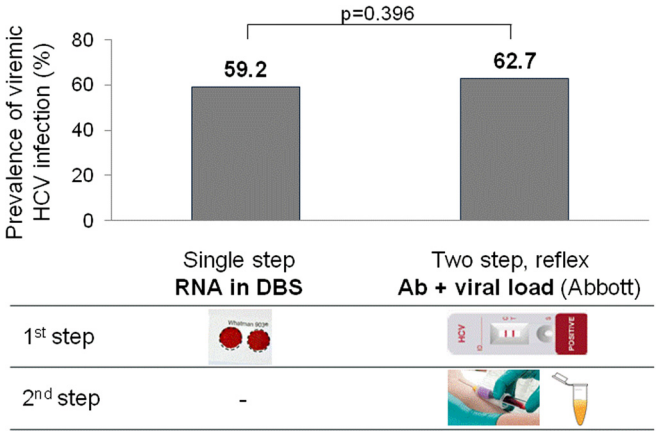


Figure 1: Comparison between diagnostics strategies.

Conclusions: This one-step diagnosis strategy presents a simple and reliable way of increasing the identification and self-knowledge of viremic HCV infections among PWID attending HRC. To improve access to care and fulfill the elimination goals set by the World Health Organization, DBS testing could enable decentralized diagnosis and treatment monitoring in this setting.

THU-117

The contribution of injecting drug use to Hepatitis C virus transmission globally, regionally, and at country level: a modelling study

A. Trickey[1], H. Fraser[1], A.G. Lim[1], J. Walker[1], A. Peacock[2], S. Colledge[2], J. Leung[3], J. Grebely[2], S. Larney[2], L. Degenhardt[2], M. Hickman[1], P. Vickerman[1]. [1]*University of Bristol, Population Health Sciences, Bristol, United Kingdom;* [2]*University of New South Wales, Sydney, Australia;* [3]*University of Queensland, Faculty of Medicine, Australia*
Email: adam.trickey@bristol.ac.uk

Background and Aims: Injecting drug use is an important risk factor for Hepatitis C virus (HCV) transmission. HCV prevalence amongst people who inject drugs (PWID) is generally high but the prevalence of PWID in most countries is <1% of adults. To assist policy-makers in prioritising resources to enhance HCV prevention, modelling was undertaken to estimate the degree to which injecting drug use contributes towards HCV transmission at country, regional and global levels.
Method: A dynamic, deterministic HCV transmission model was used to simulate the country-level HCV epidemic amongst PWID and the general population. The model for each country was calibrated using country-specific data from UN datasets and recent systematic reviews on HCV prevalence amongst PWID and the general population, and the proportion of adults that are PWID. We estimated the dynamic population attributable fraction (PAF) due to injecting drug use, defined as the proportion of all new HCV infections within each country that would be prevented if HCV transmission due to injecting drug use was set to zero for the period 2017–2037. Regional and global PAF averages were produced by weighting the PAFs for each country by their relative burden of HCV compared to the regional or global burden.
Results: The model was successfully calibrated to 82/83 of the included countries comprising 84% of the global population. Although the model predicts 0.2% of individuals will be injecting drug users in 2037, 6% of prevalent HCV in 2037 is among recent PWID. Globally, if the risks due to injecting drug use were removed, then an estimated 31% (the PAF) of all incident HCV infections would be prevented from 2017 to 2037, varying from 7% in South Asia to 74% in North America (figure). Injecting drug use contributes most to HCV transmission in high-income settings, where 62% of new HCV infections could be prevented from removing the risk due to injecting drug use, whereas in some countries (Egypt, Ghana, Maldives, Nigeria, Senegal, and Uzbekistan) this is less than 5%.

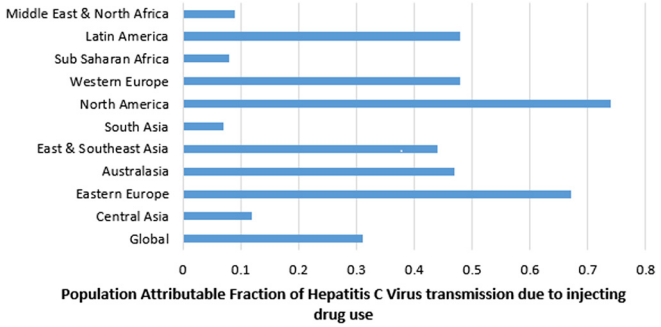

Figure 1: The population attributable fraction of HCV infections due to injecting drug use, by region.

Conclusion: Injecting drug use is a major contributor to the global burden of HCV, but this varies widely within and across regions. Scaling up HCV prevention interventions for PWID, including needle and syringe programmes, opioid substitution therapy, and HCV treatment will be essential to meet WHO elimination targets in many settings.

THU-118

Comparing the prevention gains of different treatment strategies at the global, regional, and country level: a modelling study

A. Trickey[1], H. Fraser[1], A.G. Lim[1], J. Walker[1], A. Peacock[2], S. Colledge[2], J. Leung[3], J. Grebely[2], S. Larney[2], L. Degenhardt[2], M. Hickman[1], M. May[1], P. Vickerman[1]. [1]*University of Bristol, Population Health Sciences, United Kingdom;* [2]*University of New South Wales, Sydney, Australia;* [3]*University of Queensland, School of Public Health, Australia*
Email: adam.trickey@bristol.ac.uk

Background and Aims: To meet the World Health Organization's 2030 hepatitis C virus (HCV) elimination targets, countries must efficiently allocate their resources to prevent and treat HCV infections. Policy makers need data on who to target for treatment to reduce morbidity and prevent new infections. We estimated the prevention gains of four treatment strategies in terms of infections averted (IA) across different countries, and consider how they depend on country-level factors.
Method: To simulate country-level HCV epidemics a dynamic, deterministic HCV transmission model was used, incorporating age demographics, population growth, and HCV progression. Country-specific data from systematic reviews and UN datasets were used to calibrate the model to each country's HCV epidemic. We evaluated the impact of treating 1000 infected individuals in 2017, either selected randomly, or selected amongst people who inject drugs (PWID), people age ≥30, or those with cirrhotic infection. We estimated the number of infections from 2017 to 2037 compared to if no treatment had occurred, weighting country estimates by HCV

burden for regional and global averages. Linear regression was used to identify associations between IA per treatment and a country's population growth rate, the population attributable fraction of injecting drug use to HCV transmission (PAF; defined as the percentage of a country's new HCV infections that would be prevented from 2017–2037 if risk due to injecting drug use was removed), and HCV prevalence amongst PWID.

Results: Countries (83) amassing 84% of the global population were included. Globally, the model estimates on average 0.59 IA per randomly allocated treatment 2017–2037, varying across regions (figure). Similar IA are achieved through treating cirrhotics or those aged ≥30. Overall, treating PWID is the most effective strategy globally with 1.21 IA per treatment, although this effect is reversed in countries with high chronic HCV prevalence (>50%) amongst PWID. The IA per randomly allocated treatment is positively associated with the growth rate of a country, and negatively associated with the PAF of PWID to HCV and the HCV prevalence amongst PWID.

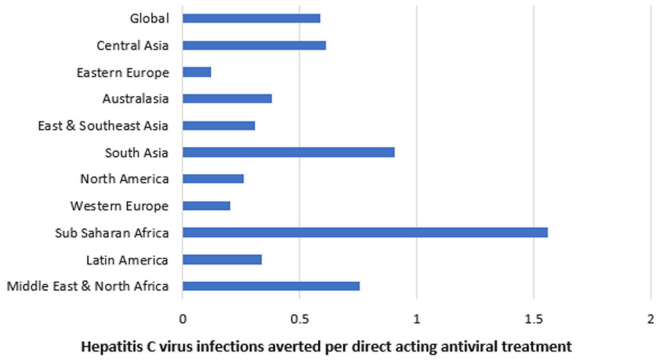

Figure 1: Hepatitis C virus infections averted per randomly allocated HCV treatment over 20 years globally, and by region.

Conclusion: The number of HCV infections averted per randomly allocated treatment is likely to be greatest in settings with high population growth, and less contribution of injecting drug use to HCV transmission. In settings where PWID drive the HCV epidemic, high treatment rates are needed to avert infection.

THU-119

Factors associated with self-reported HCV infection among people who inject opioids: the role of incarceration

P. Roux[1], N. Khadim[1], M. Salim[1], B.M. Laélia[1], L. Virginie[2], M. Marion[1], M. Stéphane[2], R.C. Daniela[2], C. Patrizia[1]. [1]*INSERM, SESSTIM, Marseille, France;* [2]*AIDES, Tour Essor, Pantin, France*
Email: perrine.roux@inserm.fr

Background and Aims: While access to opioid substitution treatment and needle exchange programs have dramatically decreased HIV epidemic among people who inject drugs, HCV infection is still highly prevalent among this population. Sharing injecting material is recognized as the major source of HCV but when this occurs in specific contexts (e.g. prison, street etc…) the risk can be even higher. We used a community-based survey among people who inject opioids to identify individual and contextual factors (prison in particular) associated with self-reported HCV infection.

Method: This cross-sectional community-based survey was conducted in harm reduction centers, in primary care practices and in medical/addiction centers, as well as through an online questionnaire (Psychoactif.org), between May and August 2015. We collected information regarding socio-demographic and behavioral profiles and self-reported HCV serostatus. Among the 557 PWID enrolled, we selected 552 respondents who had no missing data. We used a logistic regression model to identify factors associated with self-reported HCV infection.

Results: Among the selected 552 participants, 164 (29,7%) reported being HCV positive. Women represented 19% of the sample and median [IQR] age was 34[28; 41] years. Twenty-nine percent of participants reported being employed and 41% having already been incarcerated during lifetime. The main opioid regularly used by injection was buprenorphine (53%) after heroin (19%) and morphine sulfate (18%). After adjustment for known correlates (being female, unemployed, history of overdose), we found that with respect to individuals who were never incarcerated, those reporting incarceration but no drug injection in prison (OR[IC95%] = 1.84[1.14; 2.97]) and those who have injected drugs while incarcerated (OR[IC95%] = 2.17[1.17; 4.02] were more likely to report to be HCV infected. In addition, heroin injectors report being less HCV infected compared with prescription opioids injectors.

Conclusion: Our findings showed that prison experience is associated with HCV infection and that such risk is higher for those who injected in prison. Though the recent French law states equity in access to prevention and care in prison as in the general population, this principle is not yet followed. Promoting a rapid scale up of access to sterile equipment, harm reduction information and HCV treatment is urgent to reduce HCV risk in the most criminalized groups such as people who inject drugs.

THU-120

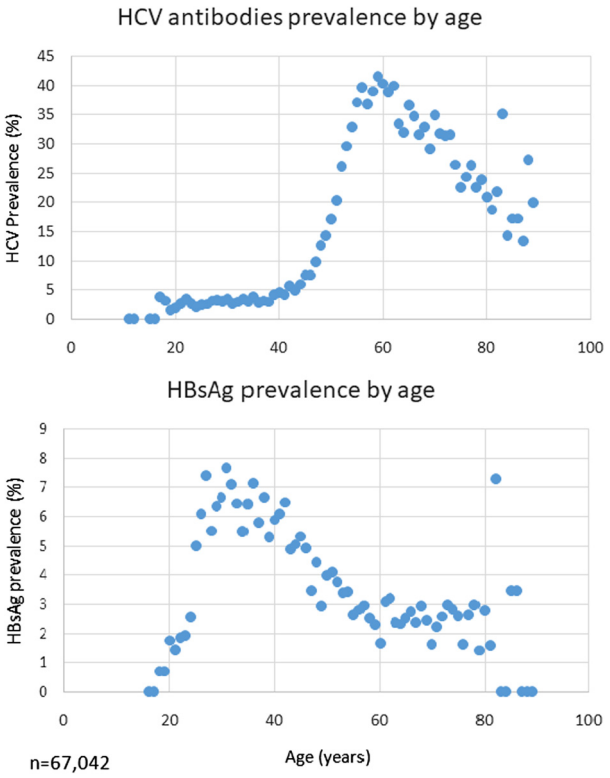
Mass screening for hepatitis B and C in South Upper Egypt: lessons learned from a real life experience

G. Soliman[1], M. Elzalabany[2], T. Hassanein[3], D. Miller[4]. [1]*Faculty of Medicine, Al-Azhar University, Tropical Medicine, Gastroenterology and Hepatology Department, Cairo, Egypt;* [2]*Ahmed Maher Teaching Hospital, Internal Medicine Department, Cairo, Egypt;* [3]*Southern California Liver Centers, Coronado, CA, United States;* [4]*John A. Burns School of Medicine, University of Hawaii, Department of Tropical Medicine, Medical Microbiology and Pharmacology, Honolulu, Hawaii, United States*
Email: dr_msf@hotmail.com

Background and Aims: Egypt has the highest HCV prevalence in the world, estimated to be up to 10% in the last 2015 Egyptian Health Issues Survey (EHIS). In an effort to control HCV infection, treatment centers were established across the country. The first center in Luxor was inaugurated in June 2016 and implemented a free screening program in South Upper Egypt (Luxor and Qena governorates), funded by Tahya Misr Fund, the Ministry of Health and local NGOs.

Method: Free screening for HCV and HBV was offered to individuals older than 16 years. Demographic data and a blood specimen were collected. Sera were tested for HCV antibodies and HBsAg using third generation enzyme immunoassays (Enzygnost® Anti-HCV and HBsAg, Siemens, Germany). Between June 2016 and May 2017, 71,952 individuals were screened and positive patients were referred to treatment centers.

Results: At the time of this analysis, data was available for 67,042 participants. 31,965 males (47.7%) and 35,077 females (52.3%) were screened with a mean age of 43.6 ± 14.3 years. 9701 patients (14.5%) were positive for HCV antibodies and 2950 (4.4%) for HBsAg. Prevalence of HCV antibodies was significantly higher in males than females (19.67% vs. 9.73% OR = 2.27; CI 2.2 to 2.4; $p < 0.001$) and the same for HBsAg (6.2% vs. 2.8% OR = 2.3; CI 2.2 to 2.5; $p < 0.001$). The prevalence of HCV antibodies was significantly associated with age ($p < 0.001$) and ranged between 1% and 4% in individuals below the age of 40 years, then increased steadily until age 59 (41.6%). In contrast, HBsAg prevalence was lower than 2% in individuals younger than 25 years, and increased to 6% in the 25–44 years age group. Above 45 years of age the prevalence was 2–4% (Figure). HCV/HBV co-infection was found in 0.16% of individuals (107/67,042). HBsAg was positive in 1.1% of HCV positive patients versus 5% in negative individuals.



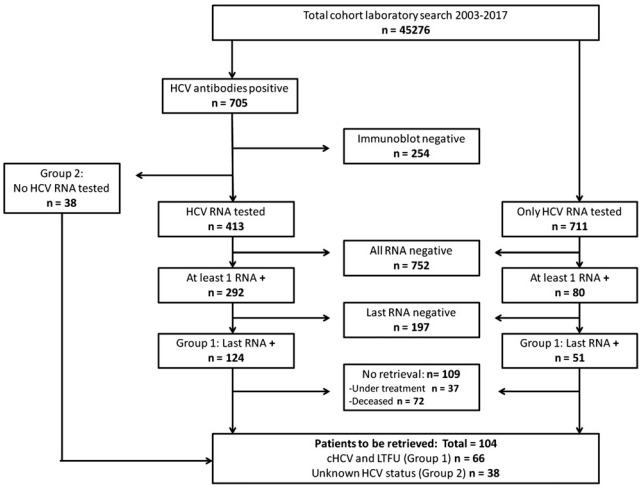
Conclusion: This screening program in South Upper Egypt rural areas showed: (1) a higher prevalence of HCV (14.5%); (2) higher prevalence of HBsAg (4.4%) than the reported prevalence in the 2015 EHIS; (3) HCV prevalence was higher in males and in patients older than 40 years. In summary, this new data underscores the importance of extending infection control efforts and screening to rural areas.

THU-121

Track, Trace & Treat: Results from a retrieval strategy to identify lost to follow-up chronic hepatitis C patients

I. Munsterman[1], J. Rahamat-Langendoen[2], J.P.H. Drenth[1], E.T.T.L. Tjwa[1].
[1]Radboud University Medical Center, Gastroenterology and Hepatology, Nijmegen, Netherlands; [2]Radboud University Medical Center, Medical Microbiology, Nijmegen, Netherlands
Email: isabelle.munsterman@radboudumc.nl

Background and Aims: There are an estimated 19.000 chronic Hepatitis C infected patients in the Netherlands. An unknown proportion has been lost to follow-up and received no adequate treatment. The advent of direct antivirals offers the prospect of safe and efficacious therapy. We designed this study to examine a retrieval strategy that identifies chronic HCV patients lost to follow up and brings them back into care.
Method: We analysed data files from the virology laboratory of the Radboud university medical centre Nijmegen to identify chronic hepatitis C (cHCV) infected patients. The laboratory serves applicants from two hospitals: a tertiary referral and liver expert centre and a rehabilitation clinic. Patients with positive HCV antibodies, immunoblot and/or HCV quantitative RNA PCR measurements between 2003 and 2017 were acquired and linked to personal data. Chart review was performed to assess possibility of loss to follow-up. Identification data was checked with the governmental citizen administration to adjust for death or change of municipality.
Results: In 1124 patients HCV RNA was tested, of which in 372 (33%) individuals at least one RNA was positive. Prevalence of HCV infection in this cohort would be estimated at 0.22%, which is similar to the prevalence in the Netherlands. In 175/372 patients (47%) the last measured RNA was still positive. Of these cHCV patients, 35/175 (20%) were still in care and 72/175 (41%) deceased. A total of 66/372 (18%) of cHCV patients is lost to follow-up and could benefit from linkage to care (group 1). Secondly, we assessed all individual HCV antibodies tested in this time period: 705/44.565 patients had positive HCV antibodies (1.6%), of which 254 (36%) could be excluded due to a negative immunoblot. In 38 patients with confirmed antibodies no HCV RNA was tested, none of them were adequately followed up (group 2). Together with group 1 they will be contacted for re-evaluation of HCV status, disease severity, and treatment if indicated.



Conclusion: Identification of patients through analysis of archival laboratory results is feasible and leads to identification of the target cHCV population. Prevalence of HCV infection in this cohort is representative of our country. The percentage of lost to follow-up cHCV patients in our tertiary referral centre emphasize the need for nationwide retrieval projects to get this group back in to care.

THU-122

Community interventions and peer support for active case finding and treatment support for underserved populations with hepatitis C in the UK, Ireland, Romania and Spain as part of the HEPCARE programme

J. Surey[1], D. Menezes[2], A. Story[3], J.M. Sanchez[4], O.A. Cristiana[5], P. Vickerman[6], W. Cullen[7], J. Lambert[8]. *[1]University College London, Institute of Global Health, London, United Kingdom; [2]University College London, The Farr Institute of Health Informatics Research, London, United Kingdom; [3]UCLH NHS Trust, Find&Treat, London, United Kingdom; [4]Hospital Universitario de Valme, Infectious Diseases and Microbiology Unit, Sevilla, Spain; [5]Victor Babes Clinical Hospital for Infectious and Tropical Diseases, Bucharest, Romania; [6]University of Bristol, School of Social and Community Medicine, Oakfield House, Bristol, United Kingdom; [7]University College Dublin, School of Medicine, Dublin, Ireland; [8]Mater Misericordiae University Hospital, Infectious Diseases Department, Dublin, Ireland*
Email: j.surey@ucl.ac.uk

Background and Aims: Hepatitis C disproportionately affects vulnerable groups such as the homeless, PWIDs and prison populations. In the age of DAAs community interventions are vital to reach these underserved populations if there is to be a chance of reducing prevalence and eventual elimination. The four EU HepCare sites (Ireland, UK, Spain, Romania) aim to improve identification and treatment of HCV, especially focusing on vulnerable populations with a commitment to sharing knowledge and practice. The HepFriend workpackage aims to utilise peer support in the community to increase awareness of the risk of HCV, the importance of testing, disease severity and provide treatment support. Peers, with their lived experience, can connect with underserved populations in a way traditional treatment services cannot.

Method: Peers were recruited and trained in HCV awareness raising and testing using a standardised method developed by the Hepatitis C Trust (UK). They were taught to deliver three simple messages: the importance of getting tested; the effectiveness of current treatment; how to avoid infection. Each site then adapted the training to meet local needs and peer networks were developed locally with NGO partners to feed into specialist HCV services. One site (London) trained peers in Fibroscan alongside the clinical team. Training was also provided in other diseases such as TB, HIV and linkage to care.
Results: To date, a total of 27 peers received training: Dublin n = 12, London n = 6, Bucharest n = 3 and Sevilla n = 6. These peers have collectively carried out 216 tests and (re-)engaged 168 patients with clinical services. Of these 82 (48.8%) were started on treatment. Three sites (Dublin, London, Bucharest) made linkages with TB services, two also with HIV advocacy NGOs (Bucharest, Sevilla). The London site offered peer support linked with a mobile health unit with trained peers carrying out 70 Fibroscans. Peers have been also incorporated into OST delivery sites (Dublin n = 4, London n = 3) and the local hospital treatment network (Bucharest, Sevilla).
Conclusion: Peers have a unique role in engaging with underserved populations and we have shown they can be successfully integrated into community interventions to improve case finding and treatment outcomes. Peers can also be a powerful resource to empower patients to access treatment, which is vital if we are to eliminate HCV as a public health concern, where traditional medical models have failed.

THU-123

Virological and clinical characterization of a hepatitis A outbreak in Barcelona involving primarily men who have sex with men

S. Rodríguez-Tajes[1,2], E. Perpiñan[1,2,3], B. Caballol[2], S. Lens[1,2,3], Z. Mariño[1,2,3], J. Costa[2,3], A. Vilella[2], S.P. del Pulgar[1,2,3], X. Forns[1,2,3], G. Koutsoudakis[1,2,3]. *[1]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain; [2]Hospital Clínic, Barcelona, Spain; [3]CIBER - Centro de Investigación Biomédica en Red, Madrid, Spain*
Email: sergio.tajes@gmail.com

Background and Aims: Acute hepatitis A (AHA) transmission occurs mainly through the faecal-oral route and/or via contaminated food or water. Moreover, men who have sex with men (MSM) are considered a high risk population and thus, vaccination is strongly recommended. Strikingly, an increasing number of cases of AHA in different European countries have been reported since the second half of 2016. Here, we aimed to evaluate the clinical and virological characteristics of the ongoing hepatitis A outbreak in our area (Barcelona).
Method: We prospectively analyzed all cases of AHA diagnosed in our hospital between January and October 2017. We evaluated demographic data, risk factors, clinical symptoms, sexual orientation, comorbidities and further sexually transmitted diseases (STD). Phylogenetic correlation of the current circulating viruses among them and previously hepatitis A reported strains in our area was assessed by sequencing the VP1/P2A viral region.
Results: So far, 64 patients have been included. Most were male (62, 97%) with a median age 32 years (range 28–39). Twenty-three (39%) patients required hospitalization, 11 (17%) due to severe acute hepatitis and the remaining patients due to severe gastrointestinal symptoms. Except for 2 patients, all had a full recovery in less than 3 months. Of note, 42 (66%) patients self-reported to be MSM. Compared with the non-MSM group, MSM reported more frequent risk sexual contacts (78% vs 10%, p = 0.00), active drug consumption during the previous month (39% vs 11%, p = 0.05) and were diagnosed with others STD (36% vs 14%, p = 0.05).
Molecular phylogenetic analyses revealed that all patients were infected by hepatitis A subgenotype IA strains, which comprised 3 distinct clusters previously reported in other ongoing outbreaks in the United Kingdom, Berlin and the Netherlands. However, these strains were not phylogenetically related to those previously reported in Barcelona during the last decades.
Conclusion: The ongoing hepatitis A outbreak in Barcelona affects primarily the MSM community and is phylogenetically linked to current hepatitis A outbreaks described in other European countries. Because of the high admission rate, these outbreaks may impact the admission pattern of referral liver units. Control measures such as vaccination programs tailored to the MSM community must be implemented to control further spreading.

THU-124

Anemia in chronic liver disease

S.J. Suh[1], H.A. Lee[2], T.H. Kim[3], Y.-S. Lee[3], Y.K. Jung[3], J.H. Kim[3], Y.S. Seo[4], H.J. Yim[3], J.E. Yeon[3], S.H. Um[3], K.S. Byun[3]. *[1]Korea University Ansan Hospital, Department of Internal Medicine, Ansan-si, Gyeonggi-do, Republic of South Korea; [2]Korea University Anam Hospital, Department of Internal Medicine, Seoul, Republic of South Korea; [3]Korea University Medical College, Internal Medicine, Seoul, Republic of South Korea; [4]KUMC Anam Hospital, Internal Medicine, Republic of South Korea*
Email: mothpickle@naver.com

Background and Aims: The anemia in liver disease is common and the prevalence is various according to the stage of liver diseases. It is reported as 21% in compensated liver cirrhosis (LC), 50–70% in alcoholic or non-alcoholic liver cirrhosis, and 67% in hepatocellular carcinoma (HCC) patients. The prevalence in chronic liver disease is difficult to describe because various stages of liver disease are included in studies. According to WHO report at 2008, global prevalence of anemia in general population is about 24.8%.
The aim of study is to investigate the prevalence of anemia according to the stage of liver disease, and the causes of anemia in chronic liver disease.
Method: The patients who visited to Korea university ansan hospital were reviewed by medical record. From January 2012 to December 2016, 2357 patients visited for liver disease. The anemia was defined as hemoglobin level <13.0 g/dl (men) or <12.0 g/dl (women) by WHO's threshold.
The causes of anemia is classified as hemorrhage (definite gastrointestinal bleeding is noted by endoscopic exam), renal diseases (eGFR, MDRD < 30 ml/min/1.73 m^2), inflammatory disorder (CRP > 3 g/dl), iron deficiency anemia (Fe/TIBC < 15% or ferritin < 18 ng/ml), direct toxicity of ethanol (alcohol etiology and MCV > 100), hypersplenism (spleen size ≥ 13 cm), and others as undetermined. This classification is modified from "the algorithm of the physiologic classification of anemia" of Harrison's Principal of Internal Medicine.
Results: 2357 patients visited for liver disease, and 1961 patients had chronic liver disease. 1317 patients had anemia. The prevalence of anemia in chronic liver diseases were 69.8% [1317/ (1961–75 missing haemoglobin data)]. Female patients had more anemia (75.5% vs. 68.2%, p = 0.048).
As the chronic liver disease worsened, more anemia was observed (chronic hepatitis 59.5%, compensated LC 64.8%, decompensated LC 98.2%, HCC 80.0%). The progression of liver disease rather than HCC was associated with anemia (hepatitis 59.5%, compensated LC ± HCC 74.3%, decompensated LC ± HCC 97.7%, p < 0.001).
The proportion of anemia was different according to the etiology of liver disease (AIH ± PBC ± PSC 51.3%, CHB 57.7%, CHC 66.8%, and alcohol 88.0%). The alcoholic patients had more anemia (alcohol 84.8% vs. non-alcohol 62.0%, p < 0.001).
The causes were hemorrhage 19.1%, renal diseases 6.4%, iron deficiency anemia, 22.3%, inflammatory 15.3%, drug side effect 2.5%, direct toxicity of ethanol 17.8%, hypersplenism 11.5%, and undetermined 5.1%.
Conclusion: The prevalence of anemia in chronic liver disease was 69.8%, higher than general population 24.8%. Attention should be paid more to the patients with progressed liver disease. The proportion of anemia was larger in alcoholic liver disease than viral or inflammatory liver disease. Because of the variety of causes, different treatment is needed for each causes.

Increasing access to treatment for hepatitis C by vulnerable, high risk patients through community pharmacy: The SuperDOT-C study in Scotland

A. Radley[1,2], L. Beer[3], C. Byrne[3], S. Inglis[3], A. Eriksen[1], S. Barclay[4], A. Fraser[5], J. Dillon[6]. [1]*NHS Tayside, Directorate of Public Health, Dundee, United Kingdom;* [2]*University of Dundee, Molecular and Clinical Medicine, Dundee, United Kingdom;* [3]*University of Dundee, Tayside Clinical Trials Unit (TCTU), Dundee, United Kingdom;* [4]*NHS Greater Glasgow and Clyde, Department of Gastroenterology, Glasgow, United Kingdom;* [5]*NHS Grampian, Summerfield House, Aberdeen, United Kingdom;* [6]*University of Dundee, Molecular and Clinical Medicines, Dundee, United Kingdom*
Email: Andrew.Radley@nhs.net

Background and Aims: New care pathways for Hepatitis C (HCV) are required to increase access to treatment among people prescribed opioid substitution therapy (OST). Existing pathways are often poorly utilised by this vulnerable group because of barriers to care including issues with stigma and health literacy and complexity of service design. This is despite OST patients having regular contact with a pharmacist. Highly effective direct-acting antiviral therapy (DAAs) for HCV have a much smaller burden of treatment than interferon-based regimes, require less monitoring and have improved adherence, making a community pharmacy treatment pathway potentially viable. The SuperDOT-C trial compares an established standard of care pathway (conventional care). with a community pharmacy-led pathway utilising directly observed therapy.
Method: Fifty-five community pharmacies have been recruited from the Tayside, Grampian and Glasgow regions of Scotland. and have been randomised to either provide HCV treatment on site (pharmacy-led arm), or refer patients to the conventional care pathway At the beginning of the study, pharmacists and support staff were trained to provide dried blood spot testing for HCV to OST recipients and to evaluate laboratory test results to determine suitability for treatment within the community pharmacy. Individuals suitable for treatment either receive therapy within their pharmacy or are referred to the conventional care pathway.
Results: To date, 280 HCV positive patients have been consented into the two SuperDOT-C treatment arms and 113 have initiated therapy. No problems have been encountered with the testing or assessment of patients for treatment. Pharmacy staff report that the opportunity to offer testing and treatment for HCV has enhanced the relationship with patients.
Conclusion: The SuperDOT-C study has shown initial promise, in terms of the ability of pharmacy staff to recruit OST patients and encourage them to initiate treatment. The study is scheduled to complete recruitment by the end of 2018.

THU-126

Drug utilization in patients with liver cirrhosis in ambulatory care

R. Weersink[1,2], T. Katja[2], S. Borgsteede[1]. [1]*Health Base Foundation, Dept. Clinical Decision Support, Houten, Netherlands;* [2]*University of Groningen, Unit PharmacoTherapy, Epidemiology & Economics, Groningen, Netherlands*
Email: sander.borgsteede@healthbase.nl

Background and Aims: Patients with liver cirrhosis are at risk to develop adverse events because of altered pharmacokinetics and pharmacodynamics. Some drugs have known safety risks in patients with cirrhosis, such as NSAIDs and benzodiazepines. There is not much known about drug use in these patients in ambulatory care, where drug use might be more risky because of less monitoring. Therefore, we aim to explore which drugs patients with liver cirrhosis use in ambulatory care.
Method: In this retrospective longitudinal cohort study, data from an out-patient pharmacy database were combined with hospitalization data (PHARMO Database Network). Patients with a clinical diagnosis of cirrhosis (ICD-9 code 571.2 or 571.5) between January 1998 and December 2015 were included in the study. The index date was the first day of discharge from hospital with the diagnosis of cirrhosis. Data on drug dispensions were analyzed during the total follow-up of a patient.
Results: In total 5,618 patients (59% males) were included with a mean age at the index date of 60.7 ± 12.5 years. Patients were followed for a median of 3 years (interquartile range (IQR) 3) after the index date. In 179 patients (3.2%) follow-up ended because of a liver transplantation. During the total follow-up, 102,297 drugs were prescribed. General practitioners prescribed 61.5% of these drugs, specialists 36.4% and the prescriber was unknown in 2.2%. Patients used a median of 6.8 unique drugs per person per year (IQR 8.4). Drugs for acid related disorders (mainly proton pump inhibitors) were the most frequently used therapeutic group (70.9% of patients) followed by diuretics (63.5%) and antibacterials for systemic use (61.9%). For individual drugs, spironolactone (48.7%), furosemide (44.0%) and pantoprazole (34.9%) where used most often. Temazepam (23.2%), diclofenac (22.2%) and paracetamol (21.3%) were the most frequently used drugs for non-liver related co-morbidities. Looking at the group of benzodiazepines and NSAIDs; they were used by respectively 46.2% and 37.1% of patients during the total follow-up.
Conclusion: Patients with cirrhosis frequently use drugs in ambulatory care. A substantial proportion of patients used drugs with known safety risks in cirrhosis, such as NSAIDs and benzodiazepines. Attention is needed for both specialists and general practitioners when prescribing drugs to these fragile patients to prevent adverse events.

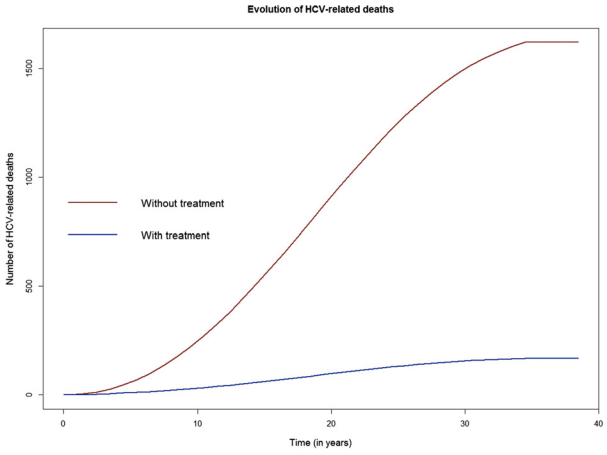
THU-127

Long-term effectiveness of Sofosbuvir-based hepatitis C regimens in Central and West Africa (ANRS 12342)

Lacombe[11]. [1]*Aix Marseille Univ, INSERM, IRD, SESSTIM (Sciences Economiques & Sociales de la Santé & Traitement de l'Information Médicale) Marseille France;* [2]*ORS PACA (Observatoire Régional de la Santé Provence-Alpes-Côte d'Azur) Marseille France;* [3]*Liverpool School of Tropical Medicine;* [4]*Imperial College, London;* [5]*IMEA, Paris, France;* [6]*Hôpital Central de Yaoundé, Hôpital de jour, Yaoundé, Cameroon;* [7]*ANRS, Paris, France;* [8]*Mereva, PACCI Abidjan, Abidjan, Côte d'Ivoire;* [9]*CHU Fann, Service des Maladies Infectieuses, Dakar, Senegal;* [10]*CHU Yopougon, Service d'hépatologie, Abidjan, Côte d'Ivoire;* [11]*INSERM UMR-S1136, Université Paris VI-APHP, Paris, France*
Email: sylvie.boyer@inserm.fr

Background and Aims: Chronic hepatitis C (CHC) is a global public health problem with long-term consequences including the development of liver cirrhosis and hepatocellular carcinoma (HCC). The short-term effectiveness of Direct Anti-Viral Agents (DAA) has been assessed for the first time in the setting of sub-Saharan Africa within the multicenter, non-randomized, open-label ANRS 12311 TAC trial.

We assessed the long term clinical benefits of treating hepatitis C patients with sofosbuvir-based treatment in Cameroun, Senegal and Côte d'Ivoire.
Method: Using a Markov cohort model, we simulated CHC with and without treatment in a cohort of 10,000 chronically infected patients. CHC treatment efficacy and costs were derived from the TAC trial, which treated a total of 120 CHC adult patients either with sofosbuvir/ribavirine (for genotype 2, n = 40) or sofobuvir/ledispavir (for genotypes 1 and 4, n = 40 and 40, respectively) in the three study countries. An extensive literature review was carried out to obtain disease progression probabilities without treatment and after cure. We compare life-years gained over the life time, as well as number of individuals with compensated cirrhosis, decompensated cirrhosis and HCC 10 and 20 years after diagnosis, with and without treatment. Sensitivity analysis were performed to evaluate model robustness.
Results: The total number of life years was 228,600 with treatment and 207,736 without treatment, i.e. 20,864 life years gained with treatment. Figure 1 shows the impact of CHC treatment on the liver-related mortality over time. Treatment prevented 1452 HCV related deaths. Disease progression outcomes showed that after 10 (20) years, 9.45% (resp. 7.36%) of the treated cohort had a compensated cirrhosis versus 24.40% (resp. 23.80%) of the non-treated cohort. Similarly, after 10 (20) years, only 0.41% (resp. 0.53%) of the treated cohort had decompensated cirrhosis versus 3.98% (resp. 5.32%) of the non-treated cohort. HCC cases represented 0.01% of the treated cohort (resp. 0.02%) and 0.10% (resp. 0.16%) of the non-treated cohort after 10(20) years.



Conclusion: Sofosbuvir-based treatment significantly reduces HCV-related mortality and allows controlling the evolution of liver disease in the setting of sub-Saharan Africa which presently pays a high burden to the global liver associated mortality. These results highlight the necessity of increasing the access to DAAs that offer large long-term health benefits in resource-limited settings.

THU-128
Cost-effectiveness of Sofosbuvir-based hepatitis C regimens in Central and West Africa (ANRS 12342)

S. Boyer[1], M. Baudoin[1,2], M. Nishimwe[1,2], M.E. Woode[3], G. Maradan[1,2], M. Lemoine[4], B. Sylla[5], C. Kouanfack[6], P. Carrieri[1,2], N. Rouveau[7], R. Moh[8], M. Seydi[9], A. Attia[10], K. Lacombe[11]. *[1]Aix Marseille Univ, INSERM, IRD, SESSTIM (Sciences Economiques & Sociales de la Santé & Traitement de l'Information Médicale); [2]ORS PACA (Observatoire Régional de la Santé Provence-Alpes-Côte d'Azur); [3]Liverpool School of Tropical Medicine, London, United Kingdom; [4]Imperial College, London, London, United Kingdom; [5]IMEA, Paris, France; [6]Hôpital Centrale de Yaoundé, Hôpital de Jour, Yaoundé, Cameroon; [7]ANRS; [8]MEREVA, PACCI Abidjan, Abidjan, Côte d'Ivoire; [9]CHU Fann, Service des Maladies Infectieuses, Dakar, Sénégal; [10]CHU Yopougon, Service d'hépatologie, Abidjan, Côte d'Ivoire; [11]INSERM UMR-S1136, Université Paris VI-APHP*
Email: sylvie.boyer@inserm.fr

Background and Aims: While low-income countries (LICs) bear the highest burden of Chronic Hepatitis C (CHC), treatment is poorly accessible in these countries mainly due to cost consideration. As part as the open-label trial for CHC treatment in Africa (TAC-ANRS 12311), we assessed the cost-effectiveness of an interferon-free regimen in patients with CHC living in Senegal, Cameroon and Cote d'Ivoire.
Method: Using a Markov cohort model, we simulated CHC with and without treatment in a cohort of 10,000 chronically infected patients. CHC treatment efficacy and costs were derived from the TAC trial, which treated a total of 120 CHC adult patients either with sofosbuvir/ribavirine (for genotype 2, n = 40) or sofobuvir/ledispavir (for genotypes 1 and 4, n = 40 and 40, respectively) in the three study countries. An extensive literature review was carried out to obtain disease progression probabilities and costs without treatment and after cure. We estimated quality adjusted life-years (QALY) gained over the life time, incremental costs and incremental cost-effectiveness ratio (ICER) of sofosbuvir-based treatment compared with the situation without treatment. We assessed uncertainty with probabilistic sensitivity analysis and cost-effectiveness acceptability curves.
Results: Sofosbuvir-based treatment increased costs by a mean of €822.5, €997.5 and €1173.2 per patient in Senegal, Ivory Coast and Cameroon, respectively. It saved 1.4, 1.2 and 1.3 QALY per patient compared with the situation without treatment. Corresponding ICER (95% Confidence Intervals) were €588.4 [330.7–1327.6], €806.6 [480.1–1533.4] and €870.8 [536.2–1760,1] per QALY in the study countries (Senegal, Ivory Coast and Cameroon, respectively). At a cost-effectiveness threshold of three times the GDP per capita, the probability to be cost-effective reached near 100% in all three countries (See Figure).

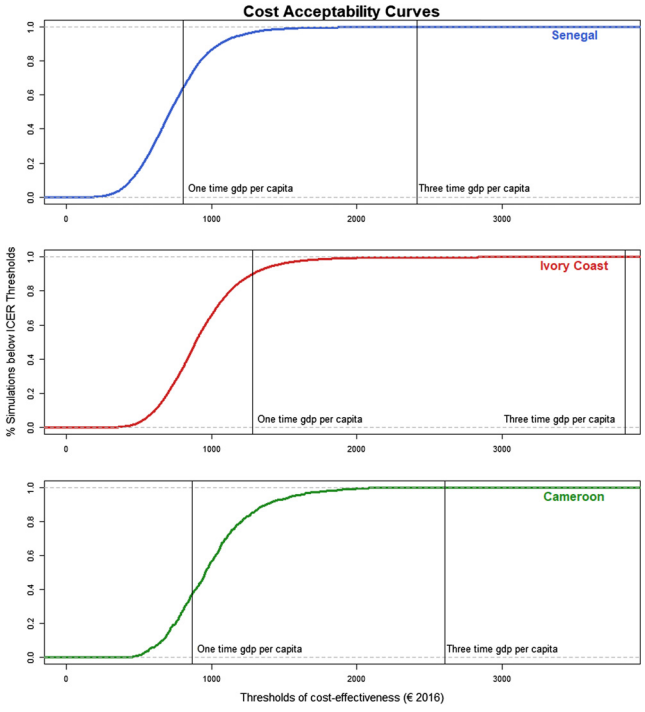


Figure 1: Cost-effectiveness acceptability curves of sofosbuvir-based treatment in West and Central Africa.

Conclusion: Our findings suggest that sofosbuvir-based treatment is cost-effective in the setting of the study countries at the cost-effectiveness threshold of three times the GDP per capita. As large reductions in DAA prices are expected with the development of generics, this treatment may even become very cost-effective in the short term. These results highlight the necessity of increasing access to DAAs that offer large long-term health benefits at additional acceptable costs in resource-limited settings.

THU-129

HCV screening in the adult general population of a basic health area in the Valencian Region (Spain)

L.G.-E. Viejo[1], A.G. Herola[1], I.S. Lloret[2], I. Clemente[2], F. Sanchez-Ruano[3], C.Q. Ivorra[1], I.A. Saavedra[1], J. Valverde[1]. *[1]Hospital Marina Baixa, Seccion Medicina Digestivo, Villajoyosa (Alicante), Spain; [2]Departamento de Salud Marina Baixa, Centro de Salud Publica Benidorm, Benidorm (Alicante), Spain; [3]Centro de Salud Callosa d'en Sarria, Departamento Salud Marina Baixa, Callosa d'en Sarria (Alicante), Spain*
Email: agherola@gmail.com

Background and Aims: Data on seroprevalence of hepatitis C (HCV) in the general population in Spain is scarce. A national cross-sectional, population-based study (PREVHEP study) recently estimated HCV seroprevalence (1.2%) and viremia prevalence (0.31%). Aim: to estimate HCV seroprevalence and prevalence of HCV viremia in the adult (25–70 years-old) general population of a basic health area in the Valencian Region.

Method: Design: observational, cross-sectional, population-based study.

Population: All 25–70 years-old adults living in a basic health area (Callosa d'En Sarrià) with universal population covering and registered in the Valencian Health Service (VHS) database.

Variables: (1) outcome: HCV serology, HCV viremia. (2) descriptive: id number, age.

Data collection: Study subjects were invited to participate and sign the study informed consent by mail. HCV serology was obtained amongst those who agreed to participate using a rapid anti-HCV finger stick blood test (Core HCV). Subjects were encouraged to contact investigators in order to communicate HCV serology status if previously known. An attempt to confirm HCV serology and HCV viremia status was done, using ELISA and PCR, respectively. Information on descriptive variables was obtained from the VHS database, whilst on risk factors associated to HCV infection were collected through personal interviews.

Analysis: descriptive analysis.

Results: 5,849 subjects were invited to participate in the study by mail. 143 subjects were excluded due to mailing address errors (study population = 5,706). Between February and April 2017, 2,637 out of 5,706 subjects directly participated in the study (46.2%). Of all the subjects to whom the rapid HCV test was performed, seven were positive; none of them were aware of their HCV infection status. Twenty-three subjects had a history of HCV infection, some of whom had been treated and/or were being followed by hepatologists. In all, 30 subjects (mean age 54.9, range: 37–71) were anti-HCV positive, resulting in an estimated prevalence of 1.1% (30/2637). All of the 30 anti-HCV positive subjects were tested for RNA-HCV (13 positive), and HCV viremia prevalence has been estimated as 0.49% (13/2637).

Conclusion: (1) HCV seroprevalence (1.1%) in the general population of the study area was similar and viremia (0.49%) was higher than those recently reported in Spain. (2) Most anti-HCV positive patients were born in 1950 to 1970. (3) The majority of patients with positive viremia were aware of their HCV status. (4) Participation in the study was very high (46.2%).

THU-130

The nature and impact of stigma in patients with chronic hepatitis B: a systematic literature review

J. Smith-Palmer[1], R. Pollock[1], K. Bonroy[2], U. Sbarigia[2], W. Valentine[1], K. Cerri[2]. *[1]Ossian Health Economics and Communications, Basel, Switzerland; [2]Janssen Pharmaceutica N.V., Beerse, Belgium*
Email: smith-palmer@ossianconsulting.com

Background and Aims: People with chronic infectious diseases can face stigma, which can negatively impact quality of life and quality of care, as well as influence treatment seeking and disclosure behavior. Stigma can be defined as a social process characterized by exclusion, rejection, blame or devaluation due to experience or anticipation of adverse social judgement of a person/group and can be classified as internalized, social or structural/institutional. A systematic literature review was performed to characterize the level and type of stigma experienced by people infected with hepatitis B virus (HBV) as well as the extent to which these influences treatment seeking, disclosure and quality of life in this patient population.

Method: A systematic literature review was performed in November 2016 using the PubMed, EMBASE and Cochrane databases to identify studies describing (quantitatively or qualitatively) stigma related to HBV. For inclusion, articles were required to be published in full text form, in English and contain data from which qualitative or quantitative data on HBV-related stigma could be extracted. No time limits were applied to the search.

Results: A total of 23 (17 quantitative and 6 qualitative) articles examined HBV-related stigma, these were almost exclusively conducted in Asian or Asian Immigrant populations, with some utilizing tools that allow the quantitative assessment of HBV-related stigma, including the HBV Stigma Instrument (n = 3) and the Hepatitis B Quality of Life Questionnaire 1.0 (n = 2). Qualitative studies were primarily conducted via patient interview. Internalized and social stigma were common in HBV-patients with >30% respondents in some studies believing that HBV brought trouble/shame to their families and that people with HBV should avoid kissing/hugging others. There was some evidence that stigma was partly attributable to lack of knowledge around transmission routes, which led to a fear of infection. HBV patients, also perceived structural/institutional stigma, with up to 20% believing that they may be denied healthcare and up to 30% stating that they may face workplace discrimination due to HBV.

Conclusion: Stigma towards patients with HBV is common and deeply entrenched in Asia and among Asian immigrant communities in North America, and is poorly characterized in non-Asian populations. Initiatives are needed to measure and document HBV-related stigma, as well as its clinical and socioeconomic consequences.

THU-131

Cost-effectiveness of scaling up Hepatitis C virus prevention, testing and treatment interventions among people who inject drugs in the US

C. Barbosa[1], H. Fraser[2], T. Hoerger[1], A. Leib[1], J. Evans[3], J. Havens[4], L. Nerlander[5], K. Page[3], A. Young[6], A. Kral[1], J. Zibbell[1], S. Hariri[5], C. Vellozzi[5], J. Ward[5], P. Vickerman[2]. *[1]RTI International; [2]University of Bristol, Population Health Sciences; [3]University of California, San Francisco; [4]University of Kentucky College of Medicine; [5]Centers for Disease Control and Prevention; [6]University of Kentucky College of Public Health*
Email: hannah.fraser@bristol.ac.uk

Background and Aims: HCV prevention and treatment interventions need to be scaled-up for people who inject drugs (PWID) to tackle the increasing HCV epidemic in the US; we undertake the first cost-effectiveness of this strategy.

Method: We calibrated two HCV-transmission and disease progression models among PWID and ex-PWID to data from rural Perry County, Kentucky (PC) and urban San Francisco (SF). Compared to PC, SF has a greater proportion with recent (last 3–6 months) access to

MAT (6% vs 12%) or SSP (0% vs 85%), which are both assumed to reduce HCV-transmission risk by about 50%, and 70% combined, based on a recent Cochrane review. HCV-treatment of PWID is currently negligible in both settings. Intervention scenarios considered: (HR) Scale-up of SSP and MAT to 50% coverage (SSP coverage at baseline is high in SF) with no HCV-treatment scale-up; and HR (50% coverage for both) plus 90% of PWID HCV-screened annually and 90% of HCV-infected PWID treated annually. Using a health-care perspective and measuring benefits in terms of quality adjusted life years (QALYs), we determined the incremental cost-effectiveness ratio (ICER) of each intervention compared to existing baseline.

Results: In PC, intervention HR would cost $14 million, gaining 782 QALYs, for an ICER of $17,698 per QALY gained, whereas HR + PWID HCV-treatment could cost $35 million, gaining 3,182QALYs, for an ICER of $11,037 per QALY gained. Conversely, the interventions were less cost-effective in SF; HR would cost $383 million, gaining 7,958QALYs, for an ICER of $48,098 per QALY gained, whereas HR + PWID HCV-treatment would cost $1,484 million, gaining 75,019 QALYs, for an ICER of $19,787 per QALY gained. Assuming a $50,000 willingness to pay threshold, both interventions are cost-effective in 100% of simulations for PC, but in SF, only for 64% of simulations for HR and 99% for HR + PWID HCV-treatment.

Conclusion: The scale-up of HCV prevention, screening and treatment interventions for PWID could be cost-effective in both rural and urban US settings.

THU-132

HEV positivity in domesticated pigs and a relative risk of HEV zoonosis among occupationally exposed individuals in Vietnam

X.H. Nghiem[1,2,3], X.H. Pham[4], V.S. Trinh[3,5], P.G. Dao[3,6], T.B. Mai[3,7], T.A. Dam[8], H.S. Le[3,6], C.-T. Bock[9], T. Hoang[3,4], L.T. Nguyen[3,4], T.P. Velavan[1,3]. *[1]Institute of Tropical Medicine, University of Tuebingen, Tuebingen, Germany; [2]108 Military Central Hospital, Institute of Clinical Infectious Diseases, Hanoi, Viet Nam; [3]Vietnamese - German Center of Excellence in Medical Research (VG-CARE), Hanoi, Viet Nam; [4]Vietnam Military Medical University, Department of Pathophysiology, Hanoi; [5]Institute of Clinical Infectious Diseases, Hanoi, Viet Nam; [6]108 Military Central Hospital, Institute of Clinical Infectious Diseases, Hanoi, Viet Nam; [7]Institute of Tropical Medicine, Tuebingen, Germany; [8]Hanoi Medical University, Pathophysiology, Hanoi, Viet Nam; [9]Robert Koch-Institute, Viral Gastroenteritis and Hepatitis Pathogens and Enteroviruses, Berlin, Germany*
Email: nghiemxuanhoan@108-icid.com

Background and Aims: Hepatitis E virus (HEV) infections by zoonosis is well documented in developed countries, and seldom known in developing countries. HEV infection can occur from eating undercooked pork or by exposure to animal faeces. HEV infection in domesticated pigs sold at markets in Hanoi metropolitan area were investigated to understand, if pigs were a potential source of HEV exposure. Additionally, we investigated on the seroprevalence of HEV exposure in general population, butchers, pig-farmers and individuals working at slaughterhouses.

Method: Liver tissues from domesticated pigs (n = 210) were screened for HEV RNA by reverse transcriptase polymerase chain reaction (rT-PCR). Serum samples from occupational workers (n = 182) and from general population (n = 340) were subjected to HEV IgG and IgM specific ELISAs, and the presence of HEV RNA was investigated by rT-PCR. Additionally, sequence analysis of HEV were done to address HEV genotypes in circulation in the region.

Results: Of the investigated pig liver tissues, 26/210 (12.4%) were positive for HEV-RNA and were characterized to be HEV Genotype 3. HEV seroprevalence was high among occupationally exposed population than the general population (anti-HEV IgM: 12% vs. 5%; p = 0.0065 and anti-HEV IgG: 67% vs. 31%; p < 0.0001, respectively). In particular, pig farmers had the highest anti-HEV IgG (92%), followed by slaughterers (66%) and butchers (49%). A similar trend for anti-HEV IgM was observed. The pig farmers had the highest anti-HEV IgM (14%), followed by slaughterers (10%) and the butchers (8%).

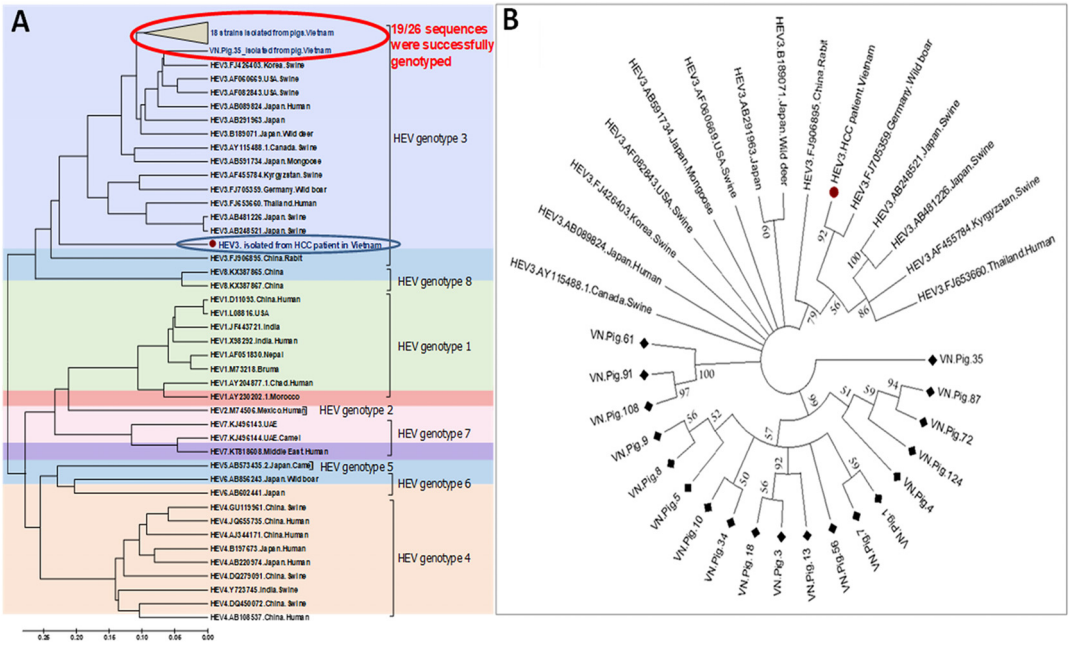

Figure 1: (abstract: THU-132): Phylogenetic analysis of HEV strains isolated from domesticated pigs. (A) Phylogenetic analysis of 19 HEV strains isolated from domestic pigs: Phylogenetic tree was reconstructed based on the alignment of 306 bp of the HEV RdRp region (ORF1), one HEV strain isolated from liver cancer patient coinfected with hepatitis B virus in Vietnam. A total of 40 full-length HEV genomes were included (all genotypes HEV-1 to HEV-8), as retrieved from NCBI database. Genetic distances were computed using the Kimura-parameter and a neighbor-joining tree was constructed with 1000 bootstrap replications. The scale indicates nucleotide substitutions per base pair. (B) Phylogenetic clade reconstructed with all available HEV 3 genotypes: The analysis involved 34 nucleotide sequences, including 19 HEV strains isolated from domestic pigs. Bootstrap analysis values (in percentage) are shown on the branches.

Conclusion: This first study reports that, HEV is circulating in domesticated pigs in Northern Vietnam. High HEV seroprevalence indicates an associated relative risk to HEV exposure. Taken together, this study provides insights on HEV transmission dynamics and domesticated pigs remain a zoonotic reservoir for HEV infection in Vietnam.

THU-133

Is HCV elimination among HIV-infected people who inject drugs possible through HCV treatment targeting HIV/HCV coinfection? A modeling analysis for Andalusia, Spain

B. Skaathun[1], A. Borquez[1], A. Rivero-Juarez[2], F. Tellez[3], M. Castano[4], D. Merino[5], J. Santos[6], J.M. Sanchez[7], A. Rivero[2], N. Martin[8,9].

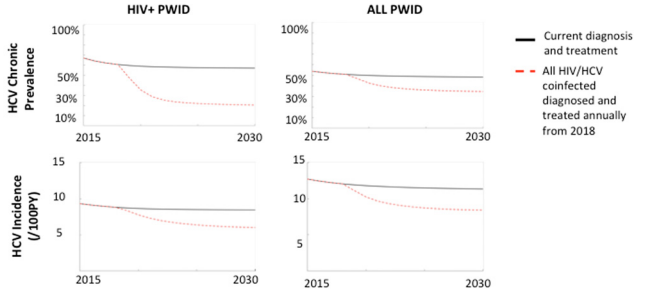
Email: natasha-martin@ucsd.edu

Background and Aims: Scale-up of HCV treatment for HIV/HCV coinfected individuals is occurring in Spain, the majority with a history of injecting drug use (IDU). However, it is unclear if this scale-up will achieve the WHO elimination target (90% reduction in incidence by 2030) among HIV-infected people who inject drugs (HIV + PWID). We assess the population impact of HCV treatment scale-up to HIV+ individuals, and its implications for elimination among HIV+ PWID in Andalusia, Spain, using dynamic modeling.
Method: A joint HIV and HCV transmission model among PWID was developed and stratified by HIV stage, HCV stage, diagnosis, and PWID status (PWID, exPWID). The model was calibrated to Andalusia (55%/70% chronic HCV prevalence among PWID/HIV+ PWID in 2010, respectively, 30% HIV prevalence among PWID in 2010, 6700 PWID in 2010, 370/2300 diagnosed coinfected PWID/exPWID in 2015). We assumed HCV treatment among diagnosed coinfected PWID and exPWID of 10.5%/year from 2004–2014, and 33%/year from 2015 (estimated from the HERACULES cohort, HIV/HCV coinfected individuals from 21 hospitals in Andalusia). We examine the impact of: (1) current treatment rates and (2) 100% screening and treatment of coinfected PWID from 2018 on HCV chronic prevalence and incidence among HIV+ PWID and PWID.
Results: Our model estimated that in 2015, 36% and 47% of HCV infected PWID and exPWID, respectively, in Andalusia were HIV/HCV coinfected. Among them, 26.8% and 60.5% of coinfections, respectively, were diagnosed. Current treatment rates could dramatically reduce the prevalent number of diagnosed coinfected people with a history of IDU (by a relative 77% from 2015–2030). However, this would only reduce HCV chronic prevalence by a relative 15% and 10% from 2015–2030 among HIV+ PWID and all PWID, respectively, due to transmission from PWID with HCV monoinfection and undiagnosed coinfection (Figure). If all coinfected PWID are diagnosed and treated annually from 2018, this could reduce chronic prevalence among HIV+ PWID by a relative 69% in 2030, but incidence by only 35% (Figure).
Conclusion: Increased HCV treatment of HIV+ individuals in Andalusia will dramatically reduce the diagnosed coinfection population, and scale-up could moderately reduce HCV incidence among HIV+ PWID, but elimination among HIV+ PWID will not be achieved through treating coinfected PWID alone. Elimination efforts among HIV+ PWID should focus on HCV diagnosis and treatment among both coinfected and monoinfected PWID.

Figure 1: Modeled HCV chronic prevalence (top panels) and incidence (bottom panels) among HIV+ PWID (left panels) and all PWID (right panels) in Andalusia, Spain. Simulations show model projections with current diagnosis and treatment rates (black lines) and scaled-up so all HIV/HCV coinfected PWID are diagnosed and treated annually from 2018.



THU-134

Incidence of hepatitis C virus infection in four prisons in New South Wales, Australia: The SToP-C study

B. Hajarizadeh[1], J. Grebely[1], M. Byrne[1], P. Marks[1], J. Amin[1], T. Butler[1], P. Vickerman[2], N. Martin[2,3], J.G. Mchutchison[4], D. Brainard[5], C. Treloar[6], A. Lloyd[1], G. Dore[1]. *[1]UNSW Sydney (University of New South Wales), The Kirby Institute, Sydney, Australia; [2]University of Bristol, School of Social and Community Medicine, Bristol, United Kingdom; [3]University of California San Diego, Division of Global Public Health, San Diego, United States; [4]Gilead Sciences Inc, Foster City, United States; [5]Gilead Sciences, Gilead Sciences, Foster City, United States; [6]UNSW Sydney (University of New South Wales), Centre for Social Research in Health, Sydney, Australia*
Email: bhajarizadeh@kirby.unsw.edu.au

Background and Aims: The Surveillance and Treatment of Prisoners with hepatitis C (SToP-C) study assesses HCV treatment as prevention in 4 prisons, in New South Wales, Australia. SToP-C consists of: (i) Surveillance phase, HCV status and risk behaviour are evaluated at study entry and monitored longitudinally; (ii) Treatment scale-up phase, participants with detected HCV RNA are offered 12 weeks sofosbuvir/velpatasvir. This analysis assessed HCV incidence before treatment scale-up.
Method: Surveillance phase data of participants enrolled before treatment scale-up (Oct 2014 to Sept 2017) was used. Participants were screened for HCV antibody (Ab) and RNA at enrolment. HCV Ab or RNA negative participants were tested 6-monthly. Those HCV Ab negative and HCV Ab positive/RNA negative were considered at risk of HCV primary infection and reinfection, respectively.
Results: Among 1,569 participants screened, 392 had detected HCV RNA (25%) and 1175 were at risk of HCV, among whom 482 had at least one follow-up visit (included in analysis, 356 and 126 at risk of primary infection and reinfection, respectively). During 388 person-years (py) of follow-up, HCV incidence was 7.9/100 py (95%CI: 5.6, 11.3). Incidence of primary infection and reinfection was 6.4/100 py (95%CI: 4.0, 10.1), and 12.3/100 py (95%CI: 7.2, 21.2), respectively. HCV incidence differed among prisons [prison A: 9.8/100 py (95%CI: 6.2, 15.3); prison B: 3.9/100 py (95%CI: 1.4, 10.3); prison C: 0/100 py (95% CI: 0, 64.2); prison D (female prison): 24.0/100 py (95%CI: 12.0, 48.0); $p < 0.001$]. HCV incidence among those with a history of injecting drugs, but not reported in the current imprisonment and among those injecting in the current imprisonment was 11.4/100 py (95%CI: 5.4, 23.9), and 21.5/100 py (95%CI: 14.1, 32.6), respectively. In a Cox proportional hazard model, adjusted for prison site, younger age (aHR per 10 years: 1.65, 95%CI: 1.35, 1.81), history of injecting, but not in the current imprisonment (vs. no injecting, aHR: 8.16, 95%CI: 1.64, 40.76), and injecting in the current imprisonment (vs. no injecting, aHR: 12.29, 95%CI: 2.82, 53.69) were associated with greater risk of HCV infection.
Conclusion: Before treatment scale-up, HCV incidence (both primary infection and reinfection) was high in SToP-C prisons and varied across prisons. HCV infection was associated with younger age and a history of injecting drugs, while those injecting in the prison were at greatest risk. These findings support the need for HCV screening and

comprehensive prevention strategies, including harm reduction and a HCV treatment as prevention evaluation.

THU-135

The French donor risk index for liver transplantation: development, internal and external validation

A. Winter[1], C. Feray[2], C. Antoine[3], O. Group[4], J.P. Daures[1], L. Paul[1].
[1]*Clinical Research University Institute, Biostatistics, Montpellier, France;* [2]*CHU Henri-Mondor, Hepatology, Créteil, France;* [3]*Agency of Biomedecine, Saint-Denis, France;* [4]*PHRC, France*
Email: audrey.winter89@gmail.com

Background and Aims: A major limitation to liver transplantation (LT) is organ shortage, leading to the use of non-optimal liver grafts. Finding the best match between a graft and its recipient is a challenge. Within the scope of a national project called OPTIMATCH, the aim was to optimize the current liver allocation system in France. A donor score, which scores the characteristics of the graft, is one of the key factors for a better matching. To determine the quality of the graft, scores such as the Donor Risk Index (DRI) or the Eurotransplant-DRI have been proposed. None of them have been validated on the French national database [*Liver Int*. 2017;37:1229–1238] possibly due to important donors' and candidates' differences between the databases.

The aim was to propose a French DRI using a derivation data from 3961 liver transplantations performed in France between 2009 and 2013, with an external validation based on a validation dataset from 1,048 French transplantations performed in 2014.

Methods: We used a Cox model, in the derivation dataset, with adjustment on recipient and transplant characteristics to create the score. We developed the French DRI score, using three different methods of selection, which we applied to construct groups at risk. Model performance was assessed through three measures of discrimination corrected by the optimism, through an internal validation. We plotted three calibration plots at months 3, 6 and 12 to evaluate the calibration of the score in the derivation dataset. An external validation [BMC 2013, 13:33] was also performed in order to evaluate calibration and discrimination of this new score in the validation dataset.

	HR	confidence interval	p value
Hazard ratios : group 0 vs 1	1.31	1.13-1.51	< 0.001
Hazard ratios : group 0 vs 2	1.96	1.60-2.42	< 0.001
Hazard ratios : group 1 vs 2	1.50	1.25-1.82	< 0.001

Group	French DRI	%	Graft survival 3 month	1 year	3 years
0	1.0 < French DRI ≤ 1.58	34.1	90.9 (89.4-92.4)	86.4 (84.5-88.2)	79.4 (77.2-81.7)
1	1.58 < French DRI ≤ 2.35	56.8	88.7 (87.4-90.0)	82.1 (80.5-83.7)	74.2 (72.3-76.1)
2	French DRI > 2.35	9.1	84.7 (81.0-88.5)	76.3 (72.0-80.8)	64.4 (59.3-70.0)

Time (in years):	0	1	2	3	4	5
Number at risk						
French DRI category 1:	1352	1160	842	589	361	176
French DRI category 2:	2250	1831	1301	880	548	252
French DRI category 3:	359	272	182	119	64	26

Figure: Survival curves using Kaplan Meier estimate for the three risk groups of the French DRI score. Graft survival at month 3, year 1 and 3, estimated using Kaplan Meier and hazard ratios through French DRI risk groups.

Results: Five donor covariates were retained: age, cause of death, intensive care unit stay, lowest MDRD clearance creatinine, liver type (split/total). The score had good properties and discriminated three groups at risk (Figure). Calibration plots showed a slight over-estimation. The performance of the model remained satisfactory even after correction by the optimism. Discrimination and calibration were preserved in the validation dataset.

Conclusion: This French DRI has good properties and is expected to be of interest for liver transplantation. The next step is to use this new DRI to explore the optimal matching between donor and recipient, taking into account the ⟪extended criteria donor⟫ graft attribution. This score will be reassessed yearly to take into account the modifications of the graft allocation system.

THU-136

Looking for the best matching between donor and recipient in liver transplantation: a sequential stratification approach

A. Winter[1], C. Feray[2], Optimatch Group[3], J.P. Daures[1], L. Paul[1]. [1]*Clinical Research University Institute, Biostatistics, Montpellier, France;* [2]*CHU Henri-Mondor, Hepatology, Créteil, France;* [3]*PHRC*
Email: audrey.winter89@gmail.com

Background and Aims: Liver transplantation (LT) is a life saving procedure for patients with end stage liver disease. The grafts are distributed according to a score calculated by recipients. The Model for End-stage Liver Disease (MELD) is the most use. The donor risk can be measured through a score: the French Donor Risk Index (DRI). Persistent shortage of donors has encouraged the use of "lower quality" grafts often accompanied with higher risk of graft loss. To whom should those grafts be given? What kind of matching would be optimal? We developed a model to explore the optimal matching. A graft, with a specific French DRI, is given to a recipient, with a known MELD. Would it be better to wait on the list for a better graft (i.e. with a lower French DRI) given the risk of clinical deterioration or death? From 8,526 patients listed between 2009 and 2014, our aim was to explore the optimal matching between donors and recipients and the use of Extended Criteria Donor (ECD) grafts according to the sequential stratification approach.

Methods: We estimated the survival benefit associated with LT in different categories of MELD and French DRI using Sequential Stratification derived from Schaubel [AJT 2008, 8:419–425.]. Briefly, this method reorganizes the observed data, and, as far as possible, reproduces a randomized controlled trial dataset. For each transplant, a stratum is created. The index patient is the patient receiving the graft, the control group is composed of all the matching waitlisted control patients. Then strata were combined and a stratified Cox regression model used. Several matching and adjustment covariates are considered in the model. The survival benefit is estimated through hazard ratios.

Results: As presented (Figure), a significant survival benefit was observed for all MELD and French DRI categories, except for low MELD and high French DRI category (i.e. ECD graft). For the latter occurrence, waiting for a graft, with a lower French DRI than the one received by the index patient, appears more appropriate.

Conclusion: In the current allocation system, high-risk grafts (or ECD graft) only provide a survival benefit to patients with medium or high MELD. In current practice, it would appear that only low MELD patients would not have a survival benefit with a high-risk transplant.

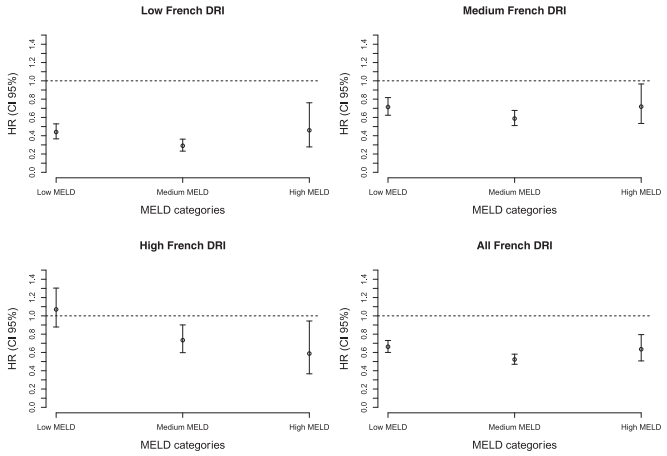


Figure: HRs through MELD and French DRI categories. With low French DRI: 1.0 < French DRI ≤ 1.58, medium French DRI: 1.58 < French DRI ≤ 2.35, high French DRI: 2.35 < French DRI, low MELD: 6 ≤ MELD ≤ 15, medium MELD: 15 < MELD ≤ 30 and high MELD: 30 < MELD.

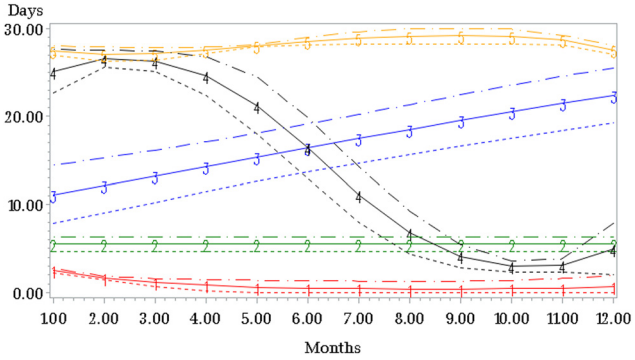
THU-137

One-year injecting frequency trajectories as predictors of hepatitis C acquisition: findings from an observational cohort study of people who inject drugs in Montréal, Canada

E. Fortier[1,2], M.-P. Sylvestre[1,3], A.A. Artenie[1,3], D. Justras-Aswad[1,4], R. Élise[5,6], J. Grebely[7], J. Bruneau[1,2]. *[1]CHUM Research Centre, Montréal, Canada; [2]Université de Montréal, Department of Family and Emergency Medicine, Montréal, Canada; [3]Université de Montréal, Department of Social and Preventive Medicine, Montréal, Canada; [4]Université de Montréal, Department of Psychiatry, Montréal, Canada; [5]Institut national de santé publique du Québec, Montréal, Canada; [6]Université de Sherbrooke, Addiction Research and Study Program, Longueuil, Canada; [7]UNSW Australia, The Kirby Institute, Sydney, Australia*
Email: Julie.bruneau@umontreal.ca

Background and Aims: Injecting frequency is a well-established risk factor for hepatitis C virus (HCV) infection, yet few studies have assessed injecting frequency variations as predictors of HCV acquisition. This investigation aimed to identify one-year injecting frequency trajectories and examine their relation with subsequent HCV acquisition among people who inject drugs (PWID).
Method: HCV-uninfected PWID enrolled in the HEPCO study (Montréal, Canada) between March 2011 and June 2016 were tested for HCV and completed an interviewer-administered questionnaire at three-month intervals. In order to examine injecting frequency, participants were questioned at each visit on the number of days during which they used injecting drugs in each of the past three months. Group-based trajectory modelling was performed to identify injecting frequency trajectories over a 12-month period and estimate probabilities of group membership (using a censored normal model). Participants were assigned a trajectory using maximum posterior probabilities. HCV incidence and confidence intervals were estimated for all trajectory groups using Poisson distribution.
Results: For trajectory modelling, 386 participants contributed 3,725 observations over 12 months (mean age 40, 82% male, 52% HCV antibody positive). Five trajectories were identified and are depicted in the figure below: sporadic injecting (group #1, 26%), infrequent injecting (group #2, 34%), increasing injecting (group #3, 15%), decreasing injecting (group #4, 11%), and frequent injecting (group #5, 13%). For subsequent HCV incidence analyses, 273 participants with at least one follow-up assessment following the 12-month period contributed 565.6 person-years of follow-up (mean age 41, 83% male, 54% HCV antibody positive). Overall, HCV incidence was 5.7 per 100 person-years (95%CI 3.9–7.9). Participants were assigned to trajectory groups as follows: sporadic injecting (n = 70, 26%), infrequent injecting (n = 103, 38%), increasing injecting (n = 41, 15%), decreasing injecting (n = 27, 10%), and frequent injecting (n = 32, 12%). HCV incidence per 100 person-years was 2.7 (95%CI 0.9–6.4) for sporadic injecting, 3.8 (95%CI 1.9–7.0) for infrequent injecting, 12.1 (95%CI 5.9–22.2) for increasing injecting, 15.6 (95%CI 6.3–32.5) for decreasing injecting, and 5.9 (95%CI 1.9–14.3) for frequent injecting.



Conclusion: Trajectories with varying injecting frequencies (increasing and decreasing injecting) were more likely to predict HCV acquisition than stable trajectories, including frequent injecting. Injecting frequency trajectories could potentially help identify most-at-risk PWID, inform harm reduction interventions, and tailor clinical care.

THU-138

Cost-effectiveness of elbasvir/grazoprevir + sofosbuvir for the treatment of chronic HCV genotype 3 infection in Argentina

E. Bissio[1], C. Nwankwo[2], S. Corman[3], H. Monsanto[4], J.L. Montes[1]. *[1]MSD Argentina, Medical Affairs, Munro, Argentina; [2]Merck & Co., Inc., United States; [3]Pharmerit International, United States; [4]Merck Sharp & Dohme (I.A.) LLC, Latin America Health Outcomes Research, Carolina, Puerto Rico*
Email: ebissio@gmail.com

Background and Aims: EBR/GZR is indicated for use in combination with sofosbuvir (SOF) for the treatment of previously untreated chronic hepatitis GT3 infections in adults in Argentina. The objective of this model was to evaluate the cost-effectiveness of treatment with EBR/GZR plus SOF compared to no treatment and to daclatasvir (DAC) plus SOF, with or without ribavirin (RBV), in treatment-naïve GT3 patients.
Method: A Markov model created to simulate the natural history of HCV and estimate the lifetime cumulative incidence of advanced liver-related diseases was used. The structure of the model is based on other published health economic models of HCV disease. The model evaluates non-cirrhotic and cirrhotic patients separately from the perspective of the healthcare system. Information concerning the treatment regimens was derived from the clinical trials and the published literature. Comparators used in this model were SOF + DAC (non-cirrhotic) and SOF + DAC + RBV (cirrhotic). Outcomes generated include total costs and QALYs associated with each treatment strategy and the incremental cost-utility ratio (ICUR) over a 30-year time horizon. A deterministic and probabilistic sensitivity analysis was conducted for key model inputs.
Results: In the base case analysis, EBR/GZR + SOF was associated with lower lifetime costs and greater QALYs compared to both SOF + DAC and no treatment in GT3 treatment-naïve, non-cirrhotic patients, and thus was economically dominant (Table). EBR/GZR + SOF was also economically dominant over both SOF + DAC + RBV and no treatment in GT3 treatment-naïve, cirrhotic patients (Table). Deterministic, one-way sensitivity analyses showed that ICURs were sensitive only to SVR for EBR/GZR + SOF in non-cirrhotic patients. The probabilistic sensitivity analysis showed that EBR/GZR + SOF was cost-effective in

more than 85% of iterations in non-cirrhotic and 99% of cirrhotic patients, regardless of willingness to pay threshold.

Table 1: Treatment-Naïve, Non-Cirrhotic

Treatment Regimen	Total Discounted Costs (ARS)	Total Discounted QALYs	Incremental Costs (ARS)	Incremental QALYs	ICUR
EBR/GZR + SOF	187,143.32	10.4713	–	–	–
DAC + SOF	193,994.71	10.4451	−6,851	0.0263	EBR/GZR + SOF dominant
No treatment	425,911.68	9.4867	−236,786	0.9846	EBR/GZR + SOF dominant
Treatment-Naïve, Cirrhotic					
EBR/GZR + SOF	282,647.87	9.8371	–	–	–
DAC + SOF	360,215.44	9.3740	−77,568	0.4631	EBR/GZR + SOF dominant
No treatment	712,929.19	7.0981	−430,281	2.7390	EBR/GZR + SOF dominant

Conclusion: EBR/GZR + SOF is cost-saving in HCV patients with GT3 infection with and without cirrhosis when compared to DAC + SOF ± RBV and no treatment.

THU-139

Molecular epidemiology of hepatitis B and D in the Pacific Islands of Kiribati

K. Jackson[1], R. Tekoua[2], A. Tonganibeia[2], M. Littlejohn[1], T. Holgate[1], S. Nicholson[3], R. Edwards[3], S. Locarnini[1]. *[1]Victorian Infectious Diseases Reference Laboratory, The Doherty Institute, Research and Molecular Development, Melbourne, Australia; [2]Ministry of Health and Medical Services, Tungaru Central Hospital, Tarawa; [3]Victorian Infectious Diseases Reference Laboratory, The Doherty Institute, Serology Department, Melbourne*
Email: kathy.jackson@mh.org.au

Background and Aims: The Pacific island of Kiribati is endemic for Hepatitis B virus (HBV) and Hepatitis D virus (HDV). Despite the introduction of HBV immunization in 1989, studies performed on serum collected in 1998 showed a HBsAg prevalence as high as 27.4% in students and 15.1% in mothers. 37.5% of these individuals also had HDV RNA detected. A 2015 review of viral hepatitis in Kiribati was carried out by the Western Pacific Regional Office of the WHO. A key recommendation of the review was the establishment of a treatment program for HBV. The aims of this study were to determine the current status of HBV and HDV infections in Kiribati with a view to enabling the provision of treatment for those that require it; and to characterize the current strains circulating in Kiribati.
Method: 219 serum samples collected in 2017 from Kiribati's Tungaru Central Hospital were sent to VIDRL for HBV and HDV serological and molecular testing. 98 matching dried blood spots (DBS) were also collected. Serum HBsAg positivity was confirmed before testing for HBeAg serology and anti-HDV. All sera were tested for liver function tests, HBV DNA load, and anti-HDV positive samples were reflexed into a HDV PCR and load assay. Sequencing and phylogenetic analysis of the HDV strains was performed. Detection of HBsAg, HBV DNA and HDV RNA was attempted from the DBS and results compared to matched sera.
Results: HBsAg was detected in 200/219 (91%) samples, however 11 of the HBsAg negative samples were positive for either anti-HBc or anti-HBe. 43/200 (21.5%) were HBeAg positive and 144 (72%) had quantifiable HBV DNA. 52/96 (54.2%) HBsAg positive subjects also had positive anti-HDV serology. 36/52 (69.2%) of these had detectable HDV RNA. HBV DNA was able to be reliably detected from DBS in subjects with a serum HBV DNA load greater than 200 IU/mL. HDV RNA was only detected from DBS in 19/35 samples where matched sera was positive. The HBV strains were confirmed as the Polynesian genotype D4 and the HDV was the unique Pacific clade of genotype 1.
Conclusion: HBV and HDV are still highly endemic in Kiribati. Provision of the laboratory results will enable the linking of care and antiviral therapy to eligible individuals. Serological and molecular testing is on-going at VIDRL however laboratory capability in Kiribati will be assessed and reinforced to facilitate the establishment of a feasible diagnostic and monitoring program on the Island.

THU-140

Screening and treatment of hepatitis C virus infection of adult general population in Spain is cost-effective

M.B. Ferret[1], R. Domínguez-Hernández[2], M. Ángel Casado[2], E. Sabater[2], R. Esteban[1]. *[1]Hospital Universitario Vall d'Hebron, Barcelona, Spain; [2]Pharmacoeconomics & Outcomes Research Iberia (PORIB), Pozuelo de Alarcón, Spain*
Email: rdominguez@porib.com

Background and Aims: Elimination of infection by hepatitis C virus (HCV) requires high diagnostic rates and universal access treatment. Approximately 40% of infected are unaware of their infection. It is necessary to set up effective screening strategies to detect this population. We analyze the efficiency (incremental cost-utility ratio, ICUR) of three HCV screening strategies: adults of general population (1938–1997 born), adults belonging to high-risk groups and the highest HCV prevalence (1938–1967 born).
Method: An analytical decision model was used to establish the susceptible population for screening and diagnosis of chronic hepatitis C (CHC) and to project the progression of disease over lifetime. Screening was performed by a single blood test to 100% of the population evaluated and HC diagnosis by the RNA-HCV presence. Epidemiological data were obtained from the literature: anti-HCV prevalence (0.56–1.54%), viremic patients (31.5%) (*Cuadrado 2017*) and percentage of total undiagnosed (35%). Diagnosed and linked to care chronic patients were assumed to be treated (82%). Response rates (>98% SVR), transition probabilities, utilities and disease management annual costs were obtained from literature. Efficiency, under the National Health System perspective, throughout the life of patients was measured as quality-adjusted life years (QALY) and total costs (screening, diagnosis, pharmacological and disease management). A discount rate of 3% was applied to costs and results.
Results: General population screening strategy identified more additional cases of chronic HCV infection compared to high-risk groups and the highest prevalence population. ICUR value was below the accepted efficiency threshold in Spain (€30,000/QALY) comparing general population vs high-risk groups or general population vs the highest prevalence population (Table).

Table 1: Analysis results

	Strategies		Strategies	
	General population	High-risk groups	General population	Highest prevalence population
Population	34,529,609		15,197,719	
Screened individuals	12,085,363	134,069	12,085,363	5,319,202
CHC patients identified	52,694	17,132	52,694	23,668
Results per patient				
Incremental QALY	2.0 (18.7 vs 16.7)		3.8 (18.7 vs 14.9)	
Incremental cost (€, 2017)	€18,157 (€35,497 vs €17,339)		€857 (€35,497 vs €34,640)	
ICUR (€/QALY)	€8,914		€226	

Conclusion: HCV screening and treatment of all adults of general population is cost-effective compared to the screening in high-risk groups or in adult population with the highest prevalence.

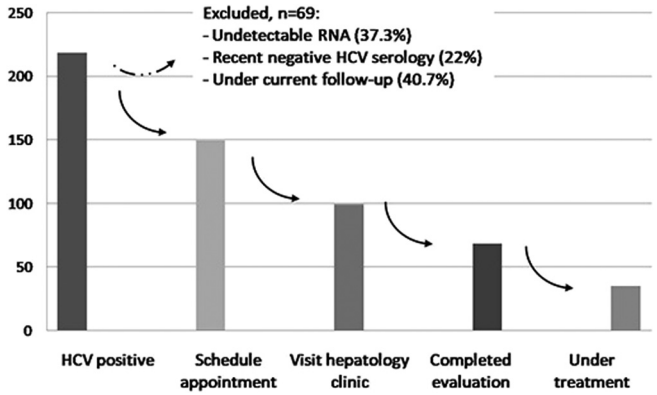
THU-141

Efficacy of a program based on on-site dried blood spot testing for hepatitis C to improve linkage to care and treatment uptake for people who injected drugs

D.M. Arraez[1], F. Gutierrez[2], E. Quintero[3], V. Casañas-Sanchez[4], A. De Vera[5], L.G.S. Gutierrez[6], E. Cuisido[7], Z.R. Marrero[6], V.P. Perez[7], A.R. Perez[6], M.J.M. Alonso[7], E.M. Carballo[8], F. Diaz-Flores[9], J.N. Casariego[4], M. Hernandez-Guerra[1]. *[1]Servicio de Aparato Digestivo. Hospital Universitario de Canarias, Hospital Universitario de Canarias, La Laguna, Spain; [2]Hospital Universitario de Canarias, Servicio de Farmacia, La Laguna, Spain; [3]Hospital Universitario de Canarias, Servicio de Aparato Digestivo, Spain; [4]Hospital Universitario de Canarias, Servicio de Farmacia, Spain; [5]Hospital Universitario de Canarias, Laboratorio Central, La Laguna, Spain; [6]Centro de Atencion a las Drogodependencias, San Miguel Adicciones Tenerife, Spain; [7]Centro de Atencion a las Drogodependencias, ANTAD Tenerife, Spain; [8]Centro de Atencion a las Drogodependencias, Proyecto Hombre Tenerife, Spain; [9]Hospital Universitario de Canarias, Laboratorio Central, Spain*
Email: mhernandezguerra@gmail.com

Background and Aims: People who injected drugs (PWID) face health and social barriers to accessing healthcare services resulting in poor engagement in hepatitis C virus (HCV) care challenging Public Health. Dried blood spot (DBS) testing has been shown to be efficacious to diagnose HCV and is recommended in this particular setting. However, facilitated referral for HCV assessment and scheduling of specialist appointments after on-site DBS on the PWID community has not been conveniently evaluated. The objective of this pilot study was to determine characteristic of PWID, rates of HCV prevalence and the engagement-in-care cascade after DBS testing. In addition, the diagnostic accuracy of DBS was evaluated.

Method: The intervention targeted subjects attending six drug clinics that serve a population of 400,000 inhabitants, from Jan-Oct/2017. Subjects were invited to participate in the program and on-site DBS testing (Whatman 903; ELISA Dia.Pro HVC AB) was performed, independently of previous HCV serum testing. A questionnaire about previous viral testing, risk factors, social and demographic variables was administered. Subjects testing positive were studied by a case manager with access to the electronic medical records and an appointment at hepatology clinic was scheduled directly to evaluate viral load, genotype and fibrotic grade.



Results: A total of 446 subjects (84.4% male, median 45.3 age [16.3–73.6]) were enrolled and 411 (92.2%) signed consent form and participated. In a sample of 336 subjects, DBS test obtained a sensibility, specificity, positive/negative predictive value, pos/neg likelihood ratio of 96.7%, 97.4%, 96.7%, 97.4%, 37.1, y 0.03, respectively. Overall 218 out of 411 (53.0%) tested positive to DBS testing. In 87% (n = 189) a HCV result was previously available in the record system (median 7.6 years [0.3–27.3]), of which 146 had a positive result. In addition, in 61.6% of subjects at least one viral load result was available. After an individualized case study, an appointment was scheduled in 149 out of 218 subjects. Figure shows the engagement-in-care cascade. At present, 23.4% of the potential candidates for treatment are under antiviral regimens.

Conclusion: On-site DBS testing in drug clinics is a feasible method for HCV diagnosis and facilitates linkage to care of previously diagnosed HCV patients without adequate care and treatment. This pilot study opens the rationale to expand our program to other drug clinics.

THU-142

Hepatitis B changes in epidemiological and molecular features of Afro-Brazilian communities, Central Brazil

A.R. Motta-Castro[1], B. Lago[2], L. Guedes[3], S. Weis[3], L. Bandeira[3], G. Rezende[3], T. Tanaka[3], G. Cesar[3], C. Niel[2], S. Gomes[2]. *[1]Federal Universitiy of Mato Grosso do Sul and Oswaldo Cruz Foundation – Virology, Campo Grande, Brazil; [2]Oswaldo Cruz Foundation – Virology, Rio de Janeiro, Brazil; [3]Federal Universitiy of Mato Grosso do Sul, FACFAN – Virology, Campo Grande, Brazil*
Email: arcm.castro@hotmail.com

Background and Aims: Hepatitis B virus (HBV) is a major cause of liver disease worldwide and persists as an important public health problem in vulnerable populations. Over ten years ago, previous studies conducted in two Afro-Brazilian communities, Furnas dos Dionisios (FD) and São Benedito (SB), detected high prevalence rates of HBV infection (42.7% and 16.0%), susceptible individuals (55.3% and 63.0%) and a low prevalence of anti-HBs alone (2.0% and 21.0%). These findings resulted in actions for health promotion such as HBV vaccine supply and referral of active hepatitis B cases for clinical care. Reassessing the epidemiological situation of HBV infection nowadays in these communities is essential to qualify the effectiveness of the measures adopted and to design future interventions.

Method: Between October 2015 and July 2016, blood samples were collected from 331 Afro-descendants (207 from FD and 124 from SB) previously interviewed regarding socioeconomic and behavioral characteristics. All serum samples were tested for HBV serological markers by enzyme-linked immunosorbent assay, screened for the presence of HBV-DNA, sequenced and phylogenetically analyzed.

Results: Considering the two communities together, the overall prevalence of HBV infection and the chronic carriers remained respectively around 30% and 5.5%. All subjects presented HBeAg-/anti-HBe+ status. After more than one decade of the first interventions, the proportion of individuals susceptible to HBV infection fell from 58.9% to 26.3% ($p < 0.0001$), while the vaccinated individuals increased from 10.7% to 43.5% ($p < 0.0001$). In FD community the proportion of vaccinated individuals increased from 2% to 45.9% ($p < 0.0001$), while of individuals susceptible to HBV infection fell from 55.3% to 18.8% ($p < 0.0001$). In SB, the proportion of vaccinated individuals increased from 21.0% to 39.5% ($p < 0.001$) and of susceptible individuals fell from 63.0% to 38.7% ($p < 0.001$), Compared to SB, FD has a lower proportion of individuals who are still susceptible to HBV (18.8% *vs* 38.7%, $p < 0.0001$), however it has a higher overall prevalence of this infection (35.3% *vs* 21.8%, $p < 0.013$). After multivariate analysis, history of family hepatitis and increasing age were factors associated with exposure to HBV infection. All samples clustered with sequences from the Asian-American clade of the HBV subgenotype A1. Genetic distances (0.8 ± 0.3%) among isolates from the communities were smaller than the intragroup divergence found among A1 Brazilian sequences.

Conclusion: These results demonstrate a significant decrease in the number of individuals susceptible to HBV infection in FD and SB communities, but also the maintenance of high levels of chronic hepatitis B infection. Epidemiological and molecular studies in

Afro-descendant communities are needed for the design of effective strategies to prevent and control HBV vulnerable populations.

THU-143

Screening for hepatitis C in Ontario, Canada: Exploring antibody positivity in the federal and provincial correctional systems

K. Beck[1], A. Majury[2,3], T. Mazzulli[4,5,6], W. Wobeser[1]. [1]*Queen's University, Department of Medicine, Kingston, Canada;* [2]*Public Health Ontario, Kingston, Canada;* [3]*Queen's University, Department of Biomedical and Molecular Sciences, Kingston, Canada;* [4]*Mount Sinai Hospital, Department of Microbiology, Toronto, Canada;* [5]*Public Health Ontario, Toronto, Canada;* [6]*University of Toronto, Toronto, Canada*
Email: k.beck@queensu.ca

Background: Hepatitis C (HCV) has been a reportable infection in Ontario, Canada, since 1991. In 2012, it was estimated to be the most burdensome infectious disease in the province. Approximately 44% of HCV-positive (HCV+) Canadians are unaware of their infection status. The potential for population-based screening is currently under discussion. Correctional settings remain a high-risk environment for HCV transmission. Thus, elimination will require attention to the unique correctional barriers that hinder quality public health programming.
Method: HCV testing data from Public Health Ontario was analysed from 1999 to 2014, inclusive, with a focus on activities undertaken in correctional facilities. A novel view of HCV screening in Ontario is presented where year of test, age, sex, HCV test result, and incarceration status are examined using the chi-square and Kruskal-Wallis tests. Odds ratios are calculated. Persons are determined HCV+ based on a positive antibody or, for a small fraction, a positive viral RNA result. Persons are defined as ever-incarcerated (EI) if at least one test result was submitted from one of 60 correctional facilities; otherwise, they obtain a community status.

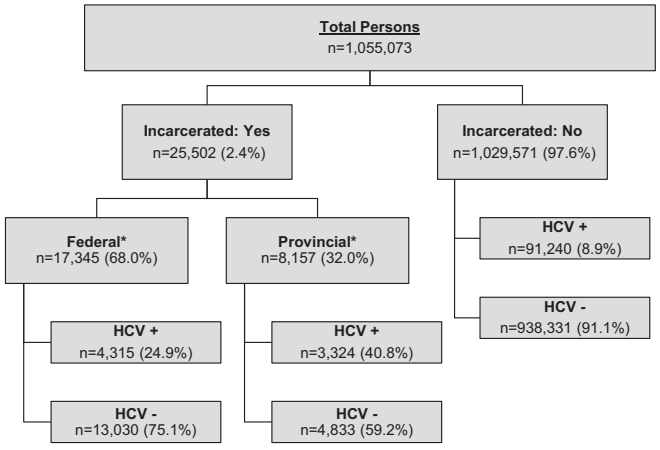


Figure 1: HCV positivity by incarceration status among persons tested in Ontario, 1999–2014.
Incarcerated HCV+: 7,639 (30.0%); Incarcerated HCV–: 17,863 (70.0%)
*Persons are defined as Federal or Provincial based on the location of their first correctional-submitted HCV test result.

Results: From 1999 to 2014, 1,729,869 tests were undertaken among 1,055,073 persons in Ontario. Of these, 44,355 (2.6%) results were submitted by correctional facilities. Of the 25,502 persons in the EI group, 30.0% are HCV+, compared to 8.9% HCV+ among those tested in the community (OR = 4.40[4.28–4.52], $p < 0.0001$). EI women are at a higher risk for HCV ($p < 0.0001$). The median age at first HCV+ test was lower among the EI group at 35(29–42) years, as opposed to 46 (37–54) years in the community ($p < 0.0001$). In addition, 68.0% (17,345) of persons had their first correctional HCV test result submitted from a federal facility. A higher proportion of persons first tested in provincial facilities are HCV+ (40.8%) than those first tested in federal facilities (24.9%) ($p < 0.0001$).
Conclusion: These results support an increased risk for HCV transmission among the incarcerated population in Ontario, with a significantly higher proportion HCV+ among those who have been incarcerated. In addition, significantly more test results are submitted from federal facilities than provincial, perhaps accounting for a lower proportion of positivity due to a larger sample size. Further research will be conducted using this data to examine trends in confirmatory testing, viral RNA testing following a positive antibody test, and the genotype distribution of positive cases.

THU-144

Can HCV be eliminated among HIV-infected MSM in Berlin? Modeling a setting with increasing incidence and high treatment rates

N. Martin[1], K. Jansen[2], M. an der Heiden[2], C. Boesecke[3], A. Boyd[4], K. Schewe[5], A. Baumgarten[6], T. Lutz[7], S. Christensen[8], A. Thielen[9], S. Mauss[10], J. Rockstroh[3], P. Ingiliz[6]. [1]*University of California, San Diego, Medicine, La Jolla, CA, United States;* [2]*Robert-Koch-Institut, Berlin, Germany;* [3]*University of Bonn, Medicine, Bonn, Germany;* [4]*Institut Pierre Louis d'Epidemiologie et de Sante Publique, INSERM, UMR_S1136, Paris, France;* [5]*ICH Hamburg, Hamburg, Germany;* [6]*Center for Infectiology, Berlin, Germany;* [7]*Infektiologikum, Frankfurt, Germany;* [8]*Centrum für Innere Medizin, Munster, Germany;* [9]*Institute for Immunology and Genetics, Kaiserslautern, Germany;* [10]*Center for HIV and Hepatogastroenterology, Dusseldorf, Germany*
Email: natasha-martin@ucsd.edu

Background and Aims: Despite widespread access to HCV direct-acting antiviral (DAA) therapy, there is a hepatitis C virus (HCV) epidemic among HIV-infected men who have sex with men (HIV+ MSM) in Germany. We use epidemic modeling to assess the impact of scaling-up DAAs on HCV incidence among HIV+ MSM in Berlin, and what DAA scale-up and behavioral risk reduction are required for HCV elimination.
Method: A dynamic HCV transmission model among HIV+ MSM was developed and calibrated to the Berlin MSM epidemic: rising HCV incidence from 0.56 per 100 person-years(/100 py) in 1996–1999 to 2.76/100 py in 2008–2012; 9.8% HCV seroprevalence in 2012, 8.2/100 py reinfection rate 2002–2014, 0.65% HCV seroprevalence among MSM at HIV diagnosis, annual number HIV-diagnosed MSM 2001–2015). Based on Berlin data, we incorporated high rates of HCV testing (twice/year) and treatment (80% initiated within 6 months of diagnosis from 2002). We assumed IFN-based SVR rates of 70%/30% for acute/chronic infection, respectively, and 95% SVR with DAAs from 2015. We modelled HCV incidence among HIV+ MSM in Berlin until 2030 under the following scenarios: (1) no change in treatment rates from 2018 on, (2) scale-up to 100% treated within 6 months of diagnosis, and 25%/year of previously diagnosed and untreated from 2018 on, (3) scale-up as in (2) and DAAs within 3 months of diagnosis. We evaluate what treatment and level of HCV transmission risk reduction among the HIV+ MSM population can achieve the WHO elimination target of 90% reduction in HCV incidence from 2016 to 2030.
Results: Modeling estimated that among the ~11,300 HIV-diagnosed MSM in Berlin in 2016, 1125 [95%CI 1025–1250] had chronic HCV and there were 342 [95%CI 307–380] incident HCV infections (3.18/100 py incidence [95%CI 2.77–3.60] in 2016). Continuing current treatment rates will marginally reduce incidence (by relative 3%) by 2030. Scaling-up to treat 100% within 6 months of diagnosis and 25%/year of those previously diagnosed and untreated could reduce incidence by 71% in 2030. This scale-up combined with DAAs within 3 months

of diagnosis could reduce prevalence by 78%. Achieving 90% incidence reduction by 2030 requires DAA scale-up plus an additional HCV transmission risk reduction among HIV-infected MSM of 35%.

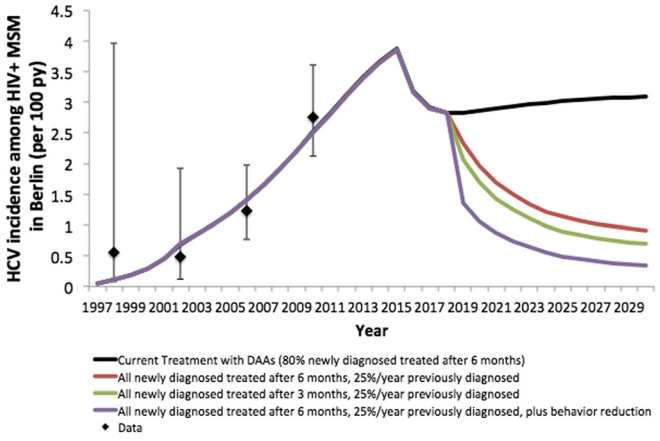

Figure: Modeled HCV incidence among HIV+ MSM in Berlin, Germany.

Conclusion: Due to escalating incidence despite high treatment rates, HCV elimination among HIV+ MSM in Berlin likely requires a combination of treatment scale-up and behavioral interventions to reduce the risk of infection.

THU-145

Hepatitis C elimination by 2030 is feasible in Brazil: a mathematical modelling approach

A. Benzaken[1], E. Catapan[1], R. Girade[1], H. Razavi[2], J. Schmelzer[2], M. Pessoa[3], M.L. Ferraz[4], P. Ferreira[5], A. Martinelli[6], M.C.M. Correa[1,7]. *[1]Ministry of Health, Brasília, Brazil, Department of Surveillance, Prevention and Control of STI, HIV/AIDS and Viral Hepatitis, Ministry of Health, Brasilia, Brazil; [2]Polaris Observatory, Center for Disease Analysis, Lafayette, CO, United States; [3]Sao Paulo University Medical School, Hospital das Clinicas, Division of Gastroenterology and Hepatology, Sao Paulo, Brazil; [4]Federal University of São Paulo, Gastroenterology Department, São Paulo, Brazil, Sao Paulo Brazil; [5]Federal University of São Paulo, Infectious Diseases Department, Sao Paulo, Brazil; [6]Ribeirão Preto School of Medicine, University of Sao Paulo, Department of Medicine, Ribeirão Preto/SP, Brazil; [7]Sao Paulo University Medical School, Tropical Institute Medicine, LIM 52, Sao Paulo, Brazil*
Email: maria.cassia@hc.fm.usp.br

Background and Aims: It is estimated that around 700,000 people are chronically infected with hepatitis C virus (HCV) in Brazil. The aim of this study is to explore potential strategies to manage the HCV disease burden in Brazil in the future.
Method: A previously described model was used to project the future disease burden up to 2030 under two different strategies: 1 – If no change is made to the HCV treatment program in Brazil; 2 – Where the World Health Organization (WHO) targets for 2030 elimination are met with diagnosis and treatment peaking before 2024. The mathematical model was calibrated using Brazilian data obtained through a literature search and prevalence data from a large national screening program conducted by the Ministry of Health of Brazil. A Delphi process was applied to gain expert consensus and validate inputs.
Results: The tables below detail the number of people that must be treated and newly diagnosed annually and the number of rapid tests that will be needed to meet the diagnosis targets for each year if screening continues to find positive cases at the current prevalence rate (0.71% anti-HCV) (Table 1a) or if high prevalence populations (defined as having five times higher prevalence than the current rate) are exclusively targeted for screening (Table 1b).

Table 1a: The number of people that need to be screened, diagnosed and treated in each different strategy

		2016	2017	2018	2019	2020	2025
Base	Treatment	36,600	25,000	19,000	12,900	12,500	12,500
	Newly Diagnosed	18,800	18,800	18,800	18,800	18,800	18,800
	Number needed to screen (gen. pop.)	3,889,000	4,040,000	4,205,000	4,305,000	4,576,000	5,818,000
Increase early efforts	Treatment	36,600	25,000	50,000	50,000	54,000	23,000
	Newly Diagnosed	18,800	24,800	40,000	50,000	52,800	25,000
	Number needed to screen (gen. pop.)	3,889,000	5,401,000	9,448,000	13,216,000	16,001,000	20,295,000

Table 1b: The number of people that need to be screened—if targeting high risk groups

	2016	2017	2018	2019	2020	2025
Base	778,000	808,000	841,000	861,000	915,000	1,164,000
Increase early efforts	778,000	1,080,000	1,890,000	2,643,000	3,200,000	3,735,000

Conclusion: Achieving the WHO Targets is feasible in Brazil with a scale-up of treatment and diagnosis over time, beginning in 2018. A major challenge will be to maintain these treatment levels into the future as the number of individuals needed to be screened increases exponentially over time. In order to continue this treatment rate in Brazil, efforts will need to be made to increase the number of diagnosed patients in order to maintain a pool of patients eligible for treatment. Screening programs targeting high prevalence populations would be an effective way to identify more cases with fewer tests.

THU-146

Micro-elemination of hepatitis C among patients with congenital bleeding disorders in Slovenia

M. Maticic[1,2], A. Lekše[2], M. Kozinc[1], M.B. Dolničar[3], D. Andoljšek[4], I. Preložnik Zupan[4], B. Faganel[5], M. Poljak[6], J. Lazarus[7,8]. *[1]Clinic for Infectious Diseases and Febrile Illnesses, University Medical Centre Ljubljana, Slovenia; [2]Faculty of Medicine, University of Ljubljana, Slovenia; [3]Slovenian Haemophilia Association; [4]Department of Haematology, University Medical Centre Ljubljana, Slovenia; [5]Department of Haematology and Oncology, University Children's Hospital, University Medical Centre Ljubljana, Slovenia; [6]Institute of Microbiology and Immunology, Faculty of Medicine, University of Ljubljana, Slovenia; [7]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Spain; [8]CHIP, Rigshospitalet, University of Copenhagen, Denmark*
Email: mojca.maticic@kclj.si

Background and Aims: In Slovenia, management of hepatitis C virus (HCV) infection in patients with congenital bleeding disorders (PCBD) infected before 1992 has been organized systematically for over two decades with all of them screened for HCV in the mid-1990s. With the advent of direct acting antivirals (DAAs), national strategy for HCV elimination in this sub-population was prepared by a multidisciplinary expert team. Aim of the study was to evaluate the strategy in the PCBD population at national level.
Method: All PCBD who tested anti-HCV positive during Slovene screening program in the 1990s were identified from national register of haemophiliacs and included in study retrospectively. Active infection was defined with HCV RNA positivity. Demographic, virological and clinical data of HCV RNA-positive patients were extracted from patients' medical documentation and analysed.

Results: Overall, 105 patients were anti-HCV positive. Seven were excluded since they died before tested for HCV RNA. 25/98 (25%) eliminated virus spontaneously leaving 73/98 (75%) HCV RNA positive. Of them, 7 died before initiating HCV treatment. 63/66 received HCV treatment, 2/66 are currently on it and treatment is being delayed in 1/66 due to severe co-morbidity. Among 63 treated patients, all were male, presenting genotypes 1, 2 and 3 in 44 (70%); 5 (8%); and 12 (19%) cases, respectively. Sustained virological response (SVR) was achieved in 62/63 (98%) as 1 died prior to treatment completion. Average age at HCV diagnosis, first treatment initiation and SVR was 26.1, 38.1 and 42.0, respectively. In 37 cases SVR was achieved after first treatment attempt (59%); SVR after second, third and fourth attempts was noted in 12 (19%), 9 (15%) and 4 (6%) patients, respectively. Treatment included interferon (IFN) (SVR 3/20; 17%), IFN/ribavirin (SVR 10/20; 50%), pegIFN/ribavirin (SVR 26/39; 67%), and regimens with DAAs including boceprevir (SVR 2/2; 100%), telaprevir (SVR 4/6; 67%), simeprevir (SVR 1/1; 100%), sofosbuvir (SVR 1/1; 100%), ombitasvir/paritaprevir/dasabuvir (SVR 6/7; 86%), ledipasvir/sofosbuvir (SVR 5/5; 100%), elbasvir/grazoprevir (SVR 2/2; 100%), and sofosbuvir/velpatasvir (SVR 2/2; 100%), all being prioritised in PCBD.

Conclusion: This study demonstrates that in Slovenia, micro-elimination of HCV in sub-population of PCBD was achieved as result of national strategy and availability of new treatments which is in line with the strategy towards viral hepatitis elimination.

THU-147

Hepatitis E in pigs in Israel: seroprevalence, molecular characterization and potential impact on humans

R. Shirazi[1], S.P. Pozzi[2], M. Wax[1], I. Bar-Or[1], E. Asulin[1], E. Mendelson[1], Z.B. Ari[3], O. Mor[1]. *[1]Sheba Medical Center, Ramat Gan, Israel; [2]Veterinary Service, Rishon LeZion, Israel; [3]Sheba Medical Center at Tel Hashomer, Center of Liver Diseases, Tel Aviv, Israel*
Email: orna.mor@sheba.health.gov.il

Background and Aims: Hepatitis E virus (HEV) is a major causative agent of acute viral hepatitis worldwide. In recent years, reports on HEV-3 infections in Europe have accumulated, and undercooked pig products were found to be a source. In Israel, while clinical cases of HEV-3 infection have not been identified, HEV-3 sequences have been identified in 14 of 169 urban sewage samples collected between 2015 and 2016 from different regions in the country. In Israel, of the 90,000 pigs farmed at any given time, 80,000 are located in 23 farms in the north (West Galilee) and 10,000 in a single farm in the south (Negev). About 200,000 pigs are slaughtered yearly, exclusively for local consumption, yet, the distribution of the virus is unknown. In this pioneer study, we aimed to assess the status of HEV in the swine population and among swine farmers in the country.

Method: Serum samples from 141 pigs, representing different age groups, from 4 breeding farms (3 of which were northern farms) were collected between 2016 and 2017. Pig faeces (n = 39) and 5 raw sewage samples (4 from the sewage pipeline serving all northern farms and 1 from the southern farm) were also collected. Blood samples from 24 swine farmers were assessed. Serum anti-HEV immunoglobulin IgG was detected using the Wantai total IgG (pigs) or IgG (humans) HEV ELISA assays (Wantai Biopharmaceutical, Inc. Beijing, China). Total nucleic acids were extracted from blood (pigs and humans), pig faeces and sewage with NucliSENS EasyMag (bioMérieu, France). HEV RNA was analysed with the RealStar HEV RT-PCR kit, version 1.0 (Altona Diagnostics GmbH, Hamburg, Germany) HEV genotype was assessed in all HEV-RNA-positive samples.

Results: The overall prevalence of antibodies to HEV in pigs was 75.1% (106/141) Seroprevalence was age-dependent, with 85% (17/20) of young pigs (1.5 months old; maternal antibodies) and 97.4% (74/76) of pigs at slaughter (>5 months) but only 34.1% (15/44) of 2–4-month-old pigs, exhibiting seropositivity (Figure 1a). HEV RNA was detected in 2.1% (3/141) of serum samples, 40% (2/5) of sewage samples (from both northern and southern pipelines) and 5.1% (2/39) of faecal samples. All HEV RNA-positive samples were from the 2–4 month-old age group. HEV RNA was not detected in samples from pigs entering the food chain (n = 60, age > 5 months). Sequencing was successful in two of the serum samples and revealed clustering with HEV-3 sequences previously identified in sewage samples (Figure 1b). All farmers (median age 42.9) were HEV IgG-positive but RNA-negative.

Conclusion: HEV-3 is endemic in local pigs. The high force of infection yields anti-HEV-positive, HEV RNA-free animals in the age group used for meat consumption. All farmers demonstrate past HEV infections. As no clinical symptoms were ever noted, continuous monitoring of HEV-3 RNA in pig farms should be considered and the potential impact on farmers and on public health should be further explored.

Email: jean-frederic.blanc@chu-bordeaux.fr

Background and Aims: Although sorafenib may be prescribed for the palliative treatment of HCC in patients with CHILD B cirrhosis, there is no evidence of its efficacy and safety in this indication. On the other hand, pravastatin has a good safety profile, even in patients with impaired liver function, and its benefit in the treatment of HCC was suggested by phase II studies. The aim of this study was to clarify the interest of sorafenib and pravastatin alone or in combination in the treatment of HCC developed on CHILD B cirrhosis.
Method: This phase II randomized, multicenter, national, open-label, four-arm parallel trial was planned to include 40 CHILD B cirrhotic patients with HCC in each arm for receiving sorafenib (800 mg/day) or pravastatin (40 mg/day) or pravastatin (40 mg / day) – sorafenib (800 mg/day) combination or best supportive care. The main objective was to evaluate the impact of treatments on time to radiological progression (TTP). Secondary objectives were overall survival (OS), progression free survival (PFS) and safety profile.
Results: 157 patients were included: 41 in group A (sorafenib), 39 in group B (pravastatin), 40 in group C (pravastatin and sorafenib) and 37 in group D (best supportive care). The characteristics of the patients are shown in the table.

	A (Sorafenib) n = 41	B (Pravastatin) n = 39	C (Prava-Sorafenib) n = 40	D (BSC) n = 37
Age (median)	67.5	63.7	66.3	66.4
CHILD A/B/C	2/38/1	0/39/0	1/39/0	0/36/1
ALBI = 3	97%	100%	100%	97%
BCLC A/B/C/D	0/4/37/0	0/6/33/0	0/5/35/0	0/4/31/2
OMS 0/1/2	5/30/6	10/20/9	6/23/11	6/22/9
Macrovascular invasion	41%	56%	60%	62%
Extra-hepatic spread	14.6%	18%	22.5%	10.8%

The safety profiles of sorafenib and pravastatin were similar to those observed in CHILD A patients. The occurrence of grade 3/4 toxicities was similar in each group (82%).
The median progression-free survival was 3.2, 2.2, 3.4 and 2.4 months in groups A, B, C and D respectively. The time to treatment failure (date of treatment discontinuation) was 3.0, 2.2 and 1,1 months in arm A, B and C and the median overall survival (OS) was 3.8, 3.1, 4.0 and 3.5 in groups A, B, C and D. In per-protocol analysis, OS was 6.5, 4.3, 5.4 and 3.5 months and PFS was 5.9, 3.6, 5.2 and 2.5 months in groups A, B, C and D.

Conclusion: In this population of patients with HCC and severe impairment of liver function, the prognosis is poor and not modified by pravastatin. The benefit of sorafenib in this population seems also limited.

THU-152

Systematic review and metanalysis establish dermatologic adverse events as a positive predictor of survival in hepatocellular carcinoma patients treated with sorafenib

A. Diaz-Gonzalez[1], M. Sanduzzi-Zamparelli[1], V. Sapena[2], F. Torres[2], N. Llarch[1], G. Iserte[1], A. Forner[1], L.G. Da Fonseca[1], J. Ríos[3], J. Bruix[4], M. Reig[1]. *[1]Hospital Clínic i Provincial de Barcelona, Barcelona Clínic Liver Cancer (BCLC) Group. Liver Unit., Barcelona, Spain; [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Medical Statistics Core Facility, Barcelona, Spain; [3]Universitat Autònoma, Biostatistics Unit, Faculty of Medicine, Spain; [4]BCLC Group, Liver Unit, Hospital Clinic, University of Barcelona, IDIBAPS, CIBEREHD, Barcelona, Spain*
Email: mreig1@clinic.ub.es

Background and Aims: Sorafenib is the established 1st-line systemic therapy for hepatocellular carcinoma (HCC) but, in an era of new options for 1st and 2nd line, it is key to fully understand the treatment related events that may drive a better outcome and thus, should prime a careful decision to interrupt therapy and move to other options because of perceived impairment of quality of life and/or irrelevant disease progression. In this regard, dermatologic adverse events (DAEs) have been suggested to be a marker of better outcome in sorafenib treated patients. The aim of this systematic review and metanalysis is to explore the impact of DAEs in HCC patients treated with sorafenib in order to unequivocally define if DAEs, as an early evolutionary event, are associated to an improved outcome.
Method: The study was done according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines. Two authors retrieved all data and a 3rd one solved discrepancies. DAEs were defined as the presence of any kind of skin symptoms that are congruent with sorafenib side effects and maintain a reasonable temporary relationship.
Results: 313 studies were identified until July/2017. 10 studies were full-text manuscripts and met the inclusion criteria. They included 926 patients (82.5% Child-Pugh A, 84% BCLC-C, and 30% ECOG-0), 2 were prospective, 7 retrospective and 1 not disclosed. Only 2 studies were focused on early DAEs. 45% of the patients developed hand foot skin reaction and 24% other dermatologic adverse events. The presence of DAE was associated with a higher probability of overall survival when compared with those patients without DAEs. The pooled Hazard Ratio was 0.49 (CI-95%; 0.41–0.58) and there was no heterogeneity for the analysis ($p = 0.307$; I^2=14.8%).
Conclusion: This metanalysis demonstrates the positive association between the development of DAEs and better prognosis in patients with HCC treated with sorafenib. This association indicates the need to investigate the mechanism underlying the pathophysiology of DAEs and how this may help to define the mechanism for a less malignant tumor progression. At the same time, development of DAEs should not be seen as a disadvantage as compared with drugs with lower rate of DAEs, but rather become part of the decision process to sense the risk/benefit balance of HCC therapy across different options.

THU-153

Comparison of the prognosis between non-viral HCC and viral HCC

N. Izumi, M. Kurosaki, K. Takaura, K. Tsuchiya, J. Itakura, H. Nakanishi. *Musasino Red Cross Hospital, Musasinoshi, Tokyo, Japan*
Email: tuf029@gmail.com

Background and Aims: The most prevalent etiology of hepatocellular carcinoma (HCC) in Japan is hepatitis C, followed by of non-viral, and hepatitis B. Recently, due to decrease in HCC caused by hepatitis

C, the prevalence of non-viral HCC patients is increasing. This study aimed to investigate the prognostic differences of HCC with different etiologies stratified by the stage of HCC.

Method: We enrolled 759 consecutive HCC patients treated by radio-frequency ablation (RFA) at Musashino Red Cross Hospital from January 1998 to December 2016. The eligible criteria for RFA treatment was liver function of Child-Pugh class A, maximum of 3 HCC nodules, and maximum diameter of 5 cm if single nodule HCC, and 3 cm if multiple nodules. The etiology was viral (hepatitis C or B) in 573 patients, and non-viral in186 patients. The overall survival and recurrence free survival was compared between viral vs. non-viral HCC after stratification by tumor factors.

Results: The overall survival was significantly better in non-viral HCC compared to viral HCC. The 5- and 10-year survival was 71.7% and 55.7% in non-viral HCC and 55.0% and 14.7% in viral HCC ($p < 0.01$). Furthermore, recurrence free survival was significantly higher in non-viral HCC compared to viral HCC. The 1-, 3- and 5-year recurrence free survival was 66.3%, 30.2% and 16.3% in non-viral HCC and 54.9%, 22.6% and 8.4% in viral HCC ($p = 0.01$). In single nodule HCC, 5- and 10-year survival was 68.4% and 54.4% in non-viral and 42.6% and 11.5% in viral ($p < 0.01$). The 1-, 3- and 5-year recurrence free survival was 68.1%, 36.1% and 20.2% in non-viral and 62.4%, 25.2% and 9.7% in viral ($p = 0.01$). However, there was no such difference in prognosis or recurrence in patients with multiple HCC nodules. By multivariate analysis, factors related with survival were non-viral etiology (hazard ratio (HR) 1.89, 95% confidence interval (CI) 1.33–2.68), ALBI grade >2 (HR 1.54, 95%CI 1.18–2.01), serum des-gamma-carboxy prothrombin (DCP) >100 mAU/ml (HR1.62, 95% CI 1.21–2.17), and serum alpha-fetoprotein >100 ng/ml (HR 1.59, 95% CI 1.20–2.10) whereas factors related to recurrence were non-viral etiology (HR1.32, 95% CI 1.04–1.68), male gender (HR 1.26, 95% CI 1.02–1.55), multiple HCC nodules (HR 1.52, 95% CI 1.22–1.89), ALBI grade >2 (HR 1.31, 95% CI 1.06–1.62), and serum DCP >100 mAU/ml (HR1.62, 95% CI 1.21–2.17).

Conclusion: In patients with early stage HCC of single nodule and treated by RFA, prognosis was better and recurrence was lower in non-viral etiology compared to viral HCC. These results suggest the need of strategy for early detection of HCC in patients with non-viral liver disease.

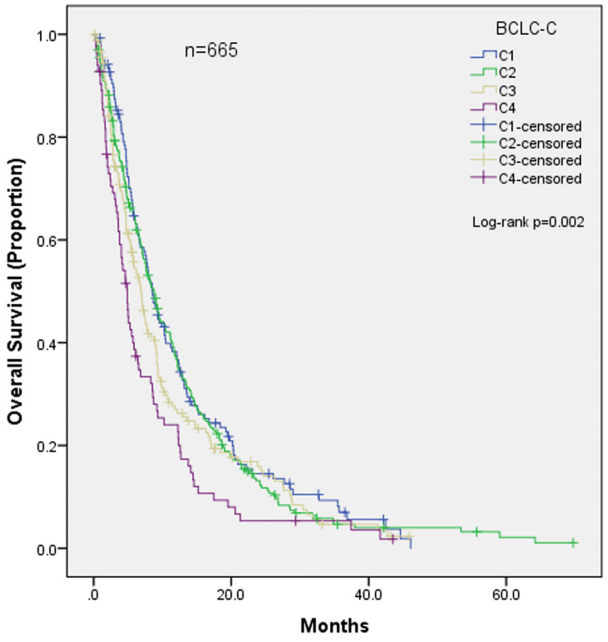
Sharma[1]. *[1]Imperial College London, Surgery & Cancer, London, United Kingdom; [2]Philadelphia Veterans Affairs Medical Center & University of Pennsylvania; [3]Humanitas Cancer Center, Medical Oncology & Haematology Unit, Italy; [4]University of Freiburg, Department of Medicine II, Germany; [5]Università degli Studi del Piemonte Orientale "A. Avogadro", Department of Translational Medicine, Italy; [6]Kindai University School of Medicine, Department of Gastroenterology and Hepatology, Japan; [7]National Cancer Center Hospital, Centre for Liver Cancer, Korea, Rep. of South; [8]Yale University School of Medicine, Department of Medicine; [9]University of Liverpool, Molecular and Cancer Medicine, United Kingdom*

Email: david.pinato09@imperial.ac.uk

Background and Aims: The Barcelona Clinic Liver Cancer (BCLC) algorithm states that patients with extra-hepatic spread (EHS), macro-vascular invasion (MVI) and ECOG performance status (PS) 1–2 are advanced stage HCC (BCLC-C). Combined use of these clinical features has been suggested, but not validated, to sub-classify BCLC-C HCC and improve treatment allocation (Giannini EG, Hepatology 2017), a clinically desirable aim now that treatment options are expanding to include immunotherapy and second-line targeted agents.

Method: We evaluated the prognostic accuracy of the BCLC-C stage sub-classification according to the following variables: C1 (PS1-2, EHS-, MVI-) C2 (any PS, EHS+, MVI-), C3 (any PS, EHS-, MVI+), C4 (any PS, EHS+, MVI+). The model was tested in a dataset of 665 patients treated with sorafenib across 6 centres in Europe and Asia (2008–2016) and validated in a cohort of 2241 patients with similar features treated at Veterans Health Administration hospitals (2006–2015) and a separate dataset of 1394 patients receiving sorafenib for advanced HCC as part of international clinical trials.

Results: In the training set, patients were 82% males, 70% HCV-positive, with a median age of 65 years. Median sorafenib duration was 2.3 months and disease progression was the most common cause of discontinuation, 72%. Median tumour size was 5.5 cm. The proportion of isolated EHS and MVI was 40% and 27% respectively, with 12% of patients being EHS+/MVI+. Median overall survival (OS) was 8.6 months in C1 and 8.8 months in C2 and significantly worse in C3 6.9 months and C4 4.9 months (Log-rank $p = 0.002$). Survival estimates were confirmed in the validation dataset ($n = 2241$) where deteriorating OS figures were observed across sub-classes: C1 ($n = 249$) 7.0 months, C2 ($n = 995$) 5.5 months, C3 ($n = 728$) 5.9 months, C4 ($n = 260$) 3.3 months (Log-rank $p = 0.001$). Despite longer survival in each subclass, the BCLC-C sub-classification retained stratifying potential in clinical trial patients: C1 ($n = 127$) 18.1 months, C2 ($n = 742$) 22.2 months, C3 ($n = 72$) 10.8 months, and C4 ($n = 414$) 10.6 months (Log-rank $p < 0.001$).



Conclusion: Advanced HCC is highly heterogeneous in routine practice and in clinical research. Combination of staging variables may facilitate risk-stratified patient management, aiding clinicians in treatment sequencing optimisation on the basis of poor prognostic features.

THU-155

A novel post-surgical prognostic system for colorectal liver metastases treated by preoperative systemic treatment, using tumoral and non tumoral pathological changes, Ras mutation and immunoscore

P. Baldin[1], M. Van Den Eynde[2], B. Mlecnik[3], G. Bindea[3], G. Beniuga[4], J. Carrasco[5], C. Hubert[6], B. Navez[6], A. Jouret-Mourin[1], J. Galon[3], M. Komuta[1]. *[1]Cliniques Universitaires Saint-Luc/Université Catholoque de Louvain (UCL), Department of Pathology, Woluwe Saint Lambert, Belgium; [2]Cliniques Universitaires Saint-Luc/Université Catholoque de Louvain (UCL), Department of Medical Oncology, Woluwe Saint Lambert,*

Belgium; [3]INSERM, UMRS1138, Laboratory of Integrative Cancer Immunology, Paris, France; [4]Institut of pathology and genetics (IPG), Department of Pathology, Charleroi, Belgium; [5]Grand Hôpital de Charleroi (GHdC), Department of Medical Oncology, Charleroi, Belgium; [6]Cliniques Universitaires Saint-Luc/Université Catholoque de Louvain (UCL), Hepatobiliary Surgery Unit, Department of Abdominal Surgery and Transplantation, Woluwe Saint Lambert, Belgium
Email: pamela.baldin@uclouvain.be

Background and Aims: Surgical control of colorectal liver metastasis (CRLM) combined with systemic treatment in patients aims to maximize survival. However, around 40% of patients develop recurrence in one-year post operation. Moreover, chemotherapy-related liver injury (CALI), such as sinusoidal obstruction syndrome (SOS), nodular regenerative hyperplasia (NRH), and steatohepatitis, have been reported to worsen operative mortality and morbidity rates. We aim to develop a prognostic scoring system to stratify patient prognosis post-hepatetomy by identifying the significant prognostic clinico-pathological-molecular factors in patients with resected CRLM.
Method: We investigated 143 patients with 403 CRLM operated from 2005–2013, including patients untreated (19 patients with 29 lesions) and treated with chemotherapy alone (33 patients with 91 lesions), chemotherapy with anti-VEGFR (47 patients with 157 lesions), and chemotherapy with anti-EGFR (44 patients with 126 lesions). All specimens were reviewed to assess tumor regression grading (TRG), histological growth pattern (HGP), and CALI. Genomic DNA from the lesions was extracted and purified from Formalin-fixed, paraffin-embedded slides. Immunoscore was assessed by the immune densities (cells/mm2) of CD3- and CD8 positive lymphocytes in the center and the invasive margin of the tumor by using morphometry. Comparisons were made using the Wilcoxon-Mann-Whitney test. Cumulative disease-free (DFS) and overall survival (OS) were analyzed using the Kaplan-Meier estimator and compared by log-rank tests. Cox proportional hazards models were used for uni- and multi-variate analysis. P value of less than 0.05 was considered statistically significant.
Results: Multivariate analysis showed that a high TRG (TRG 3–5), the worst HGP (replace growth pattern, mixed pattern), ≥ 4 lesions, positive surgical margin, CALI (steatohepatitis, NRH), RAS mutation and the worst Immunoscore were the significant prognostic factors. The prognostic scoring system combining these parameters significantly stratified post-operatively treated patients' prognosis into three groups (high risk group: 81.3% (63.1–90.3% 95CI) one-year recurrence rate, intermediate risk group: 41.3% (26.8–52.9% 95CI) one-year recurrence rate, low risk group: 13.8% (0.3–25.5% 95CI) one-year recurrence rate).
Conclusion: Our novel prognostic scoring system of CRLM assessed by tumor and non-tumor pathological changes, Ras mutation and Immunoscore, allowed us to identify the patient population with high risk of recurrence post-hepatectomy.

THU-156
Towards personalised approach in systemic treatment for hepatocellular carcinoma. The value of AGT M235T gene polymorphism

Email: mreig1@clinic.ub.es

Background and Aims: Up to now there is no biomarker that may stratify patients with hepatocellular carcinoma (HCC) treated with sorafenib according to their expected outcome. In 2013 we showed that the development of Dermatology Adverse Events (DAEs) early after treatment initiation is associated to a delayed tumor progression and improved survival. Hence, identification of predictive biomarkers for early DAEs (eDAE) would be instrumental to define a population with a major treatment impact on survival. **Aim:** To assess the value of genetic profile and baseline characteristics of sorafenib treated patients to predict the development of eDAEs, and to evaluate the potential of the identified parameters to become surrogate markers of long term survival.
Method: We prospectively included all HCC patients who started sorafenib and accepted to be included in a pharmacokinetic/genetic study at the BCLC. All patients started with 800 mg/day. Clinical and laboratory assessments were done monthly, besides of a radiologic tumour evaluation at week 4, and every 8 weeks afterwards. Genetic polymorphisms tested included: UGT1A8, CYP3A5, CYP3A4, UGT1A9, MRP2, IL23R, IL17, FOXP3, VEGF, AGT, PLA2G12A, IL-8,AT1R,ANGPT2, TNF-a, GNB3, IL-6 gens. Treatment was maintained until symptomatic progression, second-line trial initiation, significant toxicity or patient decision.
Results: We included 82 patients with a median follow-up of 18.6 months. Sixty-eight patients (83%) died, thirty-two (39%) presented eDAES, thirteen (15.9%) suffered gastrointestinal events and 10 showed (12%) performance status deterioration. Other events were registered in < 10 patients. An Angiotensinogen (AGT) gene polymorphism, AGT M235T, was the sole parameter associated to eDAE development: with AA [prevalence: 32%] as the genotype used as ref. category, the HR (95%CI) were for AG [41%]: 0.34 (0.15–0.8) and for GG [27%]: 0.97 (0.41–2.31); p = 0.0335.
Conclusion: These data show that evaluation of the AGT M235T gene polymorphism could become instrumental to evolve to precision and personalised treatment decision in patients with HCC at a time when several systemic therapies with survival benefit are expected to be available.

THU-157
A statistical model for survival risk prediction in patients with advanced hepatocellular carcinoma undergoing sorafenib treatment

S. Berhane[1], R. Fox[2], S.L. Chan[3], T. Yau[4], P. Johnson[1]. *[1]University of Liverpool, Department of Molecular and Clinical Cancer Medicine, Liverpool, United Kingdom; [2]University of Birmingham, Cancer Research UK Clinical Trials Unit, Birmingham, United Kingdom; [3]The Chinese University of Hong Kong, Department of Clinical Oncology, Hong Kong, Hong Kong; [4]The University of Hong Kong, Department of Surgery, Hong Kong, Hong Kong*
Email: sarahberhane1@gmail.com

Background and Aims: Sorafenib is the current standard of care for patients with advanced hepatocellular carcinoma (aHCC). The aim of this study is to identify baseline clinical features that influence survival in patients undergoing sorafenib treatment and thereby build a statistical model that predicts risk.
Method: We had access to 1130 sorafenib patients from control arms of two phase III randomised clinical trials – RCT1 and RCT2 – as well as 364 non-trial sorafenib patients from Hong Kong, China. Model was built using RCT1 and validated on RCT2 and Hong Kong cohorts. Univariable and multivariable analyses were undertaken using flexible parametric survival models. Risk was stratified into four groups by identifying cut-points in the linear predictor of the training

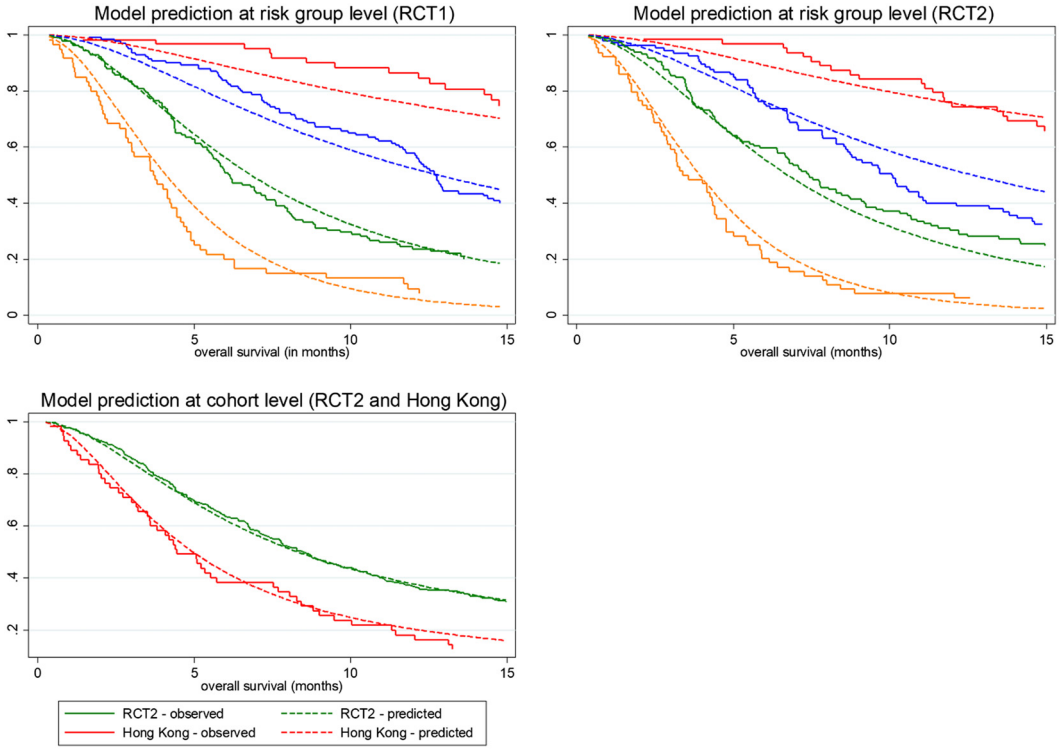

Figure: (abstract: THU-157)

set, and subsequent model predictions were grouped according to this classification. Model performance was assessed through Harrell's C statistic and comparison of observed and model-predicted survival curves and median survival times.

Results: Baseline factors that influenced survival in the multivariable model were vascular invasion, ECOG, log(AFP), albumin, log(AST), aetiology, extra-hepatic spread and tumour number. In both RCT1 and the validation sets, the model-predicted survival was very similar to the observed survival (figure). The Harrell's C indices for RCT1, RCT2 and Hong Kong cohorts were 0.73, 0.70 and 0.69 respectively indicating good prediction. The corresponding predicted and observed median overall survival for the same cohorts were 8.8, 8.3, 4.8 and 9.2, 8.5, 4.4 months respectively.

Conclusion: Model predicts survival similar to the observed. However, the model will require further validation on independent datasets.

THU-158

The ALBI and p-ALBI grades predict survival in patients with hepatocellular carcinoma undergoing transarterial chemoembolization (TACE)

C. Campani[1], G. Dragoni[1], S. Aburas[1], A. Vitale[2], E.G. Giannini[3], F. Trevisani[4], F. Marra[1] and For Ita.LI.Ca. Group[4]. [1]*Hepatology, Medicina Sperimentale e Clinica, Florence, Italy;* [2]*Surgery, Department of Surgery, Oncology and Gastroenterology, Padova, Italy;* [3]*Gastroenterology, DIMI, Genova, Italy;* [4]*Semeiotica Medica, Dipartimento di Scienze Mediche e Chirurgiche, Bologna, Italy*
Email: fabio.marra@unifi.it

Background and Aims: The prognosis of hepatocellular carcinoma is not solely influenced by the extent of the anatomic spread of the cancer but also by the severity of liver dysfunction. This makes the assessment of prognosis in individual patients difficult. Child-Pugh (CPS) and model for end-stage liver disease (MELD) scores are widely used but have considerable limitations. Recently, the prognostic value of albumin-bilirubin (ALBI) grade has been evaluated in patients undergoing resection of HCC or treatment with different modalities. Nonetheless, its predictive role specifically in patients undergoing TACE has not been evaluated. Another score based on the ALBI grade has recently been proposed, the pALBI grade that includes blood platelet count as a surrogate marker of portal hypertension.

Method: We retrospectively evaluated the prognostic significance of ALBI and pALBI in patients undergoing TACE recorded in the Ita.Li.Ca. database, and compared it with other prognostic systems, including MELD, CPS, hepatoma arterial-embolization prognostic (HAP) and mHAPII.

Results: 2283 TACE performed in 1012 consecutive patients between January 2008 and December 2016 were evaluated. Patients had a median MELD of 9 and belonged to all BCLC stages. 1168 TACE were performed in BCLC-A, 696 in BCLC-B and 419 in the BCLC-C stage. Median overall survival in the whole population was 33.9 months. Considering all TACE procedures, irrespective of the BCLC stage, the ALBI and pALBI grades were significant predictors of overall survival (P 0.001 and p < 0,0001 respectively), similar to the HAP and the mHAP scores (P < 0.0001). When patients in different BCLC stages were considered, ALBI was a significant predictor of OS only in BCLC-C (p < 0.001) patients treated with TACE, while pALBI was a significant predictor of OS in BCLC-B (p 0.001) and BCLC-C (p < 0.001) similarly to HAP and mHAPII.

Similar data were obtained when only the first TACE procedure was considered in each patient (total of 1012 patients, 520 BCLC-A, 299 BCLC-B and 193 BCLC-C). Considering all BCLC stages, ALBI was a significant predictor of overall survival (p 0,001) similar to the pALBI, HAP and mHAPII scores (p 0,003). When different BCLC stages were considered, ALBI, pALBI and HAP were significant predictors of OS in BCLC-C (p 0.008, p 0.003 and 0.008 respectively), whereas mHAPII was not significant. pALBI was also a significant predictor of OS in BCLC-B (p 0,005).

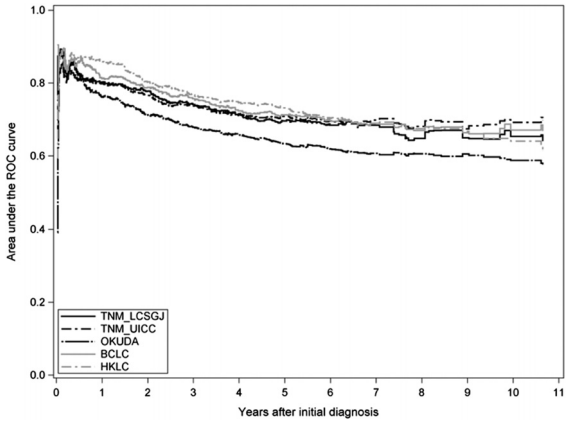
Conclusion: ALBI and pALBI offer additional simple and objective methods of assessing liver function in HCC and may be useful for selecting patients more likely to survive after TACE, especially ALBI in the BCLC –C stage and pALBI in BCLC-B and BCLC-C stages.

THU-159

Verification of staging systems and treatment algorithms for hepatocellular carcinoma: perspectives from a Japanese field practice

S. Ogasawara[1], Y. Ooka[1], M. Inoue[1], T. Chiba[1], E. Suzuki[1], M. Yokoyama[1], T. Maeda[1], T. Wakamatsu[1], K. Kobayashi[1], S. Kiyono[1], M. Nakamura[1], T. Saito[1], S. Nakamoto[1], S. Yasui[1], A. Tawada[1], M. Arai[1], H. Maruyama[1], S. Kuboki[2], M. Miyazaki[2], M. Ohtsuka[2], N. Kato[1]. *[1]Chiba University, Graduate School of Medicine, Department of Gastroenterology, Chiba; [2]Chiba University, Graduate School of Medicine, Department of General Surgery, Chiba, Japan*
Email: sadahisa@me.com

Background and Aims: In 1984, Okuda presented the first staging system for patients with hepatocellular carcinoma (HCC) which attempted to incorporate both tumor burden and liver function. The BCLC staging classification for HCC was first published in 1999 and included recommendations for first-line treatment for each stage. In 2017, the APASL and the Japanese guideline (JSH), which are not based on staging systems, were updated. The aim of this study was to verify staging systems and treatment algorithms used for HCC in a cohort of Japanese patients.
Method: Time-dependent ROC analysis was performed to determine survival outcomes in patients according to various staging systems (Okuda, BCLC, LCSGJ, AJCC/UICC, and HKLC). We also compared the prognosis of patients with HCC who received recommended treatment according to the treatment algorithms (BCLC, HKLC, APASL, and JSH) with that of patients who received non-recommended treatment.
Results: A total of 1161 new cases of HCC diagnosed between 2003 and 2015 were identified from the database of our Hospital. Among the staging systems, Okuda was found to have significantly poor predictive value with respect to survival outcomes compared with other staging systems (Figure). In terms of treatment algorithm, percentages of patients who received the recommended treatment based on BCLC, HKLC, APASL, and JSH were 72.8%, 69.1%, 86.1%, and 85.6%, respectively. Overall survival (OS) of patients who received the recommended treatment according to all four algorithms was significantly better than that of patients who received non-recommended treatment. According to BCLC, the percentages of patients with BCLC 0/A, B, and C disease who received the recommended treatment were 88.3%, 75.4%, and 11.1%, respectively. OS of patients with BCLC C who received recommended treatment was significantly poor compared with that of patients who received non-recommended treatment. Among patients with BCLC C disease, 59.8% and 60.8% patients received the recommended treatment based on APASL and JSH, respectively.



Conclusion: The prognostic relevance of Okuda was found to be poor because it created the era in which OS of majority of the patients with HCC was <1 year. Although both tumor status and liver function of patients with advanced HCC show considerable heterogeneity, diverse treatments were selected in the Japanese field practice.

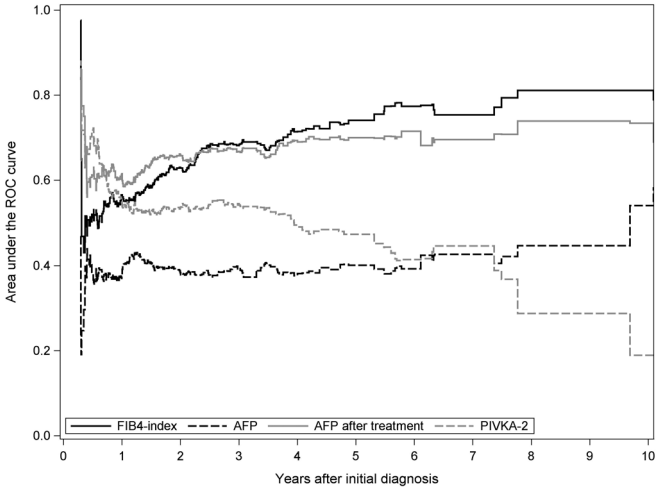
Temporal changes in recurrent incidences after curative therapies in early stage hepatocellular carcinoma

A. Kurosugi[1], S. Ogasawara[1], Y. Ooka[1], M. Inoue[1], T. Chiba[1], E. Suzuki[1], M. Yokoyama[1], T. Maeda[1], T. Wakamatsu[1], K. Kobayashi[1], S. Kiyono[1], M. Nakamura[1], T. Saito[1], S. Nakamoto[1], S. Yasui[1], A. Tawada[1], M. Arai[1], T. Kanda[1], H. Maruyama[1], S. Kuboki[2], M. Miyazaki[2], O. Yokosuka[1], M. Ohtsuka[2], N. Kato[1]. *[1]Chiba University, Graduate School of Medicine, Department of Gastroenterology, Chiba, Japan; [2]Chiba University, Graduate School of Medicine, Department of General Surgery, Chiba, Japan*
Email: sadahisa@me.com

Background and Aims: Several studies have previously reported the risk factors associated with early and late phase after curative therapies (resection/local ablation) in patients with hepatocellular carcinoma (HCC). However, a majority of the results were based on single modalities and included patients who extended from early stage HCC. During the past decade, antiviral therapies against both hepatitis B virus (HBV) and hepatitis C virus (HCV) have dramatically improved, resulting in an increase in non-viral HCC. The background of patients with HCC has varied from those reported in previous studies. The present study aimed to identify the risk factors associated with early and late recurrences in patients with HCC after receiving curative therapies and confirm temporal changes in recurrent incidences based on time-dependent receiver operating characteristic (ROC) analysis.
Method: We retrospectively retrieved the database of patients with HCC at our institution between January 2003 and December 2015. We performed multivariate analysis using Cox proportional hazard model to detect independent incidence factors of recurrence before and after 2 yeas from curative therapy. And we also analyzed the influence of each factors to recurrence in every elapsed time from curative therapy by using time-dependent ROC analysis.



Results: Of the 1161 newly diagnosed patients with HCC, 671 patients received curative therapies in early-stage HCC (resection; 225 patients, local ablation; 446 patients). Based on multivariate analysis using Cox proportional hazard model, the tumor size and number, alfa fetoprotein (AFP) before treatment, des-gamma-carboxy prothrombin (DCP), and treatment (resection vs. local ablation) were independent incidence factors of recurrence before 2 years from curative therapy. Similarly, AFP after treatment and the fibrosis-4 (FIB-4) index were independent incidence factors after 2 years. The figure shows the time-dependent ROC analysis of

recurrence of AFP before and after treatment, DCP, and the FIB-4 index.
Conclusion: Using time-dependent ROC analysis, we clarified that there were some differenced in the influential risk factors of recurrence between early and late period after curative therapy. In the early phase, tumor-related factors were mostly associated with recurrence in patients with early-stage HCC receiving curative therapies. In contrast, the FIB-4 index, which correlated with fibrosis, was related to recurrence and increased risk in a time-dependent manner. FIB-4 index appears as the most useful meter of surveillance during late phase after curative therapies.

THU-161

The predictive role of procalcitonin for guiding use of antibiotics in HCC patients with post TACE/RFA fever

S.B. Cho[1], S.-J. Kang[2], C.H. Jun[3], S. Choi[1]. *[1]Chonnam National University Hospital, Division of Hepatology, Internal Medicine, Gwangju; [2]Chonnam National University Hospital, Divison of infection, Internal Medicine, Gwangju, Rep. of South Korea; [3]Chonnam National University Hospital and Medical School, Department of Gastroenterology, Gwangju, Rep. of South Korea*
Email: portalvein@naver.com

Background and Aims: The overlap of clinical findings between inflammation and bacterial infection leading to antibiotics overuse in patients with fever after intervention for treating hepatocellular carcinoma. A procalcitonin is a serum biomarker expressed by epithelial cells in response to bacterial infection, but the roles of procalcitonin have not been elucidated in HCC patients for predicting bacterial infection.
Method: A prospective study was performed for a 97 HCC patients with fever (≥38°C) after transarterial chemoembolization (TACE) or radiofrequency ablation (RFA) among the 563 patents between Jan 2016 and Dec 2016. A inflammatory serum markers including C-reactive protein and procalcitonin, blood culture were measured on the fever day and 3 day and 7 day later after TACE or RFA in a enrolled 97 patients.
Results: Bacterial infection and chemical inflammation accounted for 9 (9.3%) and 88 (90.7%) respectively. Of total 9 cases of proven bacterial infection, hepatobiliary infection was most common (3 cases) followed by urinary tract infection, pneumonia (2 cases each), RFA site cutaneous abscess and bacteremia with unknown primary focus (1 case each). Serum PCT levels measured on the day of fever were significantly higher in patients with bacterial infection (median 0.2 ng/dl, interquartile range (IQR) 0.2–1.4) than those with chemical inflammation (median 0.1 ng/dl, IQR 0.1–0.3) (p = 0.035). The AUC of PCT on day of fever was 0.715 (95% CI 0.538–0.892), which was higher than that of CRP [AUC, (95% CI): 0.598 (0.368–0.828)], leukocytes count [AUC, (95% CI): 0.502 (0.307–0.697)] and neutrophil percentage [AUC, (95% CI): 0.647 (0.445–0.849)]. When the ROC curves were constructed based on peak value of inflammatory markers, AUC of peak PCT was 0.840 (95% CI 0.712–0.968), while other inflammatory markers showed relatively lower accuracy to predict the bacterial infection [CRP: AUC, (95% CI): 0.699 (0.563–0.834), leukocytes count: 0.576 (0.357–0.796), neutrophil percentage: 0.713 (0.565–0.862)] compared to PCT.
Conclusion: A procalcitonin is useful serum marker for differentiating bacterial infection and chemical inflammation in a HCC patients with post TACE/RFA fever. The serum level of procalcitonin is helpful for preventing overuse antibiotics.

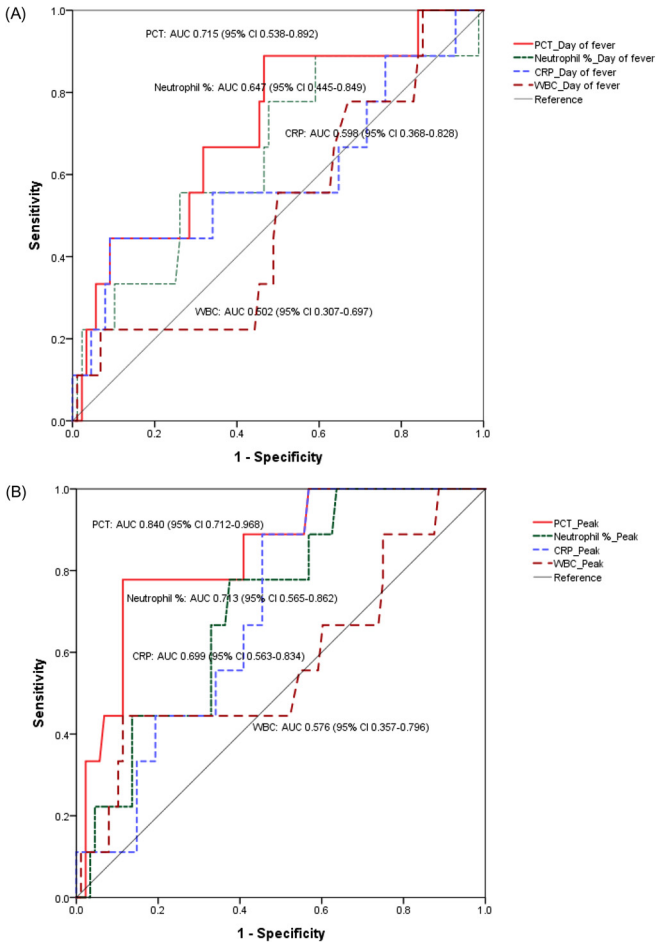


Figure 1: Receiver operating characteristics (ROC) curves and area under the curve (AUC) determined to predict the bacterial infection in patients with fever after TACE and/or RFA based on initial (day of fever) (A) and peak (within 7days of fever) (B) level of PCT, CRP, leukocytes and neutrophil percentage.

Combined therapy of transarterial chemoembolizatoin and stereotactic body radiotherapy versus transaterial chemoembolizatoin for < 5m hepatocellular carcinoma: A propensity score matching analysis

B.G. Jun[1], Y.D. Kim[1], G.J. Cheon[1], S.G. Kim[2], Y.S. Kim[2], S.W. Jeong[3], J.Y. Jang[3], S.H. Lee[4], H.S. Kim[4]. *[1]University of Ulsan College of Medicine, Gangneung Asan Hospital, Internal Medicine, Gangneung-si; [2]Soonchunhyang University College of Medicine Bucheon Hospital, Internal Medicine, Bucheon, Rep. of South Korea; [3]Soonchunhyang University College of Medicine Seoul Hospital, Internal Medicine, Rep. of South Korea; [4]Soonchunhyang University College of Medicine Cheonan Hospital, Internal Medicine, Rep. of South Korea*
Email: khskhs@schmc.ac.kr

Background and Aims: Patients are often ineligible for resection or local ablation due to poor liver function and/or difficult location. The aim of this study is to compare therapeutic outcomes of stereotactic body radiotherapy (SBRT) combined with transarterial chemoembolization (TACE) and TACE only for ≤5 cm hepatocellular carcinoma (HCC).
Method: We reviewed data of eighty five patients who received SBRT with TACE (SBRT + TACE group) and one hundred fourteen patients who underwent TACE only (TACE group) in four tertiary hospital between March 2011 and December 2016. Local control rate (LCR), progression free survival (PFS) and overall survival (OS) were compared after propensity score matching (1:1 ratio).

Results: The SBRT + TACE group showed significantly higher 1-, 3- and 5-year LCR than the TACE group (91.1%, 89.9% and 89.9%, respectively, vs 69.9%, 44.8% and 44.8%, respectively; p < 0.001). The SBRT+ TACE group showed better 1- and 3-year PFS than the TACE group (56.5% and 32.3%, respectively, vs 42.2% and 21.6%, respectively; p = 0.050). However, 1-, 3- and 5-year OS was not different between the SBRT+ TACE and TACE group (98.8%, 89.1% and 80.7%, respectively, vs 99.7%, 83.3% and 71.0%, respectively; p = 0.417). Tumor size (HR = 1.266, p = 0.005), number of tumor (HR = 3.081, p < 0.001) and Child-pugh (CP) class B (HR = 2.005, p = 0.006) were associated with PFS. CP class B (HR = 2.462, p = 0.024) was independent prognostic factor of OS.
Conclusion: SBRT-TACE is superior to TACE in terms of LCR and PFS. SBRT-TACE may be an alternative treatment for patients with ≤5 cm HCC which is unsuitable for resection or local ablation.

Table 1: Baseline characteristics before and after propensity score matching

Variable	Before propensity matching			After propensity matching	
	SBRT + TACE (n = 85)	TACE (n = 114)	P-value	TACE (n = 85)	P-value

Out of Milan criteria and worse intetion to treat results at large liver transplant center

J.H. López[1], Ángel Rubín[1], C. Viaixa[1,2], Ángel Moya[3], M. Prieto[1,4], R. López[3], M.B. Haym[1,4]. *[1]Hospital Universitario y politécnico la Fe, Hepatology and Liver Transplant Section, Digestive Medicine Department, Valencia, Spain; [2]Instituto Carlos III, Networking Biomedical Research Centre Inhepatic and Digestive Disease (CIBEREHD), Valencia, Spain; [3]Hospital Universitario y politécnico la Fe, Hepato-Biliary -Pancreatic Surgery and Transplantation Unit, Valencia, Spain; [4]Hospital Universitario y politécnico la Fe, Networking Biomedical Research Centre Inhepatic and Digestive Disease (CIBEREHD), Valencia, Spain*
Email: herreras.julia8@gmail.com

Background and Aims: Milan criteria are widely used for LT selection but have been recognized to be restrictive. Although extra-Milan criteria are increasingly being adopted, intention-to-treat analyses are still lacking. **Aim:** To analyse if patients with extra-Milan hepatocellular carcinoma (HCC) included in a waiting list (WL) for LT have different outcome than Milan patients.
Method: Retrospective study analysing the outcome of 177 HCC patients waitlisted for LT between 2012 and 2015 at a single LT centre.

Patients were included in the waiting-list (WL) for LT if they were within-Milan from time of diagnosis or had been successfully downstaged from extra to within Milan. At time of WL inclusion, all patients were within Milan criteria and started and/or continued LRT if considered necessary until LT. Patients were followed up until death or January 2017. Patient, liver, tumour (including lorcorregional therapies-LRT) and surgical variables were recorded. LT-treatment failure was defined by a combined end-point including WL death due to liver disease, WL exclusion due to tumour progression and/or HCC recurrence post-LT.

Results: 177 patients, mostly men (87%) were included. Median age was 58 years old (51–63). Hepatitis C (51%) and alcohol (41%) were the main causes of liver disease. At time of HCC diagnosis, most patients (73%) were Child Pugh score (CTP) A with a median MELD score of 9(6–27) and median alpha-fetoprotein levels at diagnosis were 3.6 mg/dL. Most HCC cases were within Milan (n = 148, 84%). The median size of the nodules was 35 (10–80 mm). Downstaging was performed in all extra-Milan cases (n = 34) with 2 (1–4) local therapy before enter waiting list. LT was eventually performed in 146 patients after a median waiting time of 6 months LT-treatment failure occurred in n patients (20%) due to WL-death due to liver disease in 44% of these, WL exclusion due to tumour progression in 20% and HCC recurrence in the remainder 36% of patients. In the univariate analysis, extra- Milan criteria, high levels of alpha-fetoprotein at diagnosis, and number of LRT were predictive variables associated with treatment failure. Extra Milan criteria was the only variable remaining in the multivariate analysis with a HR of 3,3 (95% CI 1,34–7,4 p = 0.01).

Conclusion: According to our data, out-of-Milan criteria is associated with a higher intention-to-treat LT failure from time of inclusion in the WL.

THU-164

Real-world data in patients with hepatocellular carcinoma treated with transarterial chemoembolization: the second interim analysis of OPTIMIS

M. Peck-Radosavljevic[1,2], M. Kudo[3], H.C. Lee[4], A.-LII Cheng[5], K. Nakajima[6], J.-L. Raoul[7]. *[1]Medical University of Vienna, Vienna, Austria; [2]Klinikum Klagenfurt am Wörthersee, Klagenfurt, Austria; [3]Kindai University Faculty of Medicine, Osaka, Japan; [4]Asan Medical Center, Seoul, Rep. of South Korea; [5]National Taiwan University Hospital, Taipei, Taiwan; [6]Bayer HealthCare Pharmaceuticals, Whippany, NJ, United States; [7]Institut de Cancérologie de l'Ouest, Digestive Oncology, Nantes, France*

Email: markus@peck.at

Background and Aims: Transarterial chemoembolization (TACE) is commonly used for patients with unresectable hepatocellular carcinoma (HCC). However, there are no universally accepted criteria for TACE use and in clinical practice it is often used in broader populations outside of recommended international guidelines. Retrospective studies suggest TACE treatment for unsuitable patients may cause liver function deterioration and worse overall survival. The OPTIMIS study was designed to characterize TACE utilization, post-TACE treatments, and outcomes in real-world clinical practice settings.

Method: OPTIMIS is an international, prospective, observational study of patients with HCC who were treated with TACE. The study enrolled patients classified as BCLC stage B or higher and for whom a decision to treat with TACE was made at the time of study entry. Other treatments for HCC were also documented before, during, and after TACE, including sorafenib (SOR).

Results: In this interim analysis, 977 patients had received TACE. At inclusion, 153 patients (16%) had received other prior therapeutic procedures (10% hepatectomy) and 115 (12%) had prior local anti-cancer therapy excluding surgery (9% radio-frequency ablation). Overall, 431 (44%) were deemed ineligible for TACE at inclusion according to international guidelines (40% Europe; 55% Asia; 15% Japan; 82% China; 38% Korea). At study inclusion, 227 patients (23%) were BCLC C and 9 (1%) BCLC D (Table). Of the 333 patients with available STATE scores, 97 (29%) had scores ≤18 (% by region: 44% Europe; 56% Asia; 11% Japan; 73% China; 17% Korea) and 236 (71%) had >18. Overall, 267/977 patients (27%) received SOR (% by region: 25% Europe; 29% Asia; 24% Japan; 50% China; 12% Korea). In the SOR treated population, around one-third of patients received ≥3 TACE treatments and treatment-emergent adverse events (all grade) were reported in 148/267 patients (55%).

HCC at inclusion visit

	Europe n = 318	Asia n = 208	Japan n = 172	China n = 138	Korea n = 141	Total n = 977
BCLC stage*, %						
B	73	71	94	31	71	70
C	13	25	5	67	26	23
D	1	2	0	1	1	1
Child–Pugh score†, %						
A	60	67	78	82	84	71
B	21	19	21	15	14	19
C	<1	1	0	1	0	1

*Missing n = 55; †Missing n = 90.

Conclusion: In this interim analysis of OPTIMIS, a significant number of patients were considered for TACE, despite not being adequately indicated. Results also suggest that systemic therapy is not commonly used in the real-world setting. Further observation is necessary to confirm these findings.

THU-165

Comparision of long-term outcome for single small hepatocellular carcinoma between different treatment modalities by size and tumor marker

D.H. Sinn[1], S.-G. Lee[1], D. Hyun[2], S.W. Shin[2], G.-S. Choi[3], J.M. Kim[3], T.W. Kang[2], M.W. Lee[2], W. Kang[1], G.-Y. Gwak[1], Y.-H. Paik[1], M.S. Choi[1], J.H. Lee[1], K.C. Koh[1], S.W. Paik[4], B.C. Yoo[5]. *[1]Samsung Medical Center, Department of Medicine, Seoul, Republic of South Korea; [2]Samsung Medical Center, Department of Radioogy and Center for Imaging Science, Seoul, Republic of South Korea; [3]Samsung Medical Center, Department of Surgery, Seoul, Republic of South Korea; [4]Samsung Medical Center, Department of Medicine, Seoul, Republic of South Korea; [5]Konkun University Medical Center, Department of Medicine, Seoul*

Email: sinndhn@hanmail.net

Background and Aims: For single small hepatocellular carcinoma (HCC), radiofrequency (RF) ablation can be a first-line option for patients with preserved liver function. We tested whether size and tumor marker should be considered in selecting RF ablation as a first-line option.

Method: We used a retrospective cohort of 896 consecutive, treatment-naïve, single, small sized (<3 cm) HCC who were treated with resection (n = 319), radiofrequency (RF) ablation (n = 425) or transarterial chemoembolization (TACE) (n = 152) as a first-line therapy between 2010 and 2013. Patients were grouped into three based on tumor size and PIVKA-II levels; (1) tumor sized ≤2 cm with low PIVKA-II levels (<30 mAU/ml), (2) tumor sized 2–3 cm with low PIVKA-II levels (<30 mAU/ml) or tumor sized ≤2 cm with elevated PIVKA-II levels (≥30 mAU/ml); (3) tumor sized 2–3 cm with elevated PIVKA-II levels (≥30 mAU/ml). Long-term outcome was compared between treatment modality in each group.

Results: For group 1, compared to RF ablation, resection showed similar risk of overall mortality (adjusted hazard ratio (HR), 0.29, 95% confidence interval (CI), 0.06–1.45, adjusted for age, sex, etiology, albumin-bilirubin grade, ECOG performance, and AFP levels), while TACE showed increased risk of overall mortality (adjusted HR, 2.10, 95% CI, 1.10–4.02). For group 2, resection showed similar risk of overall mortality to RF ablation while the risk was higher for those who underwent TACE. For group 3, resection showed reduced risk of

overall mortality (adjusted HR, 0.46, 95% CI, 0.01–0.26) compared to RF ablation, while the risk was similar between TACE and RF ablation (adjusted HR, 0.60, 0.14–2.54).
Conclusion: RF ablation showed comparable efficacy in terms of overall survival to surgical resection for single, small tumor when PIVKA-II level was low. However, when PIVKA-II level was elevated, RF ablation showed worse survival than resection when tumor size exceeded 2 cm. Size and PIVKA-II levels should be considered when considering RF ablation as a first-line treatment option for single small HCC.

Email: pietro.lampertico@unimi.it

Background and Aims: Management of hepatocellular carcinoma (HCC) is framed within standardized protocols released by Scientific Societies, whose applicability and efficacy in field practice need refining.
We evaluated the applicability and effectiveness of guidelines for the treatment of HCC of the American Association for the Study of the Liver (AASLD).
Method: Between January 2007 and December 2011, 370 consecutive cirrhotic patients (250 viral hepatitis/41 ethanol/79 other etiologies, median age 68 yy, 272 males, 250 Child-Pugh A) with de-novo HCC in different stages (253 BCLC A, 66 BCLC B, 51 BCLC C) received treatment through a multidisciplinary team (MDT) decision. Patients were followed until death or last follow-up up to December 2016. Patients with a previous diagnosis of liver cancer and those with poor liver function (Child–Pugh C) were excluded.
Results: HCC treatment was adherent to AASLD recommendations in 205 (81%) BCLC A patients, 36 (54%) BCLC B, and 27 (53%) BCLC C. Overall, a radiological complete response was obtained in 185 (50%) patients, 165/370 (45%) after a first-line treatment, 25/117 (21%) after a second-line treatment, and 6/39 (15%) after a third-line treatment. Eleven patients (3%) achieved a complete response more than once.
During 58 (range 1–108) months, 105 (28%) patients died, 41 (16%) BCLC A, 25 (38%) BCLC B and 39 (74%) BCLC C. In BCLC A the mean mortality rate was lower in patients treated according to AASLD recommendations than in patients otherwise treated (5.0% vs 10.4%, $p = 0.004$), corresponding to a 1, 3, 5 year survival of 100%, 86%, 77% vs 93%, 75%, 47%, respectively; whereas the upward treatment stage migration was associated to a lower mortality rate as compared to standard of treatment in BCLC B (8.6% vs 20.7%, $p = 0.029$) corresponding to a 1, 3, 5 year survival of 100%, 74%, 67% vs 100%, 43%, 23%, respectively, as well as in BCLC C (42.6% vs 59%, $p = 0.04$) corresponding to 1, 3, 5 yr survival 79%, 39%, 0% vs 42%, 1%, 0%, respectively.
Conclusion: HCC multimodality treatment including other than first-line therapy is common in clinical practice and impacts on the achievement of complete response. Personalized treatment provided survival benefits to patients whose profile is not accounted for by international recommendations.

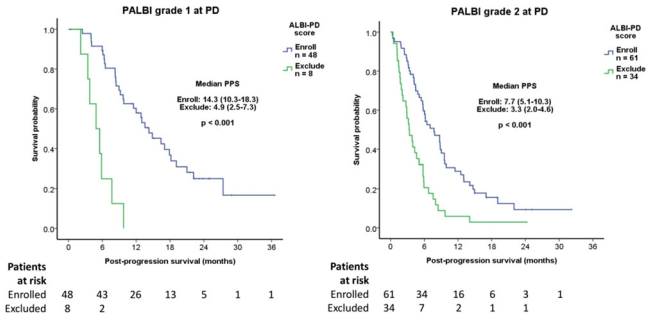
THU-167
Surgical resection is considered in resectable solitary hepatocellular carcinoma with portal vein tumor thrombosis of patients with Child A
J.M. Kim[1], C.H.D. Kwon[2], J.-W. Joh[3], G.-S. Choi[4], D.H. Sinn[5], Y.-H. Paik[4], J.H. Lee[4]. *[1]Sungkyunkwan University School, Samsung Medical Center, Seoul, Republic of South Korea; [2]Samsung Medical Center, Seoul, Republic of South Korea; [3]Sungkyunkwan University School of Medicine, Samsung Medical Center, Republic of South Korea; [4]Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of South Korea; [5]Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul*
Email: yjongman21@gmail.com

Background and Aims: Sorafenib is recommended in the hepatocellular carcinoma with portal vein tumor thrombosis. However, surgical resection and locoregional therapies such as combination transarterial chemoembolization (TACE) and/or radiation therapy (RT) are commonly used in those patients. The aim of present study is to compare the outcomes between surgical resection and combination therapy included TACE and RT in resectable solitary HCC with PVTT.
Method: We prospectively enrolled in resectable solitary HCC with PVTT between 2010 and 2015. Some hepatologists favored surgical resection and others favored locoregional therapies. Resectability was defined by three experienced surgeons. Patients were selected using propensity score matching (1:2).
Results: One-hundred sixteen patients enrolled in the study because of resectable solitary HCC with PVTT. All patients were Child-Pugh class A and ECOG performance grade $\leq$1. Forty-four patients underwent surgical liver resection (SR group) and 72 patients received combination therapies (Combination group). Age, AFP, PIVKA-II, and tumor size were significantly different between the two groups. Therefore, propensity score matching used four variables. Thirty-five patients in the SR group and 45 patients in the combination group were selected after propensity score matching. The 1-year, 2-year, and 3-year patient survival rates were 85.7%, 71.3%, and 68.2% in the SR group and 68.9%, 53.2%, and 38.1% in the combination group ($p = 0.008$). Multivariate analysis showed that surgical resection, low platelet counts, and male are closely associated patient survival in solitary HCC with PVTT.
Conclusion: Surgical resection may improve patient survival in solitary resectable HCC wih PVTT patients. Surgical liver resection is always considered as curative treatment in solitary resectable HCC with PVTT in patients with Child A.

THU-168
Performance of ALBI-PD Model and PALBI Grade in Sorafenib-failed Hepatocellular Carcinoma
P.-C. Lee[1], Y.-T. Chen[2], Y. Chao[3], T.-I. Huo[1], C.-W. Su[1], M.-C. Hou[1], Y.-H. Huang[1]. *[1]Taipei Veterans General Hospital, Gastroenterology and Hepatology, Taipei, Taiwan; [2]Taipei Veterans General Hospital, Nursing, Taipei, Taiwan; [3]Taipei Veterans General Hospital, Medical Oncology, Taipei, Taiwan*
Email: tympanum3688@gmail.com

Background and Aims: Albumin-bilirubin (ALBI) grade is superior to Child-Turcotte-Pugh (CTP) classification in prediction the survival of hepatocellular carcinoma (HCC) across all cancer stages. ALBI grade derived models, ALBI-PD and platelet-albumin-bilirubin (PALBI) grade seems to have better performance in prediction the survival of HCC. We aim to compare the performance of ALBI-PD model and PALBI in prediction the outcomes of sorafenib-failed HCC.
Method: From August 2012 to October 2015, 432 consecutive patients who received sorafenib treatment for advanced HCC in Taipei Veterans General Hospital were retrospectively reviewed. Of them, 328 experienced radiology-proved progressive diseases (PD) were enrolled into the analysis. The area under receiver-operator-

characteristic curve (AUROC), homogeneity and corrected Akaike information criterion (AICc) were compared between each system.
Results: During the median follow-up of 5.9 months, 294 deaths occurred. The median overall survival was 6.0 (95% confidence interval [CI], 5.2–6.7) months; and the post-progression survival (PPS) was 4.0 (95% CI, 3.5–4.4) months. ALBI-PD model and PALBI grade performed better in prediction the PPS than ALBI grade (AUROC of each model: 0.766, 0.757, 0.712 at 6 months and 0.766, 0.732, 0.723 at 9 months for ALBI-PD, PALBI and ALBI, respectively). ALBI-PD score had the highest homogeneity and the lowest AICc value among the three models. ALBI-PD score could further discern PPS across PALBI grades. In PALBI grade 1 patients beyond ALBI-PD criteria, the median PPS was only 4.9 month. Noteworthily, 61 (64.2%) of the 95 PALBI grade 2 patients were still within the ALBI-PD criteria, whose median PPS could achieve 7.7 months.



Conclusion: ALBI-PD, and PABLI are superior to ALBI to predict PPS after sorafenib failed. ALBI-PD model can further discriminate PPS in PALBI grade 1 and 2 sorafenib-failed HCC, and is a practical criterion to select eligible patients into second-line therapy.

Feasibility of dynamic risk assessment for patients with repeated tras-arterial chemoembolization for hepatocellular carcinoma

M.I.Y. Jeon[1], Y. Park[1], B.K. Kim[2], J.Y. Park[1], D.Y. Kim[1], S.H. Ahn[1], K.-H. Han[1], H. Kim[1], S.U. Kim[1]. *[1]Yonsei University College of Medicine, Department of Interna Medicine, Seoul, Republic of South Korea; [2]Severance Hospital, Internal Medicine, Gastroenterology, Seoul, Republic of South Korea*
Email: ksukorea@yuhs.ac

Background and Aims: The hepatoma arterial-embolization prognostic (HAP) score and its modifications (modified HAP [mHAP] and mHAP-II) predict outcomes after trans-arterial chemoembolization (TACE) for hepatocellular carcinoma (HCC). We investigated the feasibility of using HAP-related risk scores for dynamic risk assessment during repeated TACE.
Method: A total of 619 HCC patients treated with TACE from two institutions between 2003 and 2010 were included.
Results: Patients with A-B class risk scores showed significantly better survival than those with C-D class at the first (median 43.7 vs. 21.5 months for mHAP-II, 35.2 vs. 10.2 months for mHAP, and 39.8 vs. 18.6 months for HAP; all $p < 0.001$) and the second TACE (38.6 vs. 17.2 months for mHAP-II, 30.0 vs. 8.5 months for mHAP, and 32.6 vs. 17.3 months for HAP; all $p < 0.001$). Sequential assessment of risk scores at the second TACE was applied for patients with A-B class risk scores at the first TACE, which further identified two subgroups of A-B and C-D class risk scores with different outcomes (median survival 40.6 vs. 19.6 months for mHAP-II, 31.2 vs. 16.9 months for mHAP, and 35.8 vs. 21.0 months for HAP; all $p < 0.001$). The mHAP-II, compared with mHAP and HAP, showed the highest likelihood ratio (22.61 vs. 14.67 and 13.97, respectively), highest linear trend (24.43 vs. 19.67 and 14.19, respectively), and lowest Akaike information criteria value (1432.51 vs. 3412.29 and 2296.98, respectively).
Conclusion: All HAP-related risk scores dynamically predicted outcomes during repeated TACE. Sequential risk assessment using mHAP-II best identified optimal candidates for repeated TACE.

Surgical resection vs radiofrequency ablation for hepatocellular carcinoma: a propensity score matching analysis

G. Scialandrone, M.F. Valentini, S. Roselli, P. Panzera, R. Memeo, L.G. Lupo. *U.O. Chirurgia Generale "M.Rubino", DETO-Dipatimento Emergenza Trapianto D'Organi,Bari, Italy*
Email: grazisa.scialandrone@gmail.com

Background and Aims: Hepatocellular carcinoma (HCC) is the 5th cause of death among cancer. Surgical resection and local ablative therapies represent the most frequent firstline treatment adopted when liver transplantation is not indicated or not immediately applicable. Unfortunately, in literature, a lot of studies that directly compared Hepatic Resection (HR) and Radiofrequency Ablation (RFA) reports discrepant results. When comparing the efficacy of two different therapies for HCC, a major limitation is the causal inference problem.
Method: In this retrospective study we enrolled 411 patients undergoing to RFA and 147 patients undergoing to HR between January 2006 and August 2017. The Outcomes in terms of Overall Survival and Disease free Survival were analyzed using a Propensity Score Matching (PSM) method.
Results: The comparison between HR group and RFA group reveals significant differences as regards demographic characteristics, liver function and underlying disease, tumor features (number and size), Overall Survival rates (OS, $p < 0.0001$), or Recurrence-Free Survival rates (RFS, $p < 0.0001$). For the 81 patient pairs selected from the PSM analysis, the RFA group shows better OS and RFS than HR group (5yOS 49.9% vs 35.8%, $p = 0.003$ and 5y RFS 58.3% vs 30.6%, $p = 0.012$, respectively). A Cox proportional Hazard analysis demonstrates that choosing Treatment ($p = 0.004$), total Bilirubin ($p = 0.032$) and Neutrophil-Limphocyte Ratio (NLR, $p = 0.016$) were indipendent prognostic factors for OS; Treatment ($p = 0.001$), total Bilirubin ($p = 0.008$), NLR ($p = 0.003$) and HCV-rna ($p = 0.001$) were indipendent prognostic factors for RFS.
Conclusion: This study suggests that Local Ablation is equivalent to or better treatment option than Surgical Resection in patients with primitive HCC within Milan Criteria, a reliable alternative to hepatic resection in patients with functional and anatomical limitation, a first-line treatment for Downstaging and Bridge.

THU-171

Impact of the alpha-Fetoprotein model for patient selection for Liver Transplantation for Hepatocellular Carcinoma, a French experience

B. Brusset[1], Q.J. Louis[1], J. Dumortier[2], D. Cherqui[3], G.-P. Pageaux[4], S. Dharancy[5], S. Radenne[6], D. Samuel[7], D. Thomas[1]. *[1]CHU Grenoble, Grenoble, France; [2]Unité de Transplantation hépatique, Lyon, France; [3]Centre Hepatobiliaire Paul Brousse, Villejuif, France; [4]CHU Montpellier, Montpellier, France; [5]Liver Unit, CHRU Lille, Lille, France; [6]Hospices Civils de Lyon, Hepatology Department, Lyon, France; [7]AP-HP Hôpital Paul-Brousse, Centre Hépato-Biliaire, Inserm, Unité 1193, Université Paris-Saclay, Villejuif, France*
Email: bbrusset@chu-grenoble.fr

Background and Aims: The French organization for organ Sharing changed the allocation criteria for Liver transplantation (LT) in Hepatocellular carcinoma (HCC) on January 2013. The AFP Model replaced Milan criteria. Since then, only patients with an AFP score $\leq$2 access to LT. The aim of this study was to analyze the respect of the criteria and the results of LT with an intention-to-treat design since the adoption of the AFP model, and to compare them to the results before its adoption.
Method: 523 patients consecutively listed for LT for HCC between March 2011 and March 2014 in five French centers have been

included, whether they have been transplanted (n = 364) or not (n = 159). The Milan group (n = 199) consisted in patients transplanted or dropped out of list before the concrete adoption of the AFP model. The AFP group (n = 324) consisted in patients transplanted or dropped out of list since its application.

Results: In the AFP group, patients had less advanced cirrhosis and more bridging therapies than in the Milan group. Median waiting time was 7.7 months in the Milan group vs. 12.3 months in the AFP one ($p < 0.001$), mainly due to the establishing of "temporary contraindications".

The non-respect of the AFP score on the explants was highly predictive of recurrence (SHR 6.85, $p < 0.001$) and post-transplant death (HR 3.44, $p < 0.001$). There was no difference in the histological AFP score between groups ($p = 0.838$) with a global respect in 88% of patients. Independent factors predicting a non-respect of this score were a downstaging policy and an AFP score >2 on the last imaging. Dropout of list, 3-year post-listing survival and 2-year post-transplantation were similar between the groups (respectively 26.3% in Milan vs. 30.6% in AFP, $p = 0.086$; 68.2 vs. 66.7%, $p = 0.447$ and 87.4 vs. 82.7% $p = 0.100$).

However despite no significant difference in the rate of recurrence (9.2% vs. 13.2%, $p = 0.239$), the multivariate analysis showed that belonging to the AFP group, as well as the non-respect of the AFP model, a downstaging policy and preceding treatments to avoid LT, were predictors of post-LT tumor recurrence.

Conclusion: The adoption of the AFP model in France did not change the histological results but allowed a better respect of the allocation rules in comparison to Milan criteria, without significant increase in the dropout rate. A high rate of recurrence was observed in the most recent cohort, probably due to the lengthening of the waiting list and an increase of treatments. This study raises the necessity to discuss the principles of temporary contraindications and to develop solutions to cope with the organ shortage.

THU-172

Transarterial-chemoembolization and hepatocellular carcinoma. A regular interval approach avoids the 10% of the procedures and an optimal survival with the transition to systemic therapy in 80% of the patients

M.S. Zamparelli[1], M. Burrel[2], A. Darnell[3], V. Sapena[1], M. Barrufet[2], A. Sotomayor[2], N. Llarch[1], G. Iserte[1], A. Diaz-Gonzalez[1], E. Belmonte[4], A. Forner[1], J. Rimola[3], C. Ayuso[3], M. Reig[1], J. Bruix[1]. *[1]Hospital Clínic de Barcelona. BCLC group. Liver Unit. IDIBAPS. CIBERehd, Barcelona; [2]Hospital Clínic de Barcelona. BCLC group. Radiology department, Barcelona; [3]Hospital Clínic de Barcelona. BCLC group. Radiology department. Universitat de Barcelona, Barcelona, Spain; [4]Hospital Clínic de Barcelona. BCLC group. Radiology department. IDIBAPS. CIBERehd, Barcelona, Spain*

Email: jbruix@clinic.cat

Background and Aims: Chemoembolization (TACE) is the recommended treatment for patients with hepatocellular carcinoma (HCC) at BCLC-B stage or BCLC-0/A without other options. After initial response, TACE can be performed "on-demand" based on the tumor evolution or at regular intervals. Usually, TACE is performed at 0, 2 months and then at 6 months, but solid data on the benefit/needs/applicability of TACE at month 2 or on the possibility to avoid the second TACE after registering radiologic complete response (CR) after the 1st session are still lacking. Furthermore, it is controversial if a 6 months interval is appropriate or what amount of patients cannot be treated because of exceeding the criteria for the treatment. The aim of this study was to evaluate -if CR after the 1st TACE predicts the tumor de-vascularization and the futility of the 2nd TACE at month 2, -if the 1st TACE induces vascular lesions hampering the 2nd treatment, -the percentage of patients who develop untreatable-progression revealed by the regular interval schedule and -validation of the currently expexted overall survival (OS).

Method: Between 01/2014–3/2017, 106 patients (HCV 51.89%, Child-Pugh-A 92.45% y BCLC-A/B 43.4/56.6%) were included. For all patients 3 TACE (0/2/6 months) were scheduled and performed according to the radiologic and angiographic findings during the follow-up.

Results: The median follow-up was 19.3 months. Seven patients were transplanted and 39 had untreatable-progression [20.8% BCLC-B stage (n = 22), 10.3% en BCLC-C stage (n = 11) and 5.6% BCLC-D stage (n = 6)]. Two patients developed a hepatic abscess. Ninety-six patients (90.6%) had at least 1 TACE. The most common reasons for performing the angiography in spite of the 1st, 2nd and 3th TACE were: untreatable disease (6/10) for the 1st angiography, no treatable lesions for the 2nd and 3th angiography, [85.3% (n = 13/16)] and [73.7% (n = 14/19)] respectively. Twenty-one patients died during the follow-up and the median OS censoring at application of other treatment or liver transplantation was 44 months (42.6 months without censoring). Thirty-five of 44 patients (80%) who suspended TACE started systemic treatment with sorafenib.

Conclusion: 10% of the patients had CR by dynamic imaging and angiography after the first TACE and thus, may avoid a 2nd session at 2 months. The evaluation and treatment according to the regular interval schedule allowed that 80% of the patients with untreatable-progression may benefit from systemic treatment and this sequence translates into a median OS ≥ 40 months.

THU-173

Impact of regorafenib in the clinical practice and identification of second-line treatment orphan patients

M.S. Zamparelli[1], V. Sapena[1], A. Diaz-Gonzalez[1], A. Darnell[2], N. Llarch[1], E. Belmonte[3], L. Boix[1], G. Iserte[1], A. Forner[1], J. Corominas[1], L.G. Da Fonseca[1], C. Ayuso[2], J. Bruix[1], M. Reig[1]. *[1]Hospital Clinic, BCLC group. Liver Unit. IDIBAPS. CIBERehd, Barcelona, Spain; [2]Hospital Clinic, BCLC group. Radiology department. Universitat de Barcelona, Barcelona, Spain; [3]Hospital Clinic, BCLC group. Radiology department. IDIBAPS. CIBERehd., Barcelona, Spain*

Email: mreig1@clinic.cat

Background and Aims: The RESORCE study showed that regorafenib provides a significant benefit in terms of overall survival (OS) to patients with hepatocellular carcinoma (HCC) who tolerated sorafenib (400 mg/day) and presented radiologic progression. Data on regorafenib treatment in clinical practice are scarce and the percentage of patient candidates or orphans of effective second-line treatment is unknown. The purpose of this study was to investigate the feasibility and tolerance of regorafenib in clinical practice and to evaluate the proportion of patients who can benefit from it.

Method: we analysed a prospective database of patients with HCC treated with sorafenib to investigate the regorafenib applicability and assessed the outcome of patients that have received this novel option. This includes 19 patients [5 within the research trials and 14 under compassionate use]. All patients started at 160 mg/day. Treatment was continued until symptomatic progression, unacceptable adverse events or patient decision.

Results: Eighty of the 299 patients treated with sorafenib were alive at the time of regorafenib availability, 21/80 continued on sorafenib and 59 definitively discontinued (41 due to toxicity, 17 for tumor progression and 1 because of patient decision). 23% (14/59) of the patient who discontinued sorafenib started regorafenib and 14/17 (82.35%) with tumor progression started regorfenib. Among all the patients treated with regorafenib 85% were BCLC-C with the tumor progression pattern of: 15% BCLCp-B (n = 3), 35% BCLCp-C1 (n = 7) and 50% BCLCp-C2 (n = 10). The median follow-up was 19.9 and 5.6 months for the research and clinical practice patients respectively. 11/20 patients have died (range 3–32 months). The median time to 1st dose modification was 13.8 days and modifications were due to: fatigue (n = 4), skin reaction (n = 4) and diarrhoea (n = 3). Seven of the 8 patients who discontinued regorafenib did so because of symptomatic progression.

Conclusion: Since regorafenib approval for HCC, the number of patients treated with regorafenib is low but data on the tolerability and survival reproduce the RESORCE results even if presenting the poor prognosis pattern (50% BCLCp-C2). More than half of the patients treated with sorafenib are a potential candidate for regorafenib, although a relevant number of patients remains orphan for effective second-line treatment.

THU-174

Combined photodynamic therapy with systemic chemotherapy improves survival of patients with irresectable cholangiocarcinoma

M.A. Gonzalez-Carmona[1], M. Bolch[1], C. Jansen[1], A. Vogt[1], M. Sampels[1], K. van Beekum[1], R. Mahn[1], M. Praktiknjo[1], J. Nattermann[1], J. Trebicka[1], V. Branchi[2], H. Matthaei[2], S. Manekeller[2], J. Kalff[2], C.P. Strassburg[1], T. Weismüller[1]. *[1]University Hospital Bonn, Internal Medicine I, Bonn, Germany; [2]University Hospital Bonn, Visceral Surgery, Bonn, Germany*
Email: maria.gonzalez-carmona@ukbonn.de

Background and Aims: Systemic chemotherapy (SC) with gemcitabine and cisplatin is the current standard therapy for patients with irresectable cholangiocellular carcinoma. Photodynamic therapy (PDT), a local ablative procedure, has also been shown beneficial in patients with irresectable extrahepatic cholangiocarcinoma. However, the benefit of combined SC with PDT is still unclear. This retrospective study evaluated the benefit of PDT—alone or in combination with SC—compared to SC alone in patients with irresectable extrahepatic cholangiocarcinoma.
Method: 353 patients diagnosed of cholangiocarcinoma between 2004 and 2016 were treated at the University Hospital of Bonn, Germany. 96 patients suffering from irresectable extrahepatic cholangiocarcinoma were included in this study and retrospectively analyzed. Patients were stratified according to treatment: PDT-SC combination (n = 36), PDT alone (n = 34) and SC alone (n = 26).
Results: Combined PDT with SC resulted in significantly longer overall survival than SC alone (log-rank p = 0.022). Median survival was 20 months in the PDT-SC treatment group (95%CI:16.38–23.62 months), 15 months in the PDT group (95%CI:10.02–19.98) and 10 months in the SC group (95%CI:8.45–11.55 months). A multivariate analysis identified PDT-SC and PDT (hazard ratio [HR], 0.41, 95%CI: 0.22–0.77, p = 0.006), but also other local therapies, such as metal stenting and application of RFA as significant independent predictors for longer survival. Interestingly, patients with metastatic disease appeared to benefit highly of combined therapy, compared to SC alone (log-rank p = 0.014). Finally, combined therapy was well-tolerated, and adverse events were similar among the different groups (p < 0.05).
Conclusion: Combination of PDT with SC was feasible, well-tolerated and resulted in significantly longer overall survival compared to SC alone. Application of PDT significantly correlated with longer survival. This study strongly points out a relevant role of PDT but also of other local therapies in the control of advanced cholangiocarcinoma and should be evaluated in the therapy decision for this disease.

THU-175

Outcomes of single or sequential dual modality loco-regional therapies in Hepatocellular carcinoma

V.K. Balachandrakumar[1], M. Swaminathan[2], J. Evans[3], N. Kibriya[3], D. Palmer[1], T. Cross[2]. *[1]Liverpool University, Institute of Translational Medicine, Liverpool; [2]The Royal Liverpool Hospital, Hepatology, Liverpool; [3]The Royal Liverpool Hospital, Interventional Radiology, United Kingdom*
Email: vinayb96@yahoo.co.uk

Background and Aims: Hepatocellular carcinoma (HCC) in western populations commonly occurs in the context of cirrhosis. Staging of disease has been based primarily on the Barcelona Clinic Liver Cancer (BCLC) classification in the UK. Patients not fit for Orthotopic Liver Transplantation (OLT) or liver resection in stage A disease have been offered ablations whilst patients with intermediate stage B disease have been offered trans-arterial chemoembolization (TACE). The aim was to assess outcomes from patients offered single modality or dual modality therapy for HCC, and to identify prognostic factors.
Method: A single centre study of patients from the Royal Liverpool Hospital from 2003 to 2016 was analysed. Patients receiving loco-regional therapy were identified from the departmental HCC database. Patient characteristics collected included age, gender, etiology, standard biochemistry, BCLC stage, performance status, tumour size and number, and treatments offered: Radiofrequency ablation (RFA) alone, RFA-TACE, TACE alone and TACE -RFA. The primary outcome measure was survival, calculated using the log-rank method.
Results: Out of 295 patients in our cohort, 96 patients were identified who had ablation (RFA (pre-2010) or microwave ablation (from 2010)), TACE, or a combination of the 2. The median age was 67 (57–74), the BCLC grade was 0 = 9 (9%), A = 42 (44%), B = 35 (36%), C = 9 (9%), D = 1 (1%). Disease etiology was Alcoholic Liver Disease (ALD) = 27, Hepatitis B = 4, Hepatitis C = 21, Non-Alcoholic Steatohepatitis = 27, Haemochromatosis = 5, ALD + viral = 5, others = 7. Hepatoma arterial-embolization prognostic (HAP) score was available in 85 patients; HAP A = 38, B = 24, C = 21, D = 2. A total of 143 TACE and 154 ablation procedures were performed. The median survival for ablation alone was 37 months (26–48), RFA-TACE was 38 months (33–43), TACE alone was 16 months (15–17) and TACE-RFA was 34 months (22–46), log rank 13.3, p = 0.004. Survival using HAP score was; HAP A = 8 months (24–52), HAP B = 35 months (20–50), HAP C = 12 months (7–17), HAP D = 2 months (1–3), log rank 68.1, p < 0.0001.
Conclusion: Our data suggests that patients who cannot be down-staged with TACE to receive ablation do worse than patients with earlier stage disease who progress after ablation alone or who receive TACE following an ablation. This supports the use of dual sequential therapy where indicated. The HAP score is a useful tool to identify patients most likely to benefit from loco-regional treatments.

THU-176

Clinical features and prognosis of advanced stage hepatocellular carcinoma; verification of diverse progression processes

M. Yokoyama[1], S. Ogasawara[1], Y. Ooka[1], M. Inoue[1], T. Chiba[1], E. Suzuki[1], T. Maeda[1], T. Wakamatsu[1], K. Kobayashi[1], S. Kiyono[1], M. Nakamura[1], T. Saito[1], S. Nakamoto[1], S. Yasui[1], A. Tawada[1], M. Arai[1], T. Kanda[1], H. Maruyama[1], S. Kuboki[2], M. Miyazaki[2], O. Yokosuka[1], M. Ohtsuka[2], N. Kato[1]. *[1]Chiba University, Graduate School of Medicine, Department of Gastroenterology, Chiba, Japan; [2]Chiba University, Graduate School of Medicine, Department of General Surgery, Chiba, Japan*
Email: sadahisa@me.com

Background and Aims: Some of the hepatocellular carcinoma (HCC) patients progress to advanced stage during their clinical course regardless of early detection. However, because of variations in the process of progression to advanced stage HCC, its diversity in terms of clinical features and prognosis remains controversial, especially in patients who have received several treatments during their clinical courses from initial diagnosis to advanced stage HCC. The purpose of this study was to inspect the clinical courses of HCC patients and identify variations in the clinical features and prognosis of advanced HCC.
Method: We retrieved whole clinical courses of newly diagnosed HCC patients between January 2003 and December 2015. Progression process from initial diagnosis from advanced stage HCC were identified and survival outcomes were assessed from the time of diagnosed as advanced stage HCC.
Results: Of 1,161 patients, 783, 237, and 141 patients were initially diagnosed with early, intermediate, and advanced stage HCC, respectively. During the follow-up period, 57 early stage patients (7.3%) progressed to the advanced stage through the intermediate

stage and 79 (10.1%) reached the advanced stage directly from the early stage. Similarly, 130 of 408 patients (31.9%) who were diagnosed as being in the intermediate stage progressed to the advanced stage. Cumulative 3-, 5-, and 10-year incidence rates of advanced stage from the early stage were 12.5%, 22.8%, and 44.8%, respectively. Likewise, cumulative incidence rates of patients progressing to the advanced stage of the disease from the intermediate stage were 45.7% (3-year), 57.6% (5-year), and 77.8% (10-year). Of 350 patients who were diagnosed as bring in the advanced stage of HCC, 20 patients (5.7%) had only extrahepatic metastasis (EHM) and no intrahepatic lesions (IHL). With regard to patients with IHL, macrovascular invasion (MVI) could not be detected in 109 patients (31.1%) with EHM. Of the remaining patients with MVI, 169 patients (48.0%) were not identified EHM, and 51 patients (14.6%) had EHM. There were significant differences in overall survival between the four variations of advanced stage HCC [EHM only (no IHL and no MVI): 20.3 months, IHL with MVI (no EHM): 10.5 months, IHL with EHM (no MVI): 9.7 months, and IHL with both MVI and EHM: 4.2 months] ($p < 0.001$).
Conclusion: We confirmed several variations in the disease progression of HCC to its advanced stage. Although this was not a common pattern, a few patients progressed to the advanced stage without IHL and those patients had a significantly better prognosis compared with other variations. These differences in prognosis seem to be helpful to not only understand the clinical course of HCC but also to design clinical trials for advanced HCC patients.

THU-177
Soluble urokinase plasminogen activator receptor (suPAR) represents a novel serum biomarker for patients undergoing resection of colorectal liver metastases

S. Loosen[1], F. Tacke[2], M. Binnebösel[2], C. Klink[2], T.F. Ulmer[2], C. Trautwein[2], C. Roderburg[2], U. Neumann[2], T. Lüdde[2]. Email: tluedde@ukaachen.de

Background and Aims: In colorectal cancer (CRC), the liver is the most common site of metastasis. Surgical resection represents the standard potentially curative therapy for patients with colorectal liver metastases (CRLM). However, 5-year survival rates after resection do not exceed 50%, and despite existing preoperative stratification algorithms it is still not fully understood which patients benefit most from surgery. The soluble urokinase plasminogen activator receptor (suPAR) has recently evolved as a promising biomarker for distinct clinical conditions. Here, we examined a potential role of circulating suPAR as a biomarker in patients undergoing resection of CRLM.
Method: Expression levels of uPAR, the membrane-bound source of circulating suPAR, were analysed in tissue samples of CRLM using RT-PCR and IHC. SuPAR serum levels were measured by ELISA in 104 patients undergoing surgical resection of CRLM as well as 50 healthy controls. Results were correlated with clinical data.
Results: In line with an upregulation of uPAR in the CRLM tissue, serum levels of suPAR were significantly elevated in patients with CRLM compared to healthy controls. Patients with preoperative suPAR serum levels above our defined ideal cut-off value of 4.83 ng/ml showed a strikingly reduced overall survival after resection of CRLM, which could be confirmed for right- and left-sided primary CRC. Importantly, none of these patients reached long-term survival compared to patients with preoperative suPAR serum concentrations below the cut-off value. Moreover, multivariate Cox-regression analysis revealed preoperative suPAR serum levels as an independent prognostic factor in this setting. Additionally, elevated preoperative suPAR but not creatinine levels were a predictor of acute kidney injury after CRLM resection, correlating with a longer postoperative hospitalization.

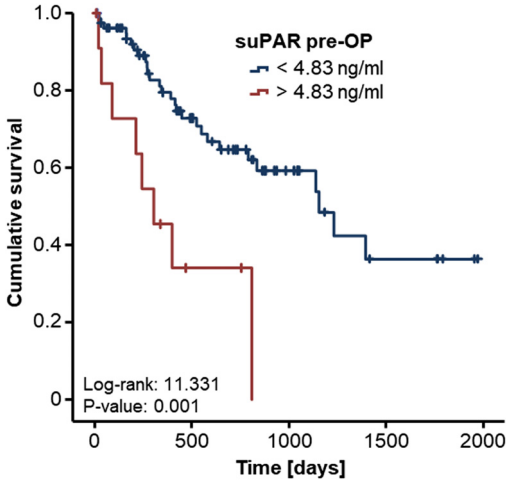

Figure 1: When applying the ideal cut-off value of 4.83 ng/ml, patients with initial suPAR serum above this cut-off show a strikingly reduced OS (median OS: 304 days) compared to patients with serum suPAR levels below this cut-off (median OS: 1154 days).

Conclusion: Serum levels of suPAR represent a promising novel biomarker in patients with resectable CRLM that might help to guide preoperative treatment decisions with regards to patients' outcome and the identification of patients particularly susceptible to post-operative acute kidney injury.

THU-178
Sarcopenia predicts survival in patients with advanced hepatocellular carcinoma treated with Sorafenib

G. Antonelli[1], E. Gigante[1], M. Iavarone[2], P. Begini[1], P. Biondetti[3], A.M. Pellicelli[4], A. Sangiovanni[2], P. Lampertico[5], M. Marignani[6]. Email: giulio.antonelli@gmail.com

Background and Aims: Sarcopenia, a condition characterized by muscle wasting and considered a parameter of malnutrition, has been associated with poor outcomes in patients with cirrhosis and solid tumors. We analyzed the influence of sarcopenia on the survival of patients with advanced hepatocellular carcinoma (HCC) treated with sorafenib, the standard of care for this stage.
Method: We conducted a multicenter, retrospective study on 96 patients with advanced HCC treated with sorafenib. Patients with an abdominal computed tomography (CT) scan within 30 days from treatment start were enrolled. Data on pre-treatment anthropometric features, baseline laboratory findings, toxicity, treatment duration and overall survival (OS) were collected. Transverse CT images corresponding to third lumbar vertebrae (L3) were collected to calculate the skeletal muscle index, defining the presence of sarcopenia.
Results: In our cohort, patients were mainly males (78%) and sarcopenia was present in 49% of patients, with a significant major prevalence in women (M 37, 3% vs F 90,5% p = 0,00001). Patients were divided into two groups according to sarcopenia and compared: age was significantly higher in the sarcopenic group [66 years (31–87) *vs* 72 years (30–84)], while all other baseline features were similar, without significant difference in albumin levels, INR, body max index, serum sodium, creatinine, bilirubin and MELD score. Patients with

sarcopenia showed a significantly shorter OS [39 (95% CI 26–50) *vs* 61 (95% CI 47–77) weeks (p = 0.02)], as well as time on treatment of sarcopenic patients [12,3 (95% CI 8–19) vs 25,9 (95% CI 15–33) weeks], while no significant differences in the cause of drug interruption were detected. At multivariate analysis, sarcopenia was found to be an independent predictor of reduced OS (p = 0.028), and of a reduced time on treatment (p = 0.0032).
Conclusion: Sarcopenia measured with CT-scan is present in nearly half of patients with advanced HCC, and it can be used as a predictor of mortality and worse response to sorafenib.

THU-179

The prognostic factors between different viral etiologies among advanced hepatocellular carcinoma patients receiving sorafenib treatment

M.-L. Yeh, J.-F. Huang, M.-L. Yu, C.-Y. Dai, C.-F. Huang, S.-C. Chen, W.-L. Chuang. *Kaohsiung Medical University Hospital, Hepatobiliary Division, Department of Internal Medicine, Kaohsiung, Taiwan*
Email: jf71218@gmail.com

Background and Aims: Sorafenib currently is the first-line therapy for advanced hepatocellular carcinoma (aHCC) patients. However, the outcomes and prognostic factors of sorafenib therapy have not been well investigated. We aimed to investigate the pre-treatment factors and outcomes among Taiwanese aHCC patients receiving sorafenib treatment.
Method: A total of 347 patients with aHCC and well-compensated liver cirrhosis (Child-Pugh A) status receiving sorafenib were consecutively enrolled from Mar 2013 through Dec 2016. Pre-treatment clinical data and viral hepatitis markers were collected and analyzed with their outcomes. The primary endpoint of the study was overall survival. The factors associated with overall survival were also investigated.
Results: The median overall survival of all the patients was 238 days (range, 9–1,504 days) with a one-year overall survival of 43.2%. Positive hepatitis B surface antigen, portal vein thrombosis, receiving other therapeutic strategies, and pre-treatment alpha fetoprotein level ≥ 3,500 ng/ml were independent factors associated with overall survival. The median duration of sorafenib therapy was 93.0 days (range, 4–1,504 days). In chronic hepatitis B patients, total bilirubin level was the only independent factor associated with overall survival, whereas HBV DNA level did not play a significant role in it. HCVRNA negativity, tumor size, portal vein thrombosis, and white blood cell count were the independent factors associated with survival among those chronic hepatitis C patients.
Conclusion: There were different prognostic factors stratified by viral etiologies in aHCC patients receiving sorafenib. Viral eradication increased survival in chronic hepatitis C patients.

THU-180

Analyses of intermediate stage hepatocellular carcinoma patients from the point of view of designing clinical trials comparing transarterial chemoembolization and systemic therapies

K. Koroki[1], S. Ogasawara[1], Y. Ooka[1], M. Inoue[1], T. Chiba[1], E. Suzuki[1], M. Yokoyama[1], T. Maeda[1], T. Wakamatsu[1], K. Kobayashi[1], S. Kiyono[1], M. Nakamura[1], T. Saito[1], S. Nakamoto[1], S. Yasui[1], A. Tawada[1], M. Arai[1], T. Kanda[1], H. Maruyama[1], S. Kuboki[2], M. Miyazaki[2], O. Yokosuka[1], M. Ohtsuka[2], N. Kato[1]. *[1]Chiba University, Graduate School of Medicine, Department of Gastroenterology, Chiba, Japan; [2]Chiba University, Graduate School of Medicine, Department of General Surgery, Chiba, Japan*
Email: sadahisa@me.com

Background and Aims: Intermediate stage hepatocellular carcinoma (HCC) patients, particularly those who have low tumor burden, are able to achieve durable tumor control by transarterial chemoembolization (TACE). On the other hand, high tumor burden patients have a high frequency of recurrence and progression to advanced stage HCC. Several promising compounds or combinations thereof, including immune oncology, have shown favorable results for HCC in early phase clinical trials. Specifically, upcoming novel systemic therapies may have the potential to replace TACE, in particular for high tumor burden intermediate stage HCC patients. The goal of the present study was to assess the outcomes of TACE from the viewpoint of designing clinical trials comparing TACE and systemic therapies.
Methods: We retrospectively retrieved whole clinical courses of HCC patients who were initially diagnosed and identified intermediate stage HCC with high tumor burden at Chiba University Hospital between January 2003 and December 2015. The outcomes of TACE of these patients were assessed according to three definitions.
Results: Of 1161 patients, 408 were diagnosed as having intermediate stage HCC during their clinical course. According to the three definitions, 143 and 265 patients (largest tumor diameter [cm] + number of tumors >7: out of up to 7 criteria), 257 and 151 patients (≥4 lesions of size ≥ 5 cm or ≥ 8 lesions), and 279 and 129 patients (≥8 lesions) were identified as having intermediate stage HCC with low and high tumor burden, respectively, at the time of their initial diagnosis as intermediate stage HCC. The fractions of patients (according to all three definitions) who progressed from low to high tumor burden stage in intermediate stage HCC were 25.9% (out of up to 7 criteria, 37 patients), 21.4% (≥4 lesions of size ≥5 cm or ≥8 lesions, 55 patients), and 21.9% (≥8 lesions, 61 patients), respectively. Overall survival of patients receiving TACE for high tumor burden intermediate stage HCC of Child–Pugh class A were 28.2 months (up to 7 out, 203 patients), 22.1 months (≥4 lesions of size ≥5 cm or ≥8 lesions, 143 patients), and 21.5 months (≥8 lesions, 132 patients), respectively. There were no significant differences between patients who progressed from low to high burden and diagnosed as high burden at the time of initial diagnosed as intermediate stage HCC.
Conclusions: Because our results indicated that outcomes of TACE in high tumor burden intermediate stage HCC were related to tumor status and not associated with previous clinical courses in intermediate stage HCC, identifying a suitable population for comparison might be significant when designing clinical trials of TACE versus systemic therapies.

THU-181

Impact of BCLC treatment stage migration in the survival of patients with hepatocellular carcinoma

S. Acosta-López[1], D.D. Bethencourt[1], J. Plata-Bello[2], E.B. Garrido[1], F.A.P. Hernández[1], A.G. Rodríguez. *[1]Hospital Universitario Nuestra Señora de la Candelaria, Liver Unit, Santa Cruz de Tenerife, Spain; [2]Hospital Universitario de Canarias, La Cuesta, Spain*
Email: sacostalopez9@gmail.com

Background and Aims: The Barcelona-Clinic Liver Center (BCLC) classification determines the best therapeutic option in each liver cancer stage. However, some clinical conditions may lead to a migration in the first-line treatment to other therapeutic option. This situation seems to be usual, but the impact of this treatment-migration has not been entirely studied. The aim of the present work is to analyze the causes and impact of treatment migration in each BCLC stages in terms of overall survival.
Method: A prospective registry of patients with a diagnosis of hepatocellular carcinoma have been performed since January 2011. One-hundred and thirty-eight patients were included in the study. The BCLC classification system was used to identify the first-line-treatment that corresponded for each stage. Treatment stage migrations were also identified and analyzed. Non-parametric tests were used to identify differences between first-line vs. migration treatment groups in each BCLC stage. Survival analysis in each BCLC stage was performed. Statistical significance was considered when p-value was below 0.05.

Results: Thirty-three percent of patients had a treatment stage migration (43.5% of patients in BCLC A; 18.9% in BCLC B; and 50% in BCLC C).
Regarding BCLC A patients, migration-treatment patients were significantly older than the patients who receive the first-line-treatment (p < 0.001). OS was significantly higher in the last group (median survival of 90.0 months vs. 24.3 months) (p < 0.001). Hazard ratio (HR) for migration-treatment group (adjusted by age) in BCLC A patients was 3.11 (95% C.I. of 1.2–7.7) (p = 0.015).
Bearing in mind BCLC B patients, migration-treatment group presented a higher number of lesions than first-line-treatment group (p = 0.01). The OS was also significantly higher in the first-line-treatment patients (median survival of 31.8 vs. 7.9 months) (p = 0.003). HR for migration-treatment was 4.9 (95% C.I. of 1.3–17.8).
Finally, BCLC C patients showed a different distribution of CHILD categories between the treatment groups. All patients in the first-line treatment group of BCLC C patients were classified as CHILD A, while only 33% of migration-treatment presented such categorization. No differences in OS were identified between both treatment groups (p = 0.225).

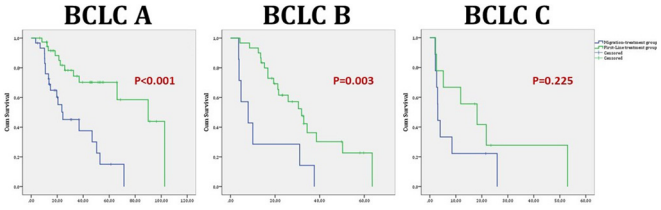

Figure 1: Kaplan-Meier survival analysis for both treatment groups in each BCLC stages where migration stage treatment was present.

Conclusion: BCLC A and BCLC B hepatocellular carcinoma patients with a treatment stage migration present a significant worse prognosis than patients with first-line-treatment options.

THU-182
ALBI is an independent predictor ofsurvival in resected patients with HCC

P. Kolly[1,2], L. von Köckritz[2], V. Isabelle[1], B. Vanessa[2], J.-F. Dufour[1,2].
[1]Hepatology, Department for BioMedical Research, University of Bern, Bern, Switzerland; [2]University Clinic for Visceral Surgery and Medicine, Inselspital, Switzerland
Email: philippe.kolly@students.unibe.ch

Background and Aims: Hepatic functional reserve is assessed by the Child-Pugh score which is a predictive factor for survival in HCC patients. In those undergoing surgical resection, the Child-Pugh score is of low significance, since most of those patients are Child-Pugh grade A. Furthermore, Child-Pugh score should not be used in non-cirrhotic patients, who mostly undergo surgical resection. We investigated whether the Albumin-Bilirubin (ALBI) score which is based on bilirubin and albumin is predictive of survival after HCC resection.
Method: Patients of the prospective Bern HCC Cohort at the University Hospital Bern, Switzerland were analyzed. The ALBI score and grade (A1-A3) was calculated for every patient. The association between overall survival (OS) and the ALBI score was assessed and multivariate Cox regressions were used to control for confounding variables. The Log-Rank statistic was used to assess the difference in survival of the ALBI grade. Additionally, the ability to predict OS was compared between the ALBI score and the total bilirubin using Nagelkerke's pseudo R2.
Results: Of 375 eligible HCC patients, 62 underwent a surgical resection. Mean ALBI score was –2.32, SD 0.56. Univariate cox regression analysis showed that the ALBI score was strongly associated with the overall survival (HR: 5.476, 95% CI: 2.137–14.031, p < 0.001). The different ALBI grades showed significant difference in their survival (p < 0.001) with a mean OS of 2309 (95% CI: 1788–2823), 1345 (95% CI: 1127–1563) and 505 (95% CI: 486–524) days for A1, A2, A3, respectively. Furthermore, the ALBI score remained independently predictive when controlling for age, sex, tumor size, number of nodules, AFP and comorbidities (alcohol consumption and diabetes). Nagelkerke's pseudo R2 was 0.49 for ALBI score and 0.28 for bilirubin.
Conclusion: The ALBI score is an independent predictor of survival in resected HCC patients. The ALBI score predicts 49% of the variance and bilirubin only 28%. Therefore, the ALBI score is a better predictor of OS than bilirubin. The different ALBI grades show significantly different mean OS and could be used in treatment allocation algorithms for surgical resection of HCC patients.

THU-183
Portal vein tumor thrombosis has a direct impact on liver function

R. Kloeckner, A. Maehringer-Kunz, D.P. Dos Santos, S. Schotten, D. Graafen, F. Meyer, S. Koch, C. Düber, P. Galle, A. Weinmann. *Medical Center of the Johannes Gutenberg University, Department of Diagnostic and Interventional Radiology, Mainz, Germany*
Email: roman.kloeckner@gmail.com

Background and Aims: Portal vein tumor thrombosis (PVTT) has a significant impact on the prognosis of patients with hepatocellular carcinoma (HCC). However, the mechanisms leading to shorter survival of such patients are still unknown. According to our clinical experience, the liver function deteriorates in such patients, considerably limiting treatment options. Aim of this study was to quantify liver function impairment due to newly diagnosed PVTT.
Method: A total of 1478 patients with proven HCC were treated in our tertiary referral center between 01/2005 and 01/2017. As we aimed for an intraindividual comparison to minimize confounding factors, we only included patients with a newly diagnosed PVTT during the observation period. Inclusion criteria were: proven HCC; PVTT-negative CT or MRI followed by at least one PVTT-positive CT or MRI; availability of all laboratory values needed to calculate Model for End-Stage Liver Disease (MELD)-, and Albumin-Bilirubin (ALBI)-score. Albumin, AST, bilirubin, MELD-, and ALBI-score were calculated before and after the diagnosis of PVTT. PVTT was diagnosed in consensus by re-evaluation of all available CT- or MRI-studies by two board certified radiologists experienced in abdominal oncologic imaging.
Results: In total, 134 patients developed a new PVTT during the observation period. Between the last PVTT-negative imaging and the first PVTT-positive imaging, AST increased from 74.8 to 95.4 U/l (p = 0.005), bilirubin from 1.53 to 2.04 mg/dl (p = 0.004), MELD from 10.4 to 11.3 points (p = 0.006), and ALBI from 2.0 to 2.2 points (p = 0.026). Albumin decreased from 32.8 to 30.4 g/l (p = 0.002).
Conclusion: New PVTT is associated with a significant impairment of liver function, considerably limiting treatment options. Therefore, meticulous evaluation of cross-sectional imaging is crucial for the clinical management of patients with HCC.

THU-184
A novel model for the outcome prediction of transarterial chemoembolization in patients with unresectable hepatocellular carcinoma with or without impaired hepatic function

H.Y. Kim[1], A.R. Choi[1], H.A. Lee[2], T.H. Kim[1], K. Yoo[1], M. Kim[3], S.Y. Choi[3].
[1]Ewha Womans University College of Medicine, Department of Internal Medicine, Seoul, Republic of South Korea; [2]Ewha Womans University Mokdong Hospital, Clinical Trial Center, Seoul, Republic of South Korea; [3]Ewha Womans University College of Medicine, Department of Radiology, Seoul, Republic of South Korea
Email: hwiyoung@gmail.com

Background and Aims: There are several prognostic systems for the assessment of patient suitability of transarterial chemoembolization (TACE) for unresectable hepatocellular carcinoma (HCC). However,

the decision of first TACE still remains challenging, especially in those with impaired hepatic function. The aims were (i) to identify prognosticators in patients undergoing TACE, (ii) to develop a prognostic scoring system, and (iii) to investigate the outcomes according to the scores in patients with/without impaired hepatic functional reserve.

Method: Between January 2006 and December 2015, a total of 240 consecutive HCC patients with baseline Child-Pugh score ≤ 8 were enrolled, who underwent TACE as an initial treatment for unresectable tumors without macrovascular invasion or extrahepatic spread. Tumor- and liver function-related risk factors for overall survival were explored using Cox model.

Results: Median age was 68.5 years, and 186 patients were male (77.5%). Etiologies of underlying liver diseases were mostly viral (n = 165, 68.8%) or alcoholic (n = 30, 12.5%). Multiple tumors were found in 120 patients (50.0%), and median maximal tumor diameter was 3.0 cm (interquartile range [IQR], 1.7–5.5). Median alpha-fetoprotein (AFP) was 19.5 ng/ml (IQR, 6.0–252.0). Child-Pugh classes were A in 194 patients (80.8%) and B in 46(19.2%), respectively. Median neutrophil-to-lymphocyte ratio (NLR) was 1.92(IQR, 1.34–3.12). Median AST and ALT were 43.5 IU/l (IQR, 32.0–64.0), and 33.0 IU/l (23.0–51.0), respectively. Hepatoma arterial-embolisation prognostic (HAP) score D and modified HAP score D were in 99 patients (41.3%) and in 49(20.4%), respectively. Albumin-bilirubin (ALBI) grades were 1 in 59 patients (24.6%), 2 in 162(67.5%) and 3 in 19(7.9%), respectively. Multivariable Cox model identified the following prognostic factors: number of tumors (hazards ratio [HR], 1.484; $p = 0.001$); ALBI grade (HR, 1.696; $p = 0.002$); Log AST (HR, 1.914; $p < 0.001$); Log NLR (HR, 1.675; $p < 0.001$); Log AFP (HR, 1.104; $p = 0.038$). A scoring system (A3N2) was developed by assigning points as shown in Table 1. C-index for the prediction of overall survival (OS) was 0.75 (95% confidence interval, 0.70–0.78, by bootstrapping [n = 100]). For all patients, median OS were 45 mo with A3N2 < 3 vs. 13 mo with A3N2 ≥ 3, respectively ($p < 0.001$). For Child-Pugh class B patients, median OS were 36 mo with A3N2 < 3 vs. 9 mo with A3N2 ≥ 3, respectively ($p = 0.030$). However, no significant differences in OS were observed in Child-Pugh class B patients using HAP score ($p = 0.709$) or modified HAP score ($p = 0.745$).

Table 1: A3N2 scoring system

	SCORE			
	0	1	2	3
ALBI grade	0	1		2
AST (IU/l)	<80	≥80		
AFP (ng/ml)	<200	≥200		
Number of tumors	1	2–3	>3	
NLR	<2	≥2		

Conclusion: A novel scoring system (A3N2) may be helpful in treatment selection in patient with unresectable HCC undergoing TACE, especially those with impaired hepatic function.

Randomized trial of preoperative administration of oral pregabalin for postoperative analgesia in patients scheduled for radiofrequency ablation of focal lesions in the liver

S. Abd-Elsalam[1], A.S. Hanafy[2]. [1]*Tanta University, Tropical Medicine Department, Tanta, Egypt;* [2]*Zagazig University, Internal Medicine Department*
Email: sheriefabdelsalam@yahoo.com

Background and Aims: The aim of this study was to evaluate the effect of preoperative pregabalin on postoperative analgesia in patients presented for radiofrequency ablation of hepatic focal lesions.

Method: This randomized controlled study was carried out on 70 adult patients with hepatocellular carcinoma presented to Tanta University Hospital for radiofrequency ablation of hepatic focal lesions. They were randomized into two groups, 35 patients in each group: Group I: Patients in this group received placebo and Group II: patients in this group received 150 mg of oral pregabalin one hour before the procedure. The primary outcome was the analgesic effect in the form of the severity of postoperative pain and the need of opioid analgesics. Our secondary outcome was the safety of the drug in the form of incidence of side effects.

Results: Regarding pain assessed by visual analogue pain scale (VAS Pain) post operatively, there were no significant differences between both groups immediately postoperative ($p = 0.84$), then a highly significant difference in pain ($p = 0.00$) between two groups had been noticed as pregabalin showed high efficacy in decreasing pain in group II compared to group I, also patients received pregabalin had decreased requirements for the use of post operative analgesics. Regarding side effects, there was no significant difference regarding blood pressure ($p = 0.74$) nor oxygen saturation ($p = 0.53$) between the two studied groups, on the other hand patients in pregabalin group showed fewer side effects as nausea, vomiting ($p = 0.01$) and bradycardia ($p = 0.02$) and were discharged earlier when compared with the other group ($p = 0.01$).

Conclusion: Oral pregabalin is safe and effective for postoperative analgesia in patients scheduled for radiofrequency ablation of focal lesions in liver.

[ClinicalTrials.gov Identifier: NCT03151213]

Comparison of efficacy between sorafenib monotherapy vs. transarterial chemoembolization – sorafenib sequential therapy in hepatocellular carcinoma patients with extrahepatic metastatis – An interim analysis of randomized controlled trial

H.J. Yim[1], S.J. Suh[1], Y.K. Jung[1], S.B. Cho[2], W.J. Chung[3], Y.S. Kim[4], S.H. Bae[5], J.Y. Park[6]. [1]*Korea University College of Medicine, Internal Medicine;* [2]*Chonnam National University Medical School, Internal Medicine;* [3]*Keimyung University College of Medicine, Internal Medicine;* [4]*Soonchunghyang University College of Medicine, Internal Medicine;* [5]*College of Medicine, The Catholic University of Korea, Internal Medicine;* [6]*Yonsei University College of Medicine, Internal Medicine*
Email: gudwns21@korea.ac.kr

Background and Aims: Sorafenib is the standard therapy for hepatocellular carcinoma (HCC) with extrahepatic metastasis (EHM). However, transarterial chemothembolization (TACE) which is a standard therapy for intermediate stage may be beneficial for controlling intrahepatic tumour, thereby providing chance of improving survival in HCC patients with EHM.

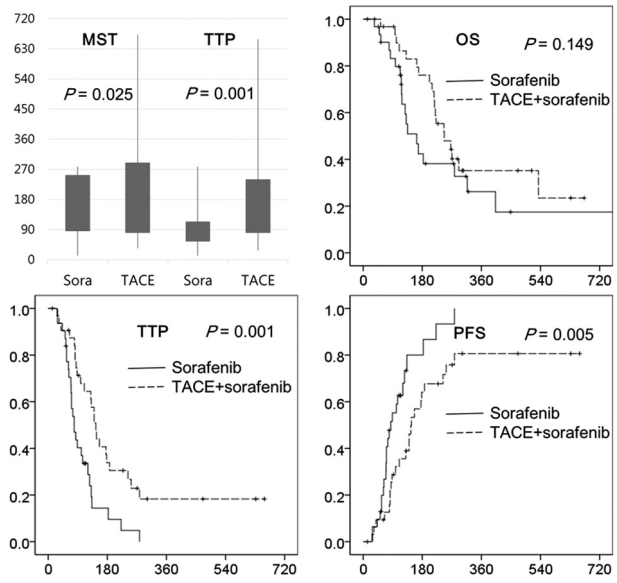
We aimed to compare the efficacy between the sorafenib monotherapy and TACE-sorafenib sequential therapy in HCC patients with EHM.

Method: This study is a prospective randomized controlled study conducted at 6 tertiary hospitals in South Korea. HCC patients with EHM were enrolled and randomized into sorafenib monotherapy or TACE-sorafenib sequential therapy group. Patients with main portal vein invasion, Child-Pugh class B or C, and history of TACE or previous systemic therapy were excluded. The sorafenib monotherapy group received sorafenib immediately after randomization while the TACE-sorafenib group received 2–4 times of TACE before starting sorafenib. Response evaluation was performed every 2 months, and time to progression (TTP), progression free survival (PFS), median survival time (MST), and overall survival (OS) were compared. We initially planned 130 patients for the present study, and the results of interim analysis are presented.

Results: A total of 64 patients were enrolled currently: 32 patients into the monotherapy and 32 into the sequential therapy group. Baseline characteristics of the patients such as gender, age, aetiology of liver disease, Child-Pugh score, HCC stage, and tumour burden were not significantly different between the groups. Median TTPs

were 77 days in the monotherapy group and 140 days in the sequential therapy group (p = 0.001). In addition, MST was longer in the sequential therapy group (117 vs. 225 days, respectively, p = 0.025).

The probability of survival rates were plotted by Kaplan-Meier curve and compared by log-rank test. The OS was not different in both groups (p = 0.149). However, the TTP rates were longer in sequential therapy group than monotherapy group (p = 0.001), and the PFS rates were also better in the sequential therapy group (p = 0.005).



Conclusion: The TACE-sorafenib sequential therapy would be a better strategy than sorafenib monotherapy for the treatment of HCC patients with EHM, especially, in controlling tumour progression.

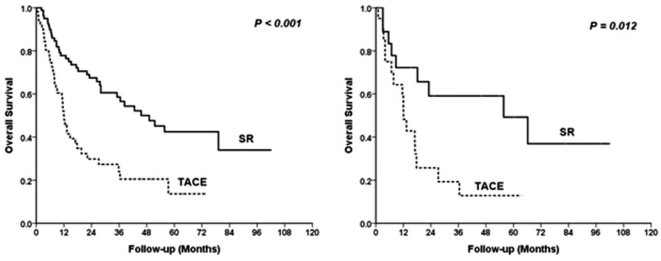
A comparison of surgical resection and transarterial chemoembolization for solitary hepatocellular carcinoma larger than 10 cm: A propensity score matching analysis

H.-S. Lu[1], C.-W. Su[1,2], W.-Y. Kao[2,3], T.-I. Huo[1,4], Y.-H. Huang[1,2,5], M.-C. Hou[1,2], H.-C. Lin[1,2], J.-C. Wu[5,6]. *[1]Taipei Veterans General Hospital, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan; [2]National Yang-Ming University, Faculty of Medicine, School of Medcine, Taipei, Taiwan; [3]Taipei Medical University Hospital, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan; [4]National Yang-Ming University, Institute of Pharmacology, Taipei, Taiwan; [5]National Yang-Ming University, Institute of Clinical Medicine, Taipei, Taiwan; [6]Taipei Veterans General Hospital, Department of Medical Research, Taipei, Taiwan*
Email: cwsu2@vghtpe.gov.tw

Background and Aims: The optimal staging (early vs. intermediate) and treatment for patients with single large hepatocellular carcinoma (HCC) is not fully elucidated. We aimed to compare the treatment efficacy and prognosis between surgical resection (SR) and transarterial chemoembolization (TACE) for patients with solitary huge HCC.

Method: We retrospectively enrolled 135 patients with treatment-naïve solitary HCC ≥ 10 cm in size, with good performance status and liver functional reserve, and without vascular invasion or extra-hepatic metastasis from 2007 to 2013. Baseline characteristics were collected to identify the risk factors determining poor overall survival (OS) after therapy by multivariate Cox proportional hazards models. Moreover, to minimize the potential selection bias between SR and TACE, we further performed a propensity score matching analysis by one-to-one nearest-neighbor matching method.

Results: A total of 84 patients and 51 patients underwent SR and TACE, respectively. The SR group were younger, higher hemoglobin level, higher serum albumin, higher BUN, and lower glucose level than the TACE group. After a median follow-up of 17.0 (interquartile range 7.3–36.9) months, 75 patients had died. The cumulative 1, 3, and 5-year OS rate were 93.7%, 73.6%, 52.2% for the SR group and 76.5%, 34.8%, 13.7% for the TACE group, respectively (p < 0.001, Figure A). A multivariate analysis showed that TACE (Hazard ratio, HR 2.764, 95% confidence interval, CI 1.707–4.475, p < 0.001), serum AFP levels > 400 ng/ml (HR 2.065, 95% CI 1.283–3.322, p = 0.003) and albumin-bilirubin grade > 1 (HR 1.688, 95% CI 1.033–2.759, p = 0.036) were the independent risk factors associated with poorer OS. After propensity score matching analysis to adjust for baseline differences, 20 pairs of matched patients were selected from each treatment arm. Patients who underwent SR still had a significantly better survival than patients who underwent TACE (p = 0.012, Figure B).



Conclusion: SR provided a better long-term survival than TACE for patients with solitary huge (≥10 cm) HCC. SR is recommended as the therapeutic priority for these patients.

THU-188

Phase II trial using combination of TACE and SBRT for unresectable single large HCC: preliminary report

M. Buckstein[1], E. Kim[2], A. Fischman[2], M. Facciuto[3], M. Sung[4], B. Taouli[2], J. Llovet[5], M. Schwartz[5], K. Rosenzweig[1]. *[1]Icahn School of Medicine at Mount Sinai, Radiation Oncology, New York, United States; [2]Icahn School of Medicine at Mount Sinai, Radiology, New York, United States; [3]Icahn School of Medicine at Mount Sinai, Surgery, New York, United States; [4]Icahn School of Medicine at Mount Sinai, Medicine, New York, United States; [5]Icahn School of Medicine at Mount Sinai, Liver Medicine, New York, United States*
Email: michael.buckstein@mountsinai.org

Background and Aims: Patients with hepatocellular carcinoma (HCC) stage A not suitable for surgical therapies are first considered for local ablation. Nonetheless, objective responses and long-term results for ablation in large tumors (i.e. those >3 cm) are suboptimal. This pilot phase II trial studies combination transarterial chemoembolization (TACE) and Stereotactic Body Radiation Therapy (SBRT) for BCLC A patients with HCC from 4 to 7 cm.

Method: Patients were eligible if they were BCLC A, Child-Pugh score ≤7, had a single HCC from 4 to 7 cm, no evidence of macrovascular invasion, no evidence of metastatic disease, ECOG 0, and were not suitable for resection or liver transplantation. Treatment consisted of drug-eluting bead (DEB)-TACE at time 0 and 1 month followed by SBRT completed within 2–3 weeks following TACE. Each DEB-TACE treatment utilized 1 vial of 100–300 micron LC Beads (BTG) loaded with 50 mg of doxorubicin. SBRT was delivered from 35 to 50 Gy in 5 fractions. The primary end-point of the study was best objective response by mRECIST (measured 1 month post-treatment and every 3 months thereafter). Secondary endpoints were progression free survival (PFS), cancer specific survival (CSS), overall survival (OS) assessed using the Kaplan-Meier method.

Results: From 2014 to 2017, 20 patients were enrolled in a single institution with a median follow of 13 months (range 1–30). Baseline patient characteristics are shown in Table 1. Every patient completed

the protocol as planned except one who only received DEB-TACEx1 before SBRT. 19 patients had at least one post treatment scan to assess mRECIST response (one patient lost to follow up). Best objective response in the target lesion was 95%: 74% complete response (n = 14), 21% partial response (n = 4), 0%stable disease, and 5% progression of disease (n = 1). PFS at 1 year was 66%, CSS at 1 year was 88%, and OS at 1 year was 69%.

Baseline characteristic	N (% or range)
Median age (yrs)	68 (52–88)
Child-Turcott-Pugh Score	
A	18 (90)
B	2 (10)
Etiology	
HCV	13 (65)
HBV	1 (5)
Other (NASH, alcohol, unknown)	7 (35)
Median tumor size (cm)	4.6 (4–6.9)
Median baseline AFP (ng/mL)	18 (2–1923)
Median SBRT dose (Gy)	45 (35–50)

Conclusion: Preliminary results from this Phase II trial show very promising response rates when combining TACE + SBRT in large, unresectable HCC with excellent PFS and CSS at one year. These preliminary data are currently being confirmed in an expanded cohort.

Berg[5]. *[1]University Hospital Leipzig, Section of Hepatology, Department of Gastroenterology, Leipzig, Germany; [2]University Hospital Leipzig, Klinik für Diagnostische und Interventionelle Radiologie, Germany; [3]University Hospital Leipzig, Klinik und Poliklinik für Nuklearmedizin, Germany; [4]University Hospital Leipzig, Onkologisches Zentrum am Universitären Krebszentrum, Leipzig, Germany; [5]University Hospital Leipzig, Section of Hepatology, Department of Gastroenterology, Germany; [6]University Hospital Leipzig, Hepatobiliäre Chirurgie und viszerale Transplantation, Germany*
Email: florian.vanboemmel@medizin.uni-leipzig.de

Background and Aims: Radioembolization by Yttrium-90 Selective Internal Radiotherapy (^{90}Y SIRT) has is associated with a similar survival as the multikinase inhibitor sorafenib in the treatment of patients with intermediate- to advanced-stage hepatocellular carcinoma (HCC). However, the role of SIRT in the multimodal treatment for HCC is not well defined. We have retrospectively assessed the efficacy and safety of SIRT in patients with advanced HCC receiving different sequential interventional or systemic treatments.
Method: 109 patients (87 male, mean age 64 ± 0.9 (range, 36–85) years, 73 with liver cirrhosis Child-Pugh A (n = 60), B (n = 12) or C (n = 1)) with advanced HCC who had received SIRT (1, 2 and 3 applications in 89, 19 and 1 patient; mean dose, 3,365 ± 1,902 GBq, 90Y glass microspheres) in terms of a multimodal HCC treatment approach between 2012 and 2016 in one center were retrospectively analysed. Before SIRT, BCLC scores A1, A2, A4, B and C applied to 2, 6, 5, 67 and 25, ECOG scores 0–3 in 56, 27, 8 and 1, ALBI scores 1–3 in 55, 47 and 5 and CLIP scores 1 to 3 in 12, 74 and 11 patients, respectively. HCC was present in the left, right or in both liver lobes in 12, 40, and in 52 patients. Before or after SIRT, transarterial chemoembolization was performed in 44 and 19 patients, and sorafenib treatment in 25 and 24 patients, respectively. Three patients received liver transplantation after SIRT.
Results: The mean overall survival (OS) after first diagnosis of HCC was 21 ± 1.5 (range, 2–78) months, as compared to 19 months estimated by CLIP score, and 12 patients survived longer than 36 months. After first SIRT the mean OS was 10 ± 0.96 (range, 0–54) months, and 45 patients (49%) showed radiological response. The mean time to progression after SIRT was 5.9 ± 0.7 (range, 0–54) months. Risk factors for shorter OS were liver adverse events (increase in ALT >5 times over baseline or worsening in Child-Pugh score) (p = 0.002) and an ALBI score of 3 at baseline (p = 0.004). Liver toxicity was diagnosed in 6 patients (7%), and associated with elevated gGT (p = 0.027) or ALT (p= 0.023) before, and an ALBI score of 3 after SIRT (p = 0.032).
Conclusion: SIRT as part of a multimodal treatment approach was safe and associated with a promising OS when compared to predicted survival by the CLIP score. Further studies may identify patients who benefit from SIRT and should investigate the potential of concomitant and sequential interventional and novel systemic treatment approaches.

THU-190

Ubr Ubiquitin ligases as modulators of inflammation in hepatocellular carcinoma

D. Leboeuf[1], M. Nesterchuk[1], E. Smekalova[2], A. Mikaelyan[1], D. Anderson[2], T. Zatsepin[1], K. Piatkov[1]. *[1]Skoltech, Translational Biomedicine, Moscow, Russian Federation; [2]MIT, Koch Institute for Integrative Cancer Research, Cambridge, United States*
Email: dominique.leboeuf@skoltech.ru

Background and Aims: The N-end rule pathway is an emerging player in the field of cancer biology, because of its capacity to positively regulate many hallmarks of cancer including angiogenesis, cell proliferation, motility and survival, offering the potential to be a target for an effective anti-tumor treatment. Hepatocellular Carcinoma (HCC) is the fifth most common cancer worldwide and the third leading cause of cancer-related deaths in the world. HCC is an aggressive cancer resistant to all conventional chemotherapies, highlighting the need to look for new therapeutic options. Therefore, the aim of this study is to investigate the role of the N-end rule pathway in the context of hepatocellular carcinoma in vivo, using an siRNA-mediated RNA interference approach for selective down-regulation of the four N-end rule-dependent ubiquitin ligases: UBR1, UBR2, UBR4 and UBR5.
Method: Downregulation of Ubrs was achieved using siRNA formulated into lipid nanoparticles (LNP). *In vitro* phenotyping was performed using proliferation assays, migration assays, and TUNEL assays. Then, LNPs were injected into mice for toxicity and efficacy studies. Blood biochemistry analysis, histology, flow cytometry, qPCR and Western Blot were used to assess toxicity and efficacy.
Results: We obtained successful downregulation of Ubrs *in vitro* and demonstrated that knock down of these four Ubr proteins negatively affects cell migration and proliferation, and renders cells more susceptible to apoptosis. Bi-weekly injections of the LNPs in mice for a period of up to 6 weeks efficiently downregulates the expression of *Ubrs* without any significant toxic effects. However, we observed a significant increase in the spleen/body weight ratio in mice treated with Ubr-LNPs, as well as an infiltration of neutrophils in the livers of these same mice. Treatment of HCC bearing mice with Ubr-LNPs worsened the tumor load due to the increased inflammation in the liver.
Conclusion: Downregulation of Ubrs leads to impaired proliferation, migration, and an increased susceptibility to apoptosis, in vitro. However, long-term downregulation of these same proteins in the liver recruits the immune system and induces inflammation. In the context of liver cancer, this leads to an increased tumor load. Using a combination of Ubr-LNPs at lower doses with chemotherapeutic drugs could harness the potential to increase apoptosis susceptibility in cancerous cells while reducing doses of chemotherapeutic drugs and their subsequent side effects.

Autoimmune and chronic cholestatic liver disease: Clinical aspects

THU-191

Extrahepatic autoimmune diseases in patients with autoimmune hepatitis and their relatives: a Danish nationwide family cohort study

L. Grønbæk[1], H. Vilstrup[2], L. Pedersen[3], P. Jepsen[3]. *[1]Aarhus University Hospital, Clinical Epidemiology, Aarhus, Denmark; [2]Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark; [3]Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus, Denmark*
Email: groenbaek.lisbet@gmail.com

Background and Aims: It is widely accepted that patients with autoimmune hepatitis (AIH) have an increased prevalence of extrahepatic autoimmune diseases, and it is widely believed that their relatives share this trait, but it has not been epidemiologically studied in a satisfactory setting. We therefore conducted a nationwide registry-based family cohort study on this issue.
Method: From the Danish healthcare registries for 1994–2015 we included 2,745 patients with AIH, 17,812 of their first- and second-degree relatives, and 27,450 general population controls age- and gender-matched to the patients. We compared the gender- and -age-specific prevalence of extrahepatic autoimmune diseases between the patients with AIH, their first- and second-degree relatives, and the controls. We computed the prevalence ratio of extrahepatic autoimmune diseases relative to the controls.
Results: In the patients with AIH, the prevalence ratio of extrahepatic autoimmune diseases ranged from 7 to 10 up to age 30 years (prevalence ratio at age 20 = 9.92, 95% confidence interval 6.21–15.83), after which it declined to about 2 in old age (prevalence ratio at age 80 = 2.37, 95% confidence interval 1.89–3.00). In the patients' families, neither first- nor second-degree relatives had an increased prevalence of extrahepatic autoimmune diseases (prevalence ratio for first- and second-degree relatives at age 20 = 1.11, 95% confidence interval 0.72–1.70; and prevalence ratio at age 80 = 0.96, 95% confidence interval 0.70–1.31).
Conclusion: These population-based findings confirm that patients with AIH are highly prone to extrahepatic autoimmune diseases, but their relatives are not. Our data do not support the notion that patients with AIH and their family members share a general autoimmune predisposition.

THU-192

Pregnancy and birth outcomes in a Danish nationwide cohort of women with autoimmune hepatitis and matched population controls

L. Grønbæk[1,2], H. Vilstrup[2], P. Jepsen[1,2]. *[1]Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus N, Denmark; [2]Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus C, Denmark*
Email: groenbaek.lisbet@gmail.com

Background and Aims: Many patients with autoimmune hepatitis (AIH) are women of fertile age. Some major concerns for these patients are related to pregnancy. We conducted a nationwide study on risk of miscarriage, birth rate, and birth outcomes in women with AIH.
Method: We collected data from Danish healthcare registries for 1994–2015. We included 1,947 women with AIH and 19,470 age- and gender-matched population controls. We calculated the risk of miscarriage and the birth rate in premenopausal women with AIH and controls. We used logistic regression to compare the odds of adverse birth outcomes (preterm birth, small for gestational age, congenital malformations, and stillbirth) between women with AIH and controls. We adjusted for mother's age and smoking habits, and we conducted separate analyses for AIH patients on vs. off immunosuppressive treatment and with vs. without cirrhosis.
Results: The risk of miscarriage was similar in women with AIH and controls: risk ratio 1.16 (95% confidence interval [CI] 0.80–1.69). At first-time birth, the age was similar in women with AIH and controls. The first-time birth rate per 1000 person-years in women with AIH was 37 (95% CI 29–46), in controls 32 (95% CI 30–35). In women with AIH there were 176 births, 70 of which were first-time births. The women with AIH had an increased risk of preterm birth (adjusted odds ratio 3.29, 95% CI 1.62–6.67) and small for gestational age children (adjusted odds ratio 4.65, 95% CI 0.83–26.04) but not of other adverse birth outcomes. Birth outcomes were similar in AIH patients on vs. off immunosuppression and with vs. without cirrhosis.
Conclusion: In this Danish cohort of women with AIH, fertility was unaffected. The women with AIH had an increased risk of preterm birth and small for gestational age children but not of other adverse birth outcomes.

THU-193

Autoantibodies against Huntingtin-interacting protein 1-related protein are superior to conventional autoantibodies in diagnosing autoimmune hepatitis in children

R. Taubert[1], J. Diestelhorst[2,3], N. Junge[2], N.T. Baerlecken[4], M. Yüksel[5], M. Hussain[5], Y. Ma[5], M.P. Manns[1], T. Witte[4], U. Baumann[2], E. Jaeckel[3]. *[1]Dept. of Gastroenterology, Hepatology and Endocrinology, Hannover Medical School, Hannover, Germany; [2]Hannover Medical School, Pediatric Gastroenterology and Hepatology, Department of Pediatric Kidney, Liver and Metabolic Diseases, Hannover, Germany; [3]Hannover Medical School, Gastroenterology, Hepatology and Endocrinology, Hannover, Germany; [4]Hannover Medical School, Clinical Immunology, Hannover, Germany; [5]King's College London, Liver Sciences; Faculty of Life Sciences & Medicine, School of Immunology and Microbial Sciences, London, United Kingdom*
Email: taubert.richard@mh-hannover.de

Background and Aims: Autoantibodies are key parameters in the diagnostic of paediatric autoimmune hepatitis (pAIH) among those with chronic liver diseases. However, conventional autoantibodies such as anti-nuclear (ANA), anti-smooth muscle (SMA), anti-liver kidney microsomal antibodies (LKM) and antibodies against soluble liver antigen (SLA) either lack high sensitivity or high specificity. We screened for alternative autoantibodies with a better clinical performance.
Method: Antibodies against Huntingtin-interacting protein 1-related protein (HIP1R) were identified via a protein macroarray in adult patients with AIH. Next, antibodies against a HIP1R fragment, measured with an ELISA, were compared to conventional autoantibodies in two independent retrospective cohorts from two center both including children with untreated AIH (total number: 67), other chronic liver disease (total number: 69) or without liver diseases (total number: 35).
Results: Children with untreated pAIH (type I and II) had the highest IgG antibody concentrations against HIP1R compared to AIH overlap syndromes, non-AIH liver diseases and children without liver diseases ($p < 0.001$ for all comparisons).
With the receiver operating characteristic the optimal cut-off for the distinction between untreated pAIH and other liver diseases was identified (43.3 arbitrary units), which is lower than in adults (52.7 arbitrary units). For the identification of untreated pAIH anti-HIP1R antibodies with this cut-off (AUC: 0.95 (confidence interval: 0.90–0.99); OR: 87.7; 21.3–362.4) achieved a significantly higher sensitivity (0.94; 0.82–0.98) and negative predictive value (0.93; 0.80–0.98) with the highest overall accuracy (0.90; 0.80–0.98) compared to ANA (0.81; 0.72–0.88), SMA (0.72; 0.62–0.80), LKM (0.51; 0.41–0.61) and SLA (0.48; 0.37–0.59) antibodies in the training cohort from Hannover/Germany (n = 96). The specificity (0.85; 0.72–0.94) and positive predictive value (0.87; 0.74–0.94) from anti-HIP1R

antibodies were not significantly different from ANA and SMA in this cohort.
In the external validation cohort from London/UK (n = 40) untreated pAIH had a bit lower anti-HIP1R antibody concentrations but still achieved the highest OR (34.3; 3.8–313.8) and overall accuracy (0.80; 0.64–0.90) compared to ANA and SMA. Due to the smaller sample number in the validation cohort only the specificity of anti-HIP1R (0.95; 0.74–1.00) was significantly higher than for SMA ($p < 0.05$).
Conclusion: Anti-HIP1R autoantibodies seem superior to conventional autoantibodies (ANA, SMA, LKM) by a better clinical prediction of AIH and by a simpler ELISA assay compared to the demanding immunofluorescence titration on rodent tissue section.

THU-194
Time trends in liver transplantation for primary biliary cholangitis in Europe over the past three decades
M. Harms[1], Q. Janssen[1], R. Adam[2], C. Duvoux[3], H.V. Buuren[1], B. Hansen[1,4], H. Metselaar[1]. *[1]Erasmus University Medical Center, Gastroenterology and Hepatology, Rotterdam, Netherlands; [2]AP-HP Paul-Brousse Hospital, Paris Sud University, Hepato- Biliary Center, Villejuif, France; [3]European Liver Transplant Registry, Paul Brousse Hospital, France; [4]Toronto General Hospital, Toronto Centre for Liver Disease, Toronto, Canada*
Email: m.h.harms@erasmusmc.nl

Background and Aims: Primary biliary cholangitis (PBC) has long been a leading indication for liver transplantation (LT). Changes in selection criteria for LT and in the epidemiology of PBC, as well as the introduction of ursodeoxycholic acid as an effective treatment may be important factors that have changed the relative importance and actual performance of LT for PBC over time. The aims of this study were to assess trends in LT for PBC over the past 30 years in Europe, including potential changes in the relevant patient population.
Method: Patients receiving LT between 1986 and 2015 in centres reporting to the European Liver Transplantation Registry (ELTR) were included. We excluded patients in case of combined organ transplantation or when aged <18 years. For PBC, annual absolute and proportional numbers of LTs, and patient characteristics were assessed over time using linear regression models and chi-square tests. Secondly, detailed subgroup analyses were performed on all PBC patients listed for LT in the Netherlands from 1986–2015.
Results: During our 30-year study period, 112,874 patients underwent LT. In 6029 patients (5.3%) PBC was the primary indication. After an initial annual increase of 21.5 patients from 1986 to 1995, the absolute number of LTs for PBC reached a relatively steady state from 2006 onwards at approximately 200 LTs annually. The percentage of LT for PBC as compared to other aetiologies fell from 20.3% in 1986 to 3.6% in 2015 (Figure). PBC was the only indication showing a constant proportional decrease over three decades. In patients with PBC, median age at LT increased from 53.9 years (IQR47.3–59.4) in the first decade to 56.1 (IQR48.4–62.4) after 2006 ($p < 0.001$). The proportion of males increased from 11.0% in the first to 15.1% in the third decade ($p < 0.001$). Median MELD scores increased from 15.3 (IQR12.2–19.2) in 1996–2005 to 16.8 (IQR12.8–21.6) in 2006–2015 ($p < 0.001$). In the Netherlands, 88.8% (71/80 evaluable patients) listed for LT could be classified as incomplete responders after one year of UDCA treatment according to the Paris-I criteria.
Conclusion: In our European-wide study on patterns in LT for PBC over 30 years, we show that despite a relative decrease, the absolute number of LTs for PBC patients has now reached a steady state. Still, more than 200 European patients with PBC undergo LT annually. Today, these patients are significantly older, have higher MELD scores, and are more likely to be males than 30 years ago.

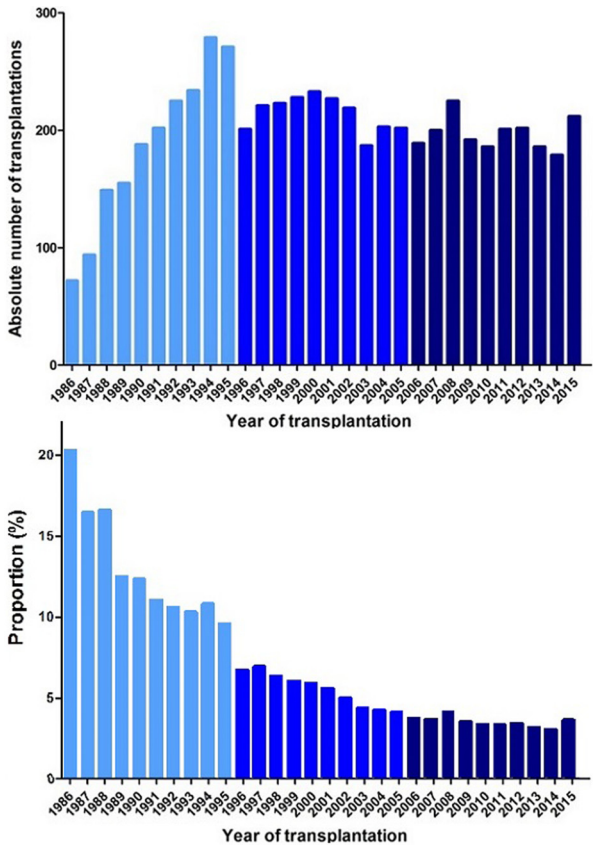

Figure: Annual absolute number of liver transplantations (LT) for PBC in Europe from 1986–2015 vs. annual proportional number of LT for PBC as compared to other aetiologies.

THU-195
The antidepressant mirtazapine improves survival in patients with primary biliary cholangitis
A.-A. Shaheen[1], G. Kaplan[2], W. Almishri[3], S. Patten[4], M.G. Swain[1]. *[1]University of Calgary, Cumming School of Medicine, Gastroenterology and Hepatology, Canada; [2]University of Calgary, Gastroenterology and Hepatology Division; [3]University of Calgary, Cumming School of Medicine, Calgary, Canada; [4]University of Calgary, Cumming School of Medicine*
Email: azshaheen@me.com

Background and Aims: Depressive symptoms are prevalent in primary biliary cholangitis (PBC) patients. However, the impact of depression and antidepressant use on PBC outcomes are unknown. Our aims were to examine the effects of depression and antidepressants on hepatic outcomes of PBC patients.
Method: We used the UK Health Improvement Network database to identify PBC patients between 1974 and 2007, and followed them to 2012. Our primary outcome was one of three clinical events: decompensated cirrhosis, liver transplantation and death. We assessed depression and each class of antidepressant medication in adjusted multivariate Cox proportional hazards models to identify independent predictors of outcomes. We included demographic, clinical, and coexisting liver conditions as covariates in our analysis. We carried out multiple sensitivity analysis to validate our findings by restricting our study population to PBC patients only using ursodeoxycholic acid (UDCA).
Results: We identified 1,177 PBC patients during our study period. In our cohort, 86 patients (7.3%) had a depression diagnosis prior to PBC diagnosis, while 79 patients (6.7%) had a depression diagnosis after PBC diagnosis. PBC patients with prior or current depression were younger than those without depression (median age 59 and 58 versus

63 years, P = 0.009), and were more commonly female (93% and 96% versus 87%, P = 0.02). Our cohort ten-year incidence of mortality, decompensated cirrhosis, and liver transplantation were 13.4%, 6.6%, and 2.0%, respectively. Approximately 70% of PBC patients were prescribed UDCA, which did not differ by depression status. Interestingly, among PBC patients without a diagnosis of depression, 24.6% were using antidepressants after their PBC diagnosis, while 11.1% used antidepressants prior to their PBC diagnosis. Mirtazapine was prescribed at a lower rate for patients with no history of depression (2.7%), or with a previous depression diagnosis (3.5%), compared to those with a current depression diagnosis (6.3%), P < 0.001. In our analysis, PBC patients with depression were less likely to die, compared to PBC patients without depression (P = 0.02). Our analyses demonstrated that depression was a confounder to the protective effect of the antidepressant mirtazapine. The effect of no other antidepressant was significant in our models. Using mirtazapine after PBC diagnosis was significantly protective (Adjusted HR 0.23: 95% CI 0.07–0.72) against poor outcomes (decompensation, liver transplant, mortality) in our adjusted models (Figure 1).

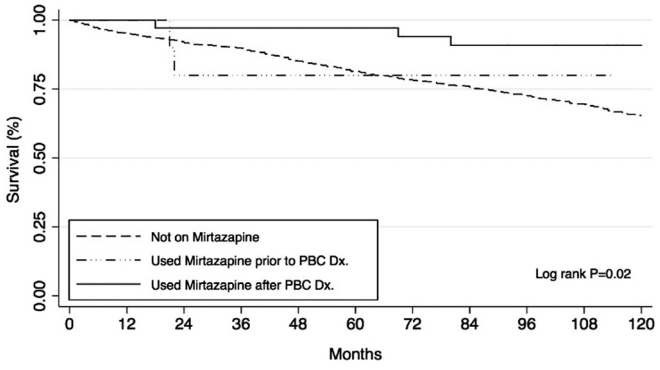

Figure 1: 10-year Kaplan-Meier Survival Curves among PBC patients according to Mirtazapine usage.

Conclusion: Mirtazapine reduced mortality, decompensated cirrhosis and liver transplantation in PBC patients. Future studies are needed to explore potential mechanisms underlying this beneficial impact of mirtazapine in PBC patients.

THU-196

Impact of access to specialized health care on the primary biliary cholangitis (PBC) patient outcomes: a Canadian experience

A.-A. Shaheen, S. Congly, K. Burak, M. Borman, M.G. Swain. *University of Calgary, Cumming School of Medicine, Gastroenterology and Hepatology, Canada*
Email: azshaheen@me.com

Background and Aims: Accessibility to health care service is a fundamental aspect of the health care system. The Canadian Health Care Act guarantees universal access to all Canadians. Access to specialized medical services in chronic diseases patients could affect disease outcome. Therefore, we assessed the impact of potential regional differences in access to specialized care on PBC patient clinical outcomes.
Method: We used the Discharge Administrative Database (DAD) to identify all PBC patients hospitalized in Alberta, Canada (2002–2017). An admission was considered a PBC-related hospitalization if PBC was the primary diagnostic code or a decompensated cirrhosis feature (ascites, variceal bleeding, hepatic encephalopathy or hepatorenal syndrome) was identified in any diagnostic field. Alberta is divided into five health regions serving 4.1 million people. Specialized health care facilities providing hepatology services are centralized in the Capital (Edmonton) and Calgary health regions, and liver transplants are only performed in Edmonton. In our analysis, we compared Albertans who live in these two health regions (direct access to specialist care) to the other three health care regions (remote access) with regards to demographics, comorbidities and cirrhosis decompensated features according to hepatology care access. We used appropriate statistical methods to compare clinical outcomes (in-hospital mortality, liver transplantation) between groups.
Results: We identified 374 PBC patients in Alberta who had PBC related hospitalizations. Among these patients, 237 (63.4%) resided in direct access health regions. PBC-related admissions were similar between groups (median, IQR; direct access: 1 (1–2), 1(1–3), P = 0.37). Both groups had similar demographics (median age: 61 vs. 60, P = 0.24; female %: 78.1% vs. 78.8%, P = 0.90; direct access vs. remote access, respectively). Both groups had similar comorbidities rates and decompensated cirrhosis features. Over 15 years of follow up, 109 patients (29.1%) died during one of their PBC-related hospitalizations. There was no difference in in-hospital mortality between direct access and remote access groups (31.2% vs. 25.5%, P = 0.29). Interestingly, PBC patients in remote access regions had higher rates of liver transplant (13.9% vs. 6.3%, P = 0.02). In our adjusted models for age, sex, comorbidities, and cirrhosis decompensation features living in a remote access area was an independent predictor of liver transplant (aOR, 95%CI: 2.27, 1.09–4.74).
Conclusion: In a single payer system with universal access, remote access to specialist care did not affect hospitalization rates, decompensated cirrhosis features, or in-hospital mortality in our large PBC cohort. Interestingly, we observed significantly higher liver transplant rates among patients with remote access.

Biliary IL8 is a marker for disease progression and risk for biliary neoplasia in primary sclerosing cholangitis

M. Färkkilä[1,2], H. Mustonen[3], K. Jokelainen[2], S. Boyd[4], J. Arola[4], H. Alfthan[5]. *[1]Helsinki University, Helsinki, Finland; [2]Helsinki University Hospital, Gastroenterology, Helsinki, Finland; [3]Helsingin yliopisto, Biomedicum, Helsinki, Finland; [4]Helsinki University Hospital, Pathology, Helsinki, Finland; [5]Helsinki University Hospital, HusLab*
Email: harri.mustonen@helsinki.fi

Background: PSC is a chronic inflammatory disease of biliary epithelium leading to strictures of bile ducts. The chronic inflammation and increased proliferation of biliary epithelial cells are associated with development of biliary dysplasia and cholangiocarcinoma [CCA] with the lifetime risk around 10%. CCA is the most common reason for death among patients with PSC. Interleukin 8 (IL8) is a chemokine encoded by the CXCL8 gene, produced by eq. neutrophils and cholangiocytes as a response to microbial antigens and pro-inflammatory cytokines. Marked elevation of IL8 in has been demonstrated previously in PSC and it has shown to be a prognostic indicator in CCA.
Aims: To evaluate the role of biliary IL8 to predict (1) the disease progression based on changes in sequential ERC's examinations and for (2) the risk of biliary dysplasia detected by brush cytology or CCA.
Method: In total, 494 patients with PSC referred for ERC for dg or surveillance were included (295 males), mean age 40.5 ± 13.7 y. During ERC bile sample was aspirated using balloon catheter and immersed in liquid nitrogen (−196°C) and stored in −80°C. Brush cytology (BC) was collected from bile ducts for Papanicolau staining for grading dysplasia and inflammation. Neutrophilic inflammation was evaluated semi quantitatively (0 = neutrophils/epithelial cells <0.05, 1 = neutrophils /epithelial cells 0.05–0.4, 2 = neutrophils/epithelial cells >0.4). Bile concentrations of IL8 were analyzed using Human IL-8/CXCL8 DuoSet ELISA®. ERC findings were scored according to modified Amsterdam score. Based on sequential ERCs and scores an ERC-load/burden was calculated and likewise variables for biliary IL8 and neutrophils in BC in relation to time were determined.
Results: During the mean follow up of 6 years 20 patients were referred for liver transplantation, and biliary dysplasia or CCA was diagnosed in 35 patients. Biliary IL8 correlated with neutrophil load in BC. HR for IL8 load for predicting progression of PSC are presented

in Table 1. The risk ratios of IL8 load for development of biliary dysplasia and CCA are shown in Table 2.

Table 1: IL8 predicting risk for disease progression based on ERC-score >8

Variable	Value	HR	Lower	Upper	p-value
logIL8 Load	Continuous	2.06	1.68	2.52	0.000
IL8 Load	>=1.1	5.51	3.19	9.53	0.000
	>=3	4.37	2.76	6.90	0.000
	>=10	3.77	2.47	5.76	0.000

Table 2: IL8 predicting risk for development of dysplasia or CCA

Variable	Value	HR	Lower	Upper	p-value
logIL8 load	Continuous	2.27	1.52	3.37	0.000
IL8 load	>=1.1	25.67	3.47	190.02	0.001
	>=3	6.88	2.58	18.36	0.000
	>=10	3.87	1.75	8.53	0.001
	>=20	2.93	1.32	6.53	0.008

Conclusion: Biliary IL8 levels are reliable surrogate markers of bile duct inflammation, and can predict progression of the bile duct disease and the risk for development of biliary neoplasia.

THU-198

Pruritus strongly reduces quality of life in PBC patients – real life data from a large national survey

S. Hönig[1], B. Herder[2], A. Kautz[2], C. Trautwein[3], A. Kremer[1]. *[1]Friedrich-Alexander-University Erlangen-Nürnberg, Department of Medicine 1, Erlangen, Germany; [2]Leberhilfe Project, gUG, Köln, Germany; [3]RWTH-University Aachen, Department of Medicine III, Aachen, Germany*
Email: andreas.kremer@uk-erlangen.de

Background and Aims: Pruritus is a common and agonizing symptom in patients with primary biliary cholangitis (PBC). Epidemiological data is however scarce and validated questionnaires investigating quality of life (QoL) have not been performed in larger cohorts of PBC patients. We aimed to investigate this symptom, its effect on QoL, self-management as well as medical treatment in a large national survey in Germany.
Methods: We developed and validated a detailed questionnaire with a total of 89 questions. QoL in regard to pruritus was measured by the validated ItchyQoL questionnaire. Itch intensity was rated on a numeric rating scale (NRS). Data is given as mean ± SD.
Results: In total 577 PBC patients were included in this national survey. Sex ratio was 9:1 in favor of women (92% women, 8% men). The mean age was 53,2 (± 14,6) years with PBC being diagnosed in average 6,9 (0–37) years ago. More 60% of patients were well informed knowing the change name of the disease, the alkaline level, and stage of fibrosis. Reported symptoms included fatigue (82%), pruritus (56%), joint pain (62%) and abdominal pain (49%) while only 8% of patients stated to be asymptomatic. More than 70% of patients reported on a reduced QoL. Two third of patients with pruritus reported to suffer since many years of this symptom. The mean itch intensity during the last four week was rated 4.2 (49.3% moderate and 9.1% severe intensity), while the worst itch reached a level of 5.5 (51.4% moderate and 25.8% severe intensity) on a NRS. The QoL of affected patients quantified by the ItchyQoL closely correlated with mean (Spearman correlation coefficient: $r = 0,46$; $p < 0.001$) and worst itch intensity ($r = 0,42$; $p < 0.001$). Self-management of patients to improve pruritus consisted among others of topical treatment (55%), cold water (33%), rubbing (27%), use of scratch tools (24%), and cold/ice pads (13%). Medical treatment was performed only in 19% of patients with the majority receiving antihistamines (63%). Other treatments consisted of cholestyramine (29%), opioid antagonists (5%), rifampicin (3%) and fibrates (3%). Only 23 patients reported on a successful anti-pruritic treatment.
Conclusion: The prevalence of pruritus in the real life setting is high. Pruritus significantly reduces the QoL of affected patients with the majority of patients being not or only inadequately treated. Patients are forced to perform self-management. Pruritus represents a major unmet clinical need in PBC.

THU-199

Functional connectivity reveals altered activation of distinct brain areas in pruritus of cholestasis

A. Kremer[1], T. Buchwald[2], M. Vetter[1], A. Dörfler[3], C. Forster[2].
[1]Friedrich-Alexander University Erlangen-Nürnberg, Department of Medicine 1; [2]Friedrich-Alexander University Erlangen-Nürnberg, Institute of Physiology and Pathophysiology, Erlangen, Germany; [3]Friedrich-Alexander University Erlangen-Nürnberg, Department of Neuroradiology
Email: andreas.kremer@uk-erlangen.de

Background and Aims: Pruritus is a frequent symptom of hepato-biliary disorders particularly in those with cholestatic features. Various substances including bile salts and lysophosphatidic acid have been discussed as potential peripheral pruritogens in the peripheral nervous system. Our aim of this study was to investigate central mechanisms involved in itch sensation in patients suffering from cholestatic pruritus.
Methods: 23 patients with primary biliary cholangitis or primary sclerosing cholangitis. Patients were divided into two groups, those suffering from pruritus (N = 9) and those without pruritus (N = 14). Baseline itch intensity was quantified using a questionnaire and a visual analogue scale. Functional magnetic resonance imaging (fMRI) scans were using a classical connectivity fMRI-design with EPI sequences to BOLD signal changes. The first fMRI sequence was free from stimulation to detect the default mode (DM) network. During further fMRI sequences heat pain and itch stimuli were applied. Individual mean BOLD time courses were extracted from the seed regions thalamus for exploring an "input" network and the periaqueductal gray (PAG) for exploring the "output" network. Pearson's correlation coefficients were calculated between the seed regions and other regions in a whole brain study. In a 2nd level analysis contrasts were calculated between the connectivity within the DMN and that of the stimulations recordings to demonstrate stimulation related changes within the network.
Results: During the DM situation higher functional connectivity (FC) was seen within the group without pruritus in the "input" network of the thalamus to anterior parts of the insular cortex of both hemispheres and to the primary and secondary somatosensory cortex S1 and S2. In the group without pruritus the output network showed higher FC to frontal regions as compared to the group with pruritus. During both stimuli the activity within the DMN decreased in the group without chronic pruritus while in the group with chronic pruritus the FC either remained unchanged (thalamus with frontal regions, S1, S2) or increased (thalamus with Insular cortex). FC of the PAG and BA10 driving the descending control increased as compared to DM in the group without pruritus and showed no changes in patients with pruritus during an itch stimulus. Simultaneously changes of the FC from the PAG to other modulating areas (BA9, anterior insular cortex, anterior cingulate cortex) were contrary in the two groups.
Conclusion: The DM network is violated in patients with chronic pruritus probably due to the continuous pruritic input. Accordingly, changes within the networks due to an additional pruritic stimulus are less pronounced in the pruritus group as compared with subjects who are not suffering from spontaneous itching. This also affects the important descending control system.

THU-200

A stepwise algorithm for biliary brush cytology shows high diagnostic performance in primary sclerosing cholangitis

E. von Seth[1], H. Ouchterlony[1], S. Haas[1], K. Dobra[2], A. Hjerpe[2], A.M. Bergquist[1]. [1]*Karolinska Institutet, Department of Medicine, Huddinge, Stockholm, Sweden;* [2]*Karolinska Institutet, Department of Laboratory Medicine, Division of Pathology, Stockholm, Sweden*
Email: Erik.von.seth@ki.se

Background and Aims: Detection of early stage cholangiocarcinoma (CCA) in primary sclerosing cholangitis (PSC) remains a diagnostic challenge. Fluorescence in-situ hybridization (FISH) increases the sensitivity for the detection of biliary tract cancer but at the cost of decreased specificity. We analyzed the diagnostic accuracy of a multistep cytological approach to biliary brush cytology and FISH for the detection of biliary malignancy in PSC patients.
Method: We included patients with well-defined large duct PSC who underwent biliary brushings for clinical indications at Karolinska University Hospital during 2009–2015. Only results from the first sampling procedure during the study period were in the analysis. Brush cytology samples were categorized as; benign, atypical, atypical with suspicion of malignancy or positive for malignancy. Specimens categorized as atypical or atypical with suspicion of malignancy was further analysed with FISH (aneuploidy for chromosomes 3, 7 and 17, deletion of locus 9p21). Clinical outcomes were CCA, dysplasia from explanted livers or alive at follow up without signs of CCA. Patients were followed for 12 months or until endpoint.
Results: We included 208 PSC patients with at least one sampling procedure during the study period. During follow-up 15 patients were diagnosed with CCA, 3 with high-grade dysplasia and 5 with low-grade dysplasia, in explanted livers. Diagnostic accuracy for CCA, CCA and high-grade dysplasia and all dysplasia types is presented in Table 1.

Table 1: Diagnostic performance for detecting cholangiocarcinoma and dysplasia in first brushing of 208 PSC patients

	Sensitivity (95% CI)	Specificity (95% CI)	PPV (95% CI)	NPV (95% CI)
CCA	80% (52–96%)	96% (92–98%)	60% (36–81%)	98% (95–100%)
CCA + HGD*	83% (59–96%)	82% (63–94%)	75% (51–91%)	89% (70–98%)
CCA + HGD + LGD*	78% (56–93%)	91% (72–99%)	90% (68–99%)	81% (61–93%)

*Only patients with follow up with liver transplantation, liver resection, biopsy or cancer related death included in analysis (n = 46).

Conclusion: In this stepwise approach to biliary brush cytology in PSC patients a positive FISH test seems to be highly predictive of CCA or biliary dysplasia.

THU-201

VCAM-1 and soluble CD-163 as novel non-invasive markers of liver fibrosis in patients with autoimmune hepatitis – a prospective study

M. Janik[1], B. Kruk[2], K. Kostrzewa[3], R.-W. Joanna[1], F. Lammert[4], M. Krawczyk[1,4], M. Milkiewicz[5], P. Milkiewicz[1]. [1]*Medical University of Warsaw, Liver and Internal Medicine Unit, Department of General, Transplant and Liver Surgery, Warsaw;* [2]*Medical University of Warsaw, Laboratory of Metabolic Liver Diseases, Department of General, Transplant and Liver Surgery, Warsaw, Poland;* [3]*Warsaw School of Economics, Warsaw, Poland;* [4]*Saarland University Medical Center, Saarland University, Department of Medicine II, Homburg, Germany;* [5]*Pomeranian Medical University in Szczecin, Medical Biology Laboratory, Poland*
Email: mjanik24@gmail.com

Background and Aims: Novel, non-invasive markers of fibrosis in patients with autoimmune hepatitis (AIH) are urgently needed. The macrophage activation marker, soluble CD163 is associated with AIH activity, but its role in assessment of fibrosis has yet to be established. Vascular cell adhesion molecule-1 (VCAM-1) has recently been linked with fibrosis, but not investigated in patients with AIH so far. The aim of this study is to assess CD163/VCAM-1 as potential fibrosis markers in patients with AIH.
Method: Studied cohort compromised 120 patients with AIH (92 women, mean age 40.5 yrs, 46 cirrhotics) who prospectively underwent liver and spleen shear wave elastography (SWE, SuperSonic Imagine Aixplorer®). CD163 and VCAM-1 were quantified using ELISA. Fibrosis-4 (FIB-4), aspartate aminotransferase (AST)-to-platelet ratio index (APRI), AST-to-alanine aminotransferase (ALT) ratio (AAR) and FibroQ were applied as surrogate indices of fibrosis.
Results: Liver SWE showed a significant correlation with CD163, VCAM-1 ($p < 0.001$), it was also significant in fibrosis indices listed above. CD 163 correlated with fibrosis indices (all $p < 0.05$), markers of liver inflammation (all $p < 0.001$) and to a lesser extend with platelet ratio or spleen SWE. VCAM-1 showed significant (all $p < 0.001$) correlations with fibrosis indices and inflammatory markers (except ALT). In contrast to CD163, VCAM-1 significantly correlated with spleen SWE and platelets as signs of portal hypertension ($p < 0.001$). This may underline its role as a new marker of liver fibrosis and portal hypertension in AIH. VCAM-1 had AUROC 0.89 (95% CI 0.79–0.97), whilst AUROC of CD163 was 0.73 (95% CI 0.61–0.85) for detecting liver cirrhosis defined by SWE >13.0 kPa. Finally, liver SWE and VCAM-1, but not CD163, showed excellent correlation with esophageal varices (EV) and history of EV ligation (all $p < 0.001$). Spleen SWE showed the best correlation with all end points (all $p < 0.001$). There was a robust correlation ($r = 0.427$, $p < 0.001$) between liver and spleen SWEs.
Conclusion: Our study demonstrates that CD163 and VCAM-1 may help in assessment of liver fibrosis in patients with AIH. In line with the publication (Gronbaek et al., 2016), CD163 correlates with active inflammation in AIH, and VCAM-1 was related to portal hypertension. Future studies with these markers are required to establish their specific roles in clinical practice.

THU-202

Rituximab treatment experience in patients with complicated type 1 autoimmune hepatitis in Europe and North America

N.N. Than[1], D. Schmidt[1], J. Hodson[2], R. Wawman[1], K. Burak[3], M. Botter[1], R.L. Jones[4], A. Montano-Loza[5], N. Gautam[1], G. Appanna[6], A. Godkin[6], C. Schramm[7], F. Lammert[8], M.G. Swain[9], D. Adams[1], G. Hirschfield[1], Y.H. Oo[1]. Email: nwenithan@gmail.com

Background and Aims: Autoimmune hepatitis (AIH) is an immune mediated liver disease and due to its progressive nature necessitating transplantation in a subset of patients, alternative therapies are required in complicated cases of AIH.
The study aim was to determine the clinical response of patients with complicated AIH to Rituximab, an anti-B-cell depletion therapy.
Method: This was a multi-centre retrospective study of 22 patients with complicated type-1 AIH. Data were collected from the United Kingdom, Germany and Canada. The clinical response of Rituximab treatment was assessed by the changes in biochemical and immunological parameters, and prognostic scores of liver disease from the period before treatment to 24-months post-treatment. The

reduction in Prednisolone requirement after Rituximab treatment and the freedom from subsequent AIH flares were also assessed.

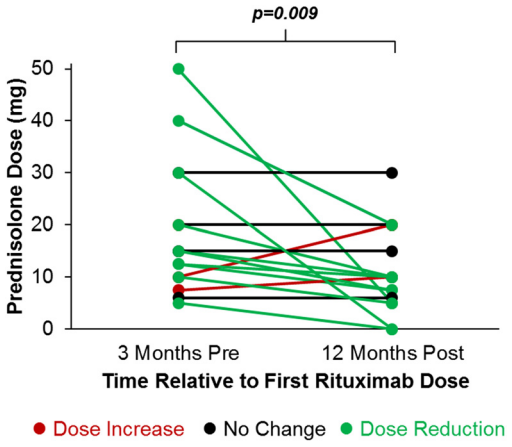

Figure 1: Changes in prednisolone doses following Rituximab therapy.

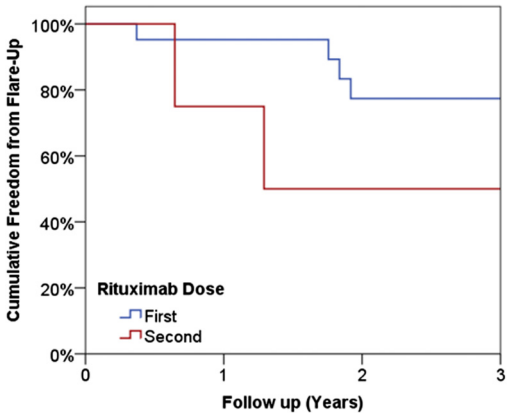

Figure 2: Kaplan-Meier curve of freedom from flare-up following Rituximab therapy.

Results: Among 22 patients, the majority were female (n = 15, 68%) and of Caucasian ethnicity (n = 18, 86%) with a median age at diagnosis of 44 years (range: 19, 79). Mean serum aminotransferase activities (ALT and AST) improved significantly following Rituximab therapy, with this improvement being sustained for the full 24 months of follow up ($p < 0.0010$). The mean ALT level improved from 167 IU/L pre-treatment to 32 IU/L at 24-months post treatment and mean AST level from 127 IU/L at pre-treatment to 29 IU/L at 24-months post treatment ($p < 0.001$). A trend toward improvement was detected in bilirubin ($p = 0.051$) and the international normalised ratio ($p = 0.068$) upon treatment. Immunoglobulin-G (Ig G) level also improved significantly from mean of 18.9 g/L pre-treatment to 13.2 g/L at 24 months ($p < 0.001$). Prednisolone requirement declined significantly by 12 months after treatment ($p = 0.009$) (Figure 1). The estimated rates of freedom from AIH flare were 95% and 77% at one and two years, respectively, following the first dose of Rituximab therapy (Figure 2).

Conclusion: Rituximab is effective in selected cases of complicated AIH patients, with improvement in biochemical liver enzymes and immunological parameters up to 24-months post-treatment.

THU-203

Primary biliary cholangitis in Spain: fewer symptoms and milder disease at presentation, but similar therapeutic response over the years

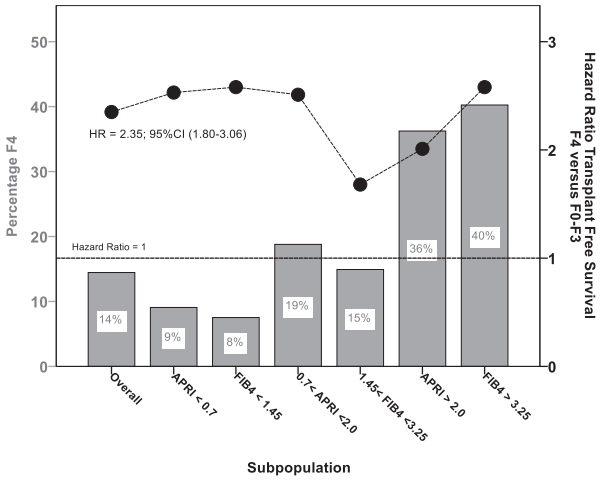
characteristics in an extensive sample of patients from different areas of the territory. Furthermore, presentation and response to treatment changes over the years have been analyzed.
Method: 1508 patients from 23 centers, diagnosed between June 1979 and July 2017, have been studied. According to the date of diagnosis, patients were divided into four periods. The demographic characteristics, symptoms and signs, biochemistry and immunology at diagnosis were evaluated, as well as presence of cirrhosis, treatment and biochemical response.
Results: There was a significant increase in the prevalence of males (from 6% to 13%) and age at diagnosis (from 52 to 56 years). A significant decrease of symptomatic patients was observed (from 40% to 23%), with lower prevalence of pruritus, asthenia, jaundice and xanthelasma. The biochemical cholestasis and hypertransaminasemia has also decreased. More than 96% of patients were treated with Ursodeoxycholic acid (UDCA). The number of patients receiving recommended adequate doses increased gradually. The prevalence of anti-mitochondrial antibodies, autoimmune (AI) comorbidities and cirrhosis at presentation were similar in all periods, as well as the response to UDCA according to Global PBC score and Barcelona criteria (table).
Conclusion: Presentation of primary biliary cholangitis has changed over the years, being diagnosed more frequently in men, in older patients, more asymptomatic and with less biochemical cholestasis. The suboptimal response to treatment remains important despite the milder presentation.

THU-204

Histologic stage is a stronger predictor of transplant free survival than APRI and FIB-4 in patients with primary biliary cholangitis

Hansen[1]. *[1]University Health Network; [2]University of Toronto; [3]Erasmus University Medical Center; [4]Hôpital Saint-Antoine; [5]University of Birmingham; [6]International Digestive Health Center; [7]Hospital Clinic I Provincial Barcelona; [8]University of Padova; [9]Arizona State University; [10]AMC; [11]University of Milan-Bicocca; [12]UT Southwestern; [13]Università degli Studi di Milano; [14]UZ Leuven; [15]Jena University Hospital; [16]University of Thessaly; [17]The Royal Free Hospital; [18]Mayo Clinic; [19]University Hospital; [20]University of Alberta; [21]Swedish Medical Center*
Email: a.gulamhusein@mail.utoronto.ca

Background and Aims: FIB-4 and the AST/Platelet Ratio Index (APRI) are indirect markers that predict fibrosis in patients with viral hepatitis. We sought to validate correlation with histology and clinical outcomes across a globally representative cohort of patietns with Primary Biliary Cholangitis (PBC).
Method: Patient data was retrieved from the Global PBC Study Group dataset. 1,952 patients with PBC and biopsy data were included. The diagnostic performance of FIB-4 and APRI was assessed and expressed as area under the ROC curve. Cox regression was performed to assess the association between histologic stage, APRI and FIB-4 and transplant free survival.
Results: The mean age of patients was 52.6 years, 90.2% were female and 91.5% were UDCA treated. There were 207 (10.6%) deaths and 156 (8%) liver transplants in the cohort. Neither APRI nor FIB-4 performed well in identifying or excluding significant degrees of fibrosis. The AUROC for APRI for ≥F2, ≥F3, =F4 was 0.62, 0.66 and 0.67, respectively. For FIB-4, the AUROC for ≥F2, ≥F3, =F4 was 0.61, 0.68 and 0.70, respectively.
Univariable Cox proprortional hazards models revealed that biopsy stage (HR 7.06 (4.9–10.2), p < 0.001), APRI (HR 6.2 (4.6–8.4), p < 0.001) and FIB-4 (HR 8.8 (6.3–12.3) p < 0.001) were significantly associated with worse transplant free survival. After adjusting for biopsy stage and non-invasive measures, histologic stage remained an independent predictor of outcome with a HR for F4 fibrosis 3.4 (2.3–5.1, p < 0.001) as did FIB-4 HR of 2.9 (1.1–7.4), p = 0.03 but APRI was no longer significant (p = 0.91).
When assessing thresholds with a high likelihood of cirrhosis (FIB-4 > 3.25 or APRI > 2), histologic cirrhosis remained a strong independent predictor of worse transplant free survival with a HR 2.4 (1.8–3.1, p < 0.001). Analysis of APRI and FIB-4 at different thresholds of fibrosis (APRI < 0.7 or FIB-4 < 1.45 and APRI >2.0 or FIB-4 > 3.25) revealed that 10–20% of patients with histologic cirrhosis were presumed to have lesser degrees of fibrosis by non-invasive testing, and these patients had worse transplant free survival (Figure 1), attesting to the suboptimal correlation between these parameters.



Conclusion: FIB-4 and APRI correlate poorly with histologic stage of fibrosis in patients with PBC and may underestimate risk for poor outcome. While they may have some predictive ability, histologic stage remains independently associated with transplant-free survival and continues to have a role in prognostication in this disease. This emphasizes the need to identify reliable non-invasive markers that strongly correlate with histology in patients with chronic cholestasis to allow non-invasive risk stratification in these patients.

Background and Aims: Patients with PBC exhibit delayed sleep-wake habits, disturbed sleep and daytime sleepiness/fatigue. Such combination of symptoms is reminiscent of delayed sleep phase syndrome (DSPS), which benefits from morning light treatment.
Method: We therefore set out to test the effect of morning light in a group of 13 well-characterised patients with PBC (all females, 53 ± 10 yrs). Six healthy individuals (4 females, 57 ± 14 yrs) and 7 patients with cirrhosis (1 female, 57 ± 12 yrs) served as controls/disease controls. At baseline, all underwent an assessment of diurnal preference, sleep quality/timing (subjective plus actigraphy), daytime sleepiness, mood, quality of life and urinary 6-sulphatoxymelatonin (aMT6s) rhythmicity. Then they underwent a 15-day course of morning bright light treatment, immediately after getting

up (light box, 10,000 lux, 45 mins) whilst monitoring sleep-wake patterns (diaries plus actigraphy) and aMT6s.
Results: At baseline, both patients with PBC and patients with cirrhosis had significantly worse subjective sleep quality compared to controls (PSQI: 13.1 ± 4.0 and 11.3 ± 4.9 *vs.* 5.3 ± 2.0, p < 0.05, respectively); patients with PBC also had significantly more daytime somnolence. Post-treatment subjective sleep quality improved in all groups (group: F = 6.73, p = 0.007; treatment: F = 22.7, p < 0.0001; group*treatment: ns) as did daytime sleepiness (group: F = 5.7, p = 0.010; treatment: F = 7.6, p = 0.011; group*treatment: ns); the effect on daytime sleepiness was more pronounced in patients with PBC. The number of self-reported night awakenings decreased in all 3 groups. For actigraphy, a trend for an increase in sleep efficiency was observed in patients with cirrhosis. Post-treatment sleep onset/get-up time were advanced by approximately 30 minutes in PBC patients and healthy volunteers, while the change was less obvious in patients with cirrhosis (group: ns; treatment: F = 7.8, p = 0.010; group*-treatment: ns). Post-treatment, aMT6s rhythmicity was stronger with significantly improved cosinor fits in all three groups (group: ns; treatment: F = 5.8, p = 0.035; group*treatment: ns).
Conclusion: In conclusion, a brief course of morning bright light treatment had positive effects on sleep timing, sleep quality and circadian rhythmicity in patients with PBC and, to a lesser extent, also in patients with cirrhosis. Such unobtrusive and side-effect free, non-pharmacological treatment is worthy of further study.

Email: jesus.banales@biodonostia.org

Background and Aims: Primary sclerosing cholangitis (PSC) is a chronic cholestatic biliary disease of unknown etiology, which increases the risk of developing cholangiocarcinoma (CCA). In addition, PSC patients frequently (80%) present inflammatory bowel disease, mainly ulcerative colitis (UC) (PSC-UC). Currently, there are not available accurate non-invasive biomarkers for surveillance or early diagnosis of PSC in UC patients, which is warranted to monitor disease progression and to guide therapeutic strategies. We recently showed [Arbelaiz A. et al. HEPATOLOGY 2017] that serum extracellular vesicles (EVs) contain protein biomarkers for the differential diagnosis of PSC, CCA and hepatocellular carcinoma (HCC). The aim of this study was to investigate the usefulness of protein biomarkers in serum EVs for the differential diagnosis of PSC-UC and UC patients, which could help in the early diagnosis of PSC in UC patients.
Methods: Serum EVs were isolated from PSC-UC (n = 21), UC (n = 66; without PSC) and healthy individuals (n = 62) using ultracentrifugation/filtration methods. EVs characterization was performed by transmission electron microscopy (TEM), nanoparticle tracking analysis (NTA) and immunoblot. The proteome of EVs was analyzed by mass spectrometry-based proteomics.
Results: Serum EVs showed round morphology (by TEM), similar size (~180 nm diameter by NTA) and markers (CD9, CD63 and CD81 by immunoblotting) consistent with exosomes and small-size microvesicles. The proteomic profiles of serum EVs revealed 45 proteins to be differentially expressed in UC vs. controls, 66 in PSC-UC vs. controls, and 62 in PSC-UC vs. UC patients with high diagnostic performance (sensitivity and specificity). In particular, proteins such as Aminopeptidase N (AMPN), Polymeric immunoglobulin receptor (PIGR), G-protein coupled receptor family C group 5 member C (GPC5C) and Pantetheinase (VNN1)were exclusively upregulated ($p < 0.05$) in PSC-UC patients compared to UC and healthy controls. In contrast, proteins such as Complement factor I (CFAI), Ficolin-2 (FCN2) and Fibronectin (FINC) were downregulated ($p < 0.05$) in PSC-UC patients compared to UC and healthy controls.
Conclusion: Proteomic signatures found in serum EVs of PSC-UC and UC patients show potential as non-invasive tools for diagnosis and follow-up.

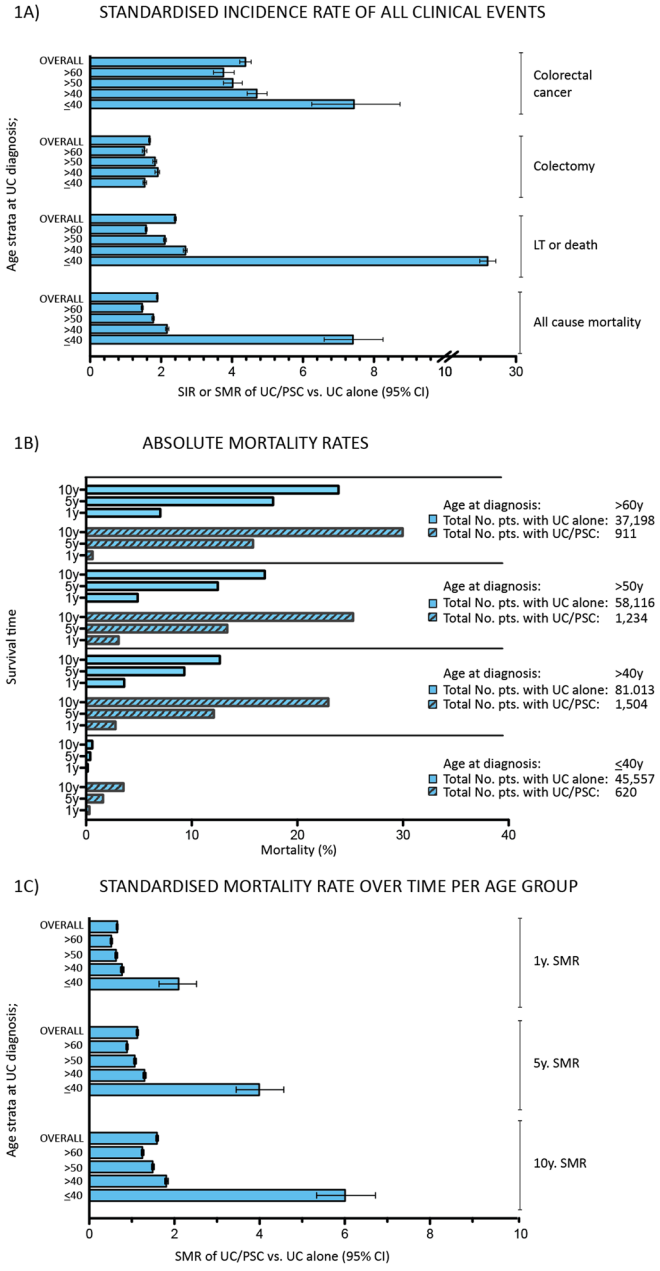
A nationwide population-based evaluation of mortality and cancer-risk in patients with ulcerative colitis/primary sclerosing cholangitis – young age at diagnosis and the unmet need to reduce mortality

P. Trivedi[1,2,3,4], J. Mytton[5], F. Evison[5], S.K. Kamarajah[6], J. Reece[7], T. Iqbal[3], R. Cooney[8], F. Thompson[2], M. Walmsley[9], J. Ferguson[10,11], G. Hirschfield[10,11,12]. *[1]University of Birmingham, National Institute of Health Research (NIHR) Birmingham and Centre for Liver Research, Birmingham, United Kingdom; [2]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Liver Unit, Birmingham; [3]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Dept. of Gastroenterology, Birmingham; [4]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital Birmingham, Centre for Rare Diseases, Institute of Translational Medicine; [5]University Hospitals Birmingham NHS Foundation Trust, Department of Informatics, Birmingham; [6]University of Birmingham, National Institute of Health Research (NIHR) Birmingham and Centre for Liver Research, Birmingham; [7]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Dept. of Gastroenterology, Birmingham, United Kingdom; [8]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Dept. of Gastroenterology; [9]PSC Support (UK); [10]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Liver Unit; [11]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Centre for Rare Diseases, Institute of Translational Medicine; [12]University of Birmingham, National Institute of Health Research (NIHR) Birmingham and Centre for Liver Research*
Email: p.j.trivedi@bham.ac.uk

Background: Advancing age is proposed as a risk factor for mortality in primary sclerosing cholangitis (PSC). However outcomes against a matched control population need evaluation.
Aim: Provide data-driven prioritisation of unmet need by comparing pts. with ulcerative colitis (UC) and coexisting primary sclerosing cholangitis (PSC) vs UC alone in a dedicated age-stratified outcomes' analysis.
Method: A population-based study was performed via linkage to the national Hospital Episode Statistics registry, which records every adult (>18 y of age) hospital attendance, admission or clinic event within England since 2006. Across the entire registry we captured all incident cases of UC alone (group I); and UC with an

established diagnosis of PSC, or UC diagnosed with PSC subsequently (group 2). Case finding/definition was as per Jess et al (Gastro 2012), by applying ICD10 codes for UC overall (inclusion K51), UC/PSC more specifically (inclusion K51 + K83.0) and excluding other causes of liver injury (K70-77, K80.3/4, B16-19). Cases were captured till 03/2015; follow-up ending 1 y thereafter. Event rates (colectomy, colorectal cancer [CRC], liver transplantation [LT]/death, and all-cause mortality) were stratified according to age strata at UC diagnosis.



Results: Over 10 years, 128,694 incident UC cases were identified (annualised incidence/100,000 population: 23.8 in 2006; rising to 25.1 in 2015). Of this group, 2,124 were diagnosed with PSC at some point (incidence in 2006 and 2015: 0.29 and 0.4, respectively). Observing the UC cohort in entirety, we observed 210 1st LT (206 in group I), 9,413 individuals who came to colectomy, 1,208 CRC cases, and 11,177 pt. deaths. The leading cause of mortality was coronary disease (1%) in group 1; whereas liver-related death (5.9%), cholangiocarcinoma (4.6%) and CRC (1%) predominated in group 2. The incidence rate ([IR] / 1000-pt.yrs.) was greater in the UC/PSC group for colectomy (17.3 vs 13.7), CRC (5.6 vs 1.5), LT/death (38.5 vs 15.1), and all cause mortality (26.4 vs 15.1); $p < 0.001$ for all. Time-dependent Cox regression validated the negative impact of PSC onset for each endpoint (adjusted hazard ratio: 1.62, 3.31, 2.47 and 1.62, respectively; $p < 0.001$ for all). Compared to UC alone, the standardised incidence ratio (SIR) for CRC was greatest in UC/PSC of young presenting age (<40 y.); a 7-fold increase (Figure 1A). This contrasted to pts. diagnosed above age 40 (SIR ~4). Although absolute mortality rate was elevated in older ages (Figure 1B) it was in young pts. with UC/PSC that the contrast vs UC alone was most evident at 5 y (1.6% vs 0.4%) at 10 y (3.6% vs 0.6%); a 4 and 6-fold increase, respectively. Indeed, standardised mortality (SMR) was the greatest across the ≤40 age group, plateauing with older diagnosis age (Figure 1C).

Conclusion: In pts. diagnosed aged ≤40 y with UC, development of PSC is associated with 6-fold increase in mortality and 7-fold increased risk of CRC.

THU-209

Differentiation of acute icteric autoimmune hepatitis from idiosyncratic drug-induced liver injury by histological and biochemical criteria

M. Sebode[1], U. Drebber[2], H.-P. Dienes[3], T. Krech[4], S.A. Weidemann[4], E. Vettorazzi[5], A. Lohse[1], C. Schramm[1]. *[1]University Medical Center Hamburg-Eppendorf, I. Department of Medicine, Hamburg, Germany; [2]University of Cologne, Institute for Pathology, Cologne, Germany; [3]Medical University of Vienna, Institute of Pathology, Vienna, Austria; [4]University Medical Center Hamburg-Eppendorf, Department of Pathology, Hamburg, Germany; [5]University Medical Center Hamburg-Eppendorf, Institute of Medical Biometry and Epidemiology, Hamburg, Germany*
Email: marcialsebode@web.de

Background and Aims: The clinical, biochemical, serological and histological presentation of acute icteric autoimmune hepatitis (AIH) and idiosyncratic drug induced liver injury (DILI) can be similar. The differentiation of the two entities is important as treatment differs: AIH requires long-term immunosuppression, whereas DILI does not. The aim of our study was to investigate biochemical, serological or histological criteria which could be used to differentiate acute AIH from DILI.

Method: 26 acute icteric cases of each entity who had received a liver biopsy at the time of presentation were analysed retrospectively. Final diagnosis was confirmed by clinical follow-up. To assure a comparable degree of liver damage between the two groups, AIH and DILI cases were matched for the value of total bilirubin at initial presentation. Patients with liver cirrhosis were excluded. Four independent liver pathologists extensively re-evaluated the liver histologies in a blinded manner.

Results: The most frequent drugs within this DILI cohort were phenprocoumon (23%) and antibiotics (15%). Serum levels of alanine aminotransferase (1311 U/l vs. 1149 U/l, p = 0,65), MELD scores (17 vs. 19,5, p = 0,59) at the time of initial presentation and bilirubin levels at the time of liver biopsy (12 vs. 11,5 mg/dl, p = 0,99) did not differ significantly between AIH and DILI. Including all biochemical, serological or histological criteria, a serum IgG-level above the upper limit of normal was the best predictor to differentiate AIH from DILI (ROC-AUC 0,866, 95%-CI 0,747–0,985) with a sensitivity of 68% and specificity of 90% (diagnostic odds ratio of 17,7). The predictive value of IgG could not be improved by any other biochemical, serological or histological criterion. The histological criteria that could best differentiate AIH from DILI were the grade of fibrosis and the presence of plasma cells. The accuracy of making the correct diagnosis differed significantly among the four pathologists (ROC-AUC 0,479–0,792).

Conclusion: Among histological criteria, the grade of fibrosis and the presence of plasma cells can differentiate acute icteric AIH from DILI

reasonably well. However, the best discriminator between the two entities is an elevation of serum IgG levels.

THU-210

Patients with primary biliary cholangitis exhibit reduced hippocampal volume and MRI evidence of neuroinflammation

V. Mosher, M.G. Swain, B. Goodyear. *University of Calgary, Calgary, Canada*
Email: mosher.v@gmail.com

Background and Aims: Primary biliary cholangitis (PBC) is associated with impaired cognition and altered mood – processes critically regulated by the hippocampus. Major depressive disorder (MDD) and a number of neuro-inflammatory diseases (e.g. MS, Alzheimer's Disease) are characterized by hippocampal alterations, including decreased volume and/or neuroinflammation. Neuroinflammation, characterized by iron deposition, can be non-invasively assessed via MRI and quantitative susceptibility mapping (QSM). Therefore, we used MRI to define how PBC impacts hippocampal volume and susceptibility.

Method: Seventeen female non-cirrhotic PBC patients and 17 age-matched healthy female controls underwent MRI. All patients were taking UDCA for ≥6 months prior to scanning. QSM and high-resolution hippocampal images (FreeSurfer v6.0) were collected to estimate susceptibility and hippocampal volume, respectively. QSM was analyzed using Cerebra-QSM to create brain susceptibility maps, and hippocampal regions from FreeSurfer applied to estimate hippocampal susceptibility. Hippocampal volume and susceptibility values were entered into a General Linear Model with age and intracranial volume as covariates. PBC patients completed the PBC-40 and HAM-D depression questionnaires prior to scanning, and impact of disease/symptom severity on hippocampal volume and QSM determined.

Results: The hippocampus was significantly smaller (5.3 ± 0.8% [SEM], $p = 0.023$), and exhibited significantly increased susceptibility ($p = 0.025$) in PBC patients as compared to healthy controls. These changes were not related to disease severity (liver stiffness, serum biochemistry), symptom severity (PBC-40 score), or biochemical response to UDCA treatment. No PBC patient was depressed based on history or HAM-D score.

Conclusion: PBC patients demonstrate significantly decreased hippocampal size (similar in magnitude to patients with MDD and MS) in association with increased neuroinflammatory changes. These hippocampal alterations were independent of disease/symptom severity, or UDCA response. Clearly PBC induces significant changes in the hippocampus. Although we did not find a link to symptoms in our patient cohort, these hippocampal changes are likely important and may represent an objective marker for assessing improvements in brain changes associated with response to therapeutic interventions in PBC.

THU-211

Younger age is associated with lower transplant-free survival relative to a general population in patients with Primary Biliary Cholangitis

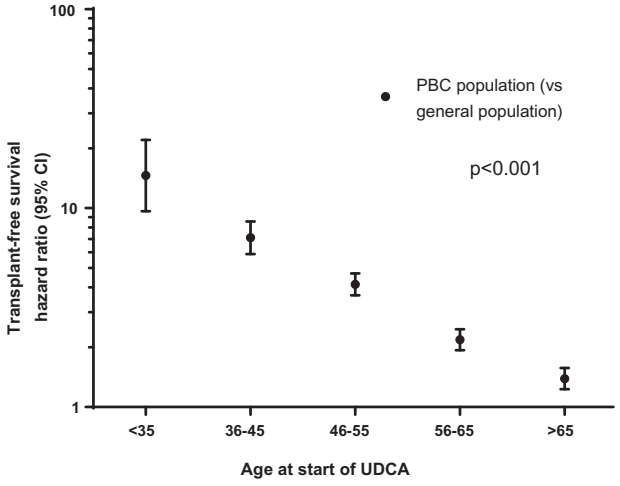
Email: bettina.hansen@utoronto.ca

Background and Aims: The prognostic impact of age on survival in Primary Biliary Cholangitis (PBC) patients is difficult to determine due to the relatively small proportion of young patients. Although asymptomatic patients over 55 years old have been shown to have the same mortality rate as a matched general population, the impact of age in a representative cohort of PBC patients remains unclear. The aim of this study was to identify whether presenting age at start of ursodeoxycholic acid (UDCA) therapy is associated with distinct transplant-free survival relative to the general population. It is important to assess survival relative to the general population because it is expected that older PBC patients have worse survival compared to younger patients.

Method: Patient data was retrieved from the Global PBC Study group database, which comprises data from 17 centers across Europe and North America. A total of 4355 UDCA-treated patients diagnosed between 1961 and 2014 were included in the analyses. The patients were grouped according to age at the start of UDCA treatment and transplant-free survival was compared. Furthermore, life table survival and Cox regression analyses within each age group compared transplant-free survival of PBC patients to an age-, gender-, and birth year-matched general Dutch population.



Results: Patients were grouped according to age at the start of treatment: ≤35 (n = 199), 36–45 (n = 727), 46–55 (n = 1305), 56–65 (n = 1234), >65 (n = 890). On Kaplan-Meier analysis, the 10-year transplant-free survival rate decreased with age in the corresponding age groups from youngest to oldest: 89.4%, 87.0%, 82.4%, 77.7%, and 64.1% (p < 0.001). In contrast, the transplant-free survival hazard ratio (HR) relative to the general population significantly decreased with age: ≤35 (HR 14.59, 95% CI 9.66–22.02), 36–45 (HR 7.10, 95% CI 5.87–8.58), 46–55 (HR 4.14, 95% CI 3.65–4.70), 56–65 (HR 2.18, 95% CI 1.93–2.46), and >65 (HR 1.39, 95% CI 1.23–1.57) (p < 0.001). Patients that were ≤35 years old had the highest hazard ratio and patients >65 years of age had the lowest (Figure).
Conclusion: Younger age in PBC is associated with lower transplant-free survival relative to a matched general population. This emphasizes the need for increased monitoring and additional therapies in younger patients.

THU-212

Risk factors for hepatocellular carcinoma in a large cohort of patients affected by primary sclerosing cholangitis

F. Saffioti[1,2], D. Roccarina[1], A. Marshall[1], M. Pinzani[1], D. Thorburn[1].
[1]UCL Institute for Liver and Digestive Health, The Royal Free Sheila Sherlock Centre, Royal Free Hospital, London; [2]University of Messina, Department of Clinical and Experimental Medicine, Division of Clinical and Molecular Hepatology, Messina, Italy
Email: fsaffioti.83@gmail.com

Background and Aims: Primary sclerosing cholangitis (PSC) patients are at risk of biliary tract cancer [cholangiocarcinoma (CCA) 5–10% of patients, gallbladder cancer (GBC) 2–4% of cases] and colorectal cancer (CRC). It has been suggested that the risk of developing hepatocellular carcinoma (HCC) may be lower in patients with PSC than in other causes of liver disease. There are no specific recommendations for HCC surveillance in this population. Our aim was to report the incidence of HCC in a large single centre cohort of PSC patients and consider the potential risk factors for HCC in this population.
Method: A retrospective analysis of the PSC database of our tertiary centre was performed, excluding patients with incomplete data. Demographics, type, location (intra/extrahepatic), duration and severity of PSC, IBD type and duration, prevalence of biliary tract cancers, HCC and CRC, pharmacological treatment, duration of follow-up (FUP) and outcome were recorded. FUP and patients-years at risk calculation started at time of PSC diagnosis. FUP was censored at occurrence of HCC, liver transplant (LT), death or last FUP. All the abovementioned variables were correlated with the incidence of HCC. Cox proportional hazard model was used for risk analysis.
Results: 281 patients followed-up between 1988 and 2016 were included. Patient's characteristics are summarized in Table 1. Eighty-two (29%) patients underwent LT/death. Eleven (3.9%) developed HCC (1 incidental on explant), 13 (4.6%) CCA, 2 (0.7%) GBC, 2 (0.7%) pancreatic cancer, 11 (3.9%) CRC. All HCC occurred in cirrhotic patients. The only variable significantly associated to the development of HCC at the univariate analysis was the presence of cirrhosis (p = 0.003). Statistical significance was not maintained on Cox regression (p = 0.161, HR 0.020). Incidence of HCC was 0.6% for the 1756 years FUP covering the entire cohort, 1.1% with regard to the 996 patient-years with cirrhosis.
Conclusion: In our cohort, incidence of HCC was low, as has been previously observed. Presence of cirrhosis was the only variable associated to HCC development, but risk proportion is unclear. Given the low incidence of HCC in this population, it further questions whether a strategy of surveillance for HCC in PSC patients with cirrhosis is justified.

Table 1: Characteristics of the study population

Patients, n (%)	281 (100)
Males, n (%)	181 (64)
Age, mean (SD)	48 (16)
Age at diagnosis, mean (SD)	41 (16)
Months from PSC diagnosis, median (range)	57 (6–413)

Optimal institution of azathioprine maintenance therapy in autoimmune hepatitis: a multicenter cohort study

S. Pape[1], T. Gevers[1], I. Mustafajev[1], F. van den Brand[2], K. van Nieuwkerk[2], G. Bouma[2], J.M. Vrolijk[3], B.V. Hoek[4], J. Hartl[5], A. Lohse[5], C. Schramm[5], G.W. Wong[6], M. Heneghan[6], J.P. Drenth[1].
[1]Radboud University Medical Center, Gastroenterology and Hepatology, Nijmegen, Netherlands; [2]VU University Medical Center, Gastroenterology and Hepatology, Amsterdam, Netherlands; [3]Rijnstate Hospital, Gastroenterology and Hepatology, Arnhem, Netherlands; [4]Leiden University Medical Center, Gastroenterology and Hepatology, Leiden, Netherlands; [5]University Medical Center Hamburg-Eppendorf, 1st Department of Medicine, Hamburg, Germany; [6]King's College Hospital, Institute of Liver Studies, London, United Kingdom
Email: Simon.Pape@radboudumc.nl

Background and Aims: Current treatment of autoimmune hepatitis (AIH) consists of induction therapy with prednisone followed by azathioprine (AZA) maintenance therapy. The EASL Clinical Practice Guideline on AIH advises on initiation of AZA after two weeks of prednisone treatment while the AASLD guideline advises on AZA initiation at onset of therapy. Delaying introduction of AZA at start of therapy discriminate between AZA-induced hepatotoxicity and primary non-response. However, the effect on remission is unknown. This study aims to compare both strategies in a cohort of patients with newly established AIH.
Method: We investigated the effect of early (<2 weeks) versus late (>2 weeks) initiation of AZA in AIH in an international multicenter cohort using chart review data from six centers. Eligible patients had an established AIH diagnosis, were ≥18 years old and initiated treatment with AZA. Primary outcome was biochemical remission, defined as a normal transaminases at 24 weeks of therapy. Secondary outcome was discontinuation of AZA before 24 weeks. We performed logistic regression to determine differences in primary outcome between the early and late groups, with correction for center, weight, baseline ALT, AST, bilirubin and AZA dose. Odds ratios (OR) with 95%-confidence intervals were calculated. We used chi-square testing for the secondary outcome.
Results: Primary analysis included 233 patients: the majority was female (78,1%) and mean age at diagnosis was 51,6 years (SD 17.5). The early AZA group consisted of 89 patients while 144 patients received AZA after >2 weeks of therapy. Early starters had significantly higher baseline transaminases (ALT, p < 0.01; AST p < 0.01), bilirubin (p < 0.01) and IgG (p < 0.01), while mean AZA dosage was lower (57.0 mg/day vs. 66.7 mg/day, p < 0.01). Biochemical remission at week 24 was higher in late starters when compared to early starters (72.9% vs. 64.0%), but this difference was not significant after correction for confounders (OR 0.76 (0.37–1.56, p = 0.45)). Patients in the late group discontinued AZA less frequently compared to the early group (2.1% vs. 9.0%, p = 0.02).

Conclusion: Delaying of azathioprine therapy does not decrease the likelihood of biochemical remission in AIH and might be associated with lower discontinuation rates of the drug.

THU-214

The risk predictive values of UK-PBC and GLOBE scoring system and performance of biochemical response criteria in Chinese patients with primary biliary cholangitis (PBC) on ursodeoeycholic acid

A. Huang[1], Y. Sun[1], Z. Zou[1], C. Wang[2,3], Y. Wang[2], J. Chen[2], T. Wu[2], V. Wu[2], G. Lau[4]. *[1]Centre of Non-Infectious Liver Diseases, Beijing 302 Hospital, Beijing, China; [2]Humanity and Health Research Centre, Hong Kong, Hong Kong; [3]State Key Laboratory of Organ Failure Research, Guangdong Provincial Key Laboratory of Viral Hepatitis Research, Nanfang Hospital, Southern Medical University, Department of Infectious Diseases, Guangzhou, China; [4]Humanity and Health Research Centre, Unit 1505, Hong Kong, Hong Kong*
Email: gkklau@netvigator.com

Background and Aims: The biochemical response to ursodeoxycholic acid (UDCA) in primary biliary cholangitis (PBC) is a strong predictor of long-term outcome and thus facilitates the rapid identification of patients needing new therapeutic approaches. Numerous criteria for predicting outcome of treatment have been studied based on biochemical response to UDCA at 1 year. We sought to determine whether biochemical response based on these criteria could identify Chinese patients with PBC at risk of clinical adverse outcome, as defined by liver-related death, liver transplantation, and complications of cirrhosis.
Method: 119 consecutive patients (median age 46, female sex 83.2, median follow-up of 3.8 [range: 1.1–9.1]) all with biopsy-proved PBC treated with UDCA from one of the biggest tertiary hospitals in China (Beijing 302 hospital) were included. Clinical characteristics and liver biochemistry were collected at every 6-month interval. Death, liver transplantation (LT) and complications of cirrhosis were used as clinical adverse outcome. Cox proportional hazards regression analysis was used to identify the risk factors for progression after a year of UDCA treatment. The prognostic ability of UK-PBC score and GLOBE score were evaluated alongside those of the Barcelona, Paris-I, Rotterdam, and Paris-II criteria. The Area-Under-the-Receiver-Operating-Curve (AUROC) for survival analysis (c-statistics) was used to determine the performance of each prognostic method.
Results: The survival rates without adverse clinical outcome at 2, 5 and 8 years were 95.8% and 78.7% and 61.8% respectively. Under UDCA therapy, laboratory liver parameters experienced the most prominent improvement at 1st year (all $p < 0.05$). The Paris I and Paris II, but not the Rotterdam and Barcelona definition applied at 1st year after UDCA therapy significantly discriminated the patients in terms of long-term clinical outcome. Paris I was the most powerful predictor among four criteria (HR: 3.6, 95%CI: 1.5–8.3, AUROC 0.65) for non-responders versus responders. According to Paris I criteria 8-yrs survival was 79.6% for responders and 43.6% for non-responders. The AUROC was 0.78 for GLOBE scoring system (HR: 2.9, 95%CI: 1.9–4.4). Patients with a GLOBE score > 0.3 (non-responders) had a significantly diminished survival compared with those with a score <=0.3 (responders), and the 3-, 5- and 8-year clinical adverse outcome free survival rates were 95% vs. 74%, 91% vs. 64%, and 87% vs. 35%, respectively. The AUROC was 0.739, 0.738 and 0.738 for 3-, 5-, 8-year UK-PBC risk score.
Conclusion: This analysis confirms the prognostic value of previously proposed response criteria and scoring systems. Paris I was the most powerful predictor among all the criteria while GLOBE score predicted more accurate than UK-PBC score in Chinese cohort.

THU-215

Biochemical response to ursodeoxycholic acid predicts histologic primary biliary cholangitis progression

T. Namisaki[1], Y. Fujinaga[2], K. Moriya[1], M. Kitade[1], K. Kaji[1], H. Kawaratani[3], K. Seki[1], H. Takaya[1], S. Sato[1], Y. Sawada[1], T. Akahane[1], H. Yoshiji[1]. *[1]Nara Medical University, Third Department of Internal Medicine, Kashihara, Japan; [2]Nara Medical University, Third Department of Internal Medicine; [3]Nara Medical University, Third Department of Internal Medicine*
Email: tadashin@naramed-u.ac.jp

Background and Aims: The prognosis and natural history of primary biliary cholangitis (PBC) have improved; its clinical endpoint needs to be discovered. We aimed to identify the surrogate markers for predicting histologic PBC progression.
Method: We enrolled the 99 patients to evaluate the potential correlation between biochemical response to ursodeoxycholic acid (UDCA) and histological stage at baseline according to both Scheuer (SC) and Nakanuma (NA) systems. We then conducted sequential biopsies in 35 patients with PBC treated with UDCA. They were divided into UDCA responders (R; n = 14) and non-responders (N; n = 21) based on reductions in γ-glutamyl transpeptidase levels at 1 year post UDCA therapy initiation (Nara criteria). We analyzed correlations between magnitude of biochemical response to UDCA and progression of histological changes of PBC. The Nakanuma system grades liver fibrosis (fibrosis score) and bile duct loss (BDL score).
Results: The proportion of R to N was significantly higher among patients in Scheuer and Nakanuma stages 1–3 and those with BDL scores of 0–2 compared with those in Scheuer and Nakanuma stages 4 and those with BDL score of 3, respectively ($P < 0.05$ for all). The number of stage 1, 2, 3, or 4 cases according to the SC was 6, 12, 17, and 0, respectively; according to the NA, it was 4, 18, 11, and 2, respectively. As per the SC, 1 patients had improved histological findings (I), 21 had stable histological findings (S), and 13 had histological progression (P); the NA categorized 4, 23, and 8 patients as I, S, and P, respectively. The fibrosis score progressed in 13 patients, while 1 showed improvement and 21 showed no progression; 4 patients exhibited improved BDL scores, while 23 showed no change and 8 showed worsening. In R (n = 14), proportions of patients with I, S, or P according to the SC were 0% (0/14), 78.5% (11/14), and 21.4% (3/14), respectively; this proportion per the NA was 14.3% (2/14), 57.1% (8/14), and 14.3% (4/14), respectively. Proportions of patients with improved, stable, or worsened fibrosis score were 0% (0/14), 64.3% (9/14), and 35.7% (5/14), respectively; as per BDL scores, it was 14.3% (2/14), 71.4% (10/14), and 14.3% (2/14), respectively. In N (n = 21), this proportion according to the SC was 4.8% (1/21), 47.6% (10/21), and 47.6% (10/21), respectively; per the NA, it was 9.5% (2/21), 71.4% (15/21), and 19.1% (4/21), respectively. The proportion for fibrosis score was 4.8% (1/21), 57.1% (12/21), and 38.1% (8/21), respectively; for the BDL score, it was 9.5% (2/21), 61.9% (13/21), and 28.6% (6/21), respectively. Histological progression rate per the SC and deterioration rate of BDL score was significantly higher in N than in R ($p < 0.01$ and $p < 0.05$, respectively).
Conclusion: The biochemical response to UDCA according to Nara criteria predicts the histological progression of PBC.

THU-216

Durable response in the markers of cholestasis through 36 months of open-label extension study of obeticholic acid in primary biliary cholangitis

M. Trauner[1], F. Nevens[2], M. Shiffman[3], J.P.H. Drenth[4], C. Bowlus[5], V.M.V. Blasco[6], P. Andreone[7], R. Pencek[8], E.S. Malecha[8], L. Macconell[8], D. Background and Aims: Obeticholic Acid (OCA) is a selective and potent farnesoid X receptor agonist indicated for treatment of primary biliary cholangitis (PBC). POISE is a 12-month double-blind (DB), placebo (PBO)-controlled, Phase 3 PBC study including an open-label extension (OLE). The purpose of the OLE is to assess safety and durability of the OCA effect on serum markers of cholestasis.
Method: Key POISE inclusion criteria: PBC diagnosis, ALP ≥1.67× ULN and/or total bilirubin (TB) >ULN to <2× ULN, stable UDCA dose or unable to tolerate UDCA. During the DB phase, 216 patients were randomized and dosed to: daily PBO, n = 73; OCA 5–10 mg (titration after 6 months based on response and tolerability), n = 70; or OCA 10 mg, n = 73. In the OLE, all patients were initially treated with OCA 5 mg regardless of DB treatment with the option to increase after 3 months based on response and tolerability.
Results: 193 of 198 (97%) patients completing the DB phase of the study enrolled in the OLE; 165 reached 36 months of the OLE: PBO, n = 49; OCA 5–10 mg, n = 59; OCA 10 mg, n = 57. At the end of the DB phase, patients on OCA had significant reductions in ALP and patients on PBO did not (Table 1). ALP reduction observed in OCA-treated patients was durable through 36 months OLE. PBO-treated patients experienced a significant reduction in ALP after switching to OCA, which was durable through 36 months OLE. Similar durable improvements were seen for GGT, ALT, and AST (data not shown). For OCA-treated patients, mean TB remained below BL through 36 months OLE. For PBO-treated patients, mean TB increased at 12 months DB, but trended back toward baseline (BL) with 36 months of OCA during OLE. During the OLE, 28 (15%) patients discontinued treatment, 7 (4%) patients for pruritus.

Table 1: ALP and TB mean change from BL through 36 month OLE

DB Phase Treatment Group	PBO	OCA 5–10 mg	OCA 10 mg
ALP (U/L)			
DB BL	327 (115)	326 (116)	316 (104)
Δ DB 12 mo†	−8 (88)	−104 (87)***	−118 (73)***
Δ OLE 24 mo‡	−101 (87)***	−121 (97)***	−103 (79)***
Δ OLE 36 mo‡	−113 (90)***	−101 (110)***	−85 (137)***
TB (μmol/L)			
DB BL	11.8 (7.2)	10.2 (5.5)	11.3 (6.6)
Δ DB 12 mo†	1.5 (4.1)	−0.5 (3.4)**	−1.2 (4.3)***
Δ OLE 24 mo‡	1.9 (7.6)	−0.4 (3.6)	−0.6 (4.8)
Δ OLE 36 mo‡	0.5 (3.6)	−0.5 (3.4)	−0.9 (4.1)

*p < 0.05, **p < 0.01, ***p < 0.0001. Values are Mean (SD).
†P-value for comparing active treatments to PBO is obtained using an ANCOVA model with Baseline value as a covariate and fixed effects for treatment and randomization strata factor.
‡P-value for the within treatment comparisons are obtained using the Student's t- test.

Conclusion: OCA treatment results in improvement in liver biochemistry; this improvement is shown to be durable in this analysis. For patients initially treated with PBO, switching to OCA is also associated with a durable biochemical response. Consistent with the DB phase, pruritus was the most common side effect of OCA, but discontinuation due to pruritus continues to be infrequent.

Email: emina.halilbasic@meduniwien.ac.at

Background and Aims: Changes of bile composition play a role in the pathogenesis and progression of cholangiopathies. Phosphatidylcholine (PtdCh) is the major biliary phospholipid counteracting bile acid toxicity and may be targeted by novel therapeutic strategies. However studies on bile composition in patients are scarce due to invasive nature of bile sampling. PtdCh concentration can be assessed with ^{31}P MR spectroscopy (MRS) in human bile. Therefore, our aim was to investigate this non-invasive method for detection of the PtdCh concentration in the gall bladder of healthy controls in comparison with primary sclerosing cholangitis (PSC) and primary biliary cholangitis (PBC) patients.
Method: Biliary PC concentrations were studied in 4 healthy volunteers (3m/1f), 6 PBC (2m/4f) and 4 PSC (2m/2f) patients using ^{31}P MR spectroscopic imaging on a 7T Magnetom System (Siemens Healthineers, Erlangen, Germany) with a double-tuned ^{1}H/^{31}P surface coil. All PSC and PBC patient were treated with ursodeoxycholic acid. The signal quantification was based on a 3D sequence covering the liver and gall bladder of patients. The signal distribution of PtdC was then referenced to the corresponding localizer images and calibrated to mean γ-resonance of adenosine triphosphate concentration.
Results: Typical spectral from gall bladder region and homogeneous hepatic tissue was obtained in all included subjects. Calculated PtdCh concentration of the healthy volunteers was 11.77 ± 1.18 mmol/l (n = 4) comparable with previously published concentrations. In PSC patients, PtdCh content was much lower with 6.92 ± 0.80 mmol/l (n= 4) compared to controls (p < 0.001), whereas its concentration in PBC patients averaged at 12.81 ± 11.22 mmol/l (n = 6) and did not differ from control s. Interestingly, lowered PtdCh concentration (7.05 ± 1.76 mmol/l) was observed in all 4 female PBC patients (p < 0.01).
Conclusion: This pilot study confirmed that ^{31}P MRSI can be used to quantify the biliary PC concentration in non-invasive manner. Low biliary PtdCh concentration in PSC and female PBC patients strengthens the hypothesis that biliary composition may be an important pathogenetic factor. Further investigations are needed to validate ^{31}P MRS as a novel non-invasive method for addressing the role of PtdCh in cholangiopathies.

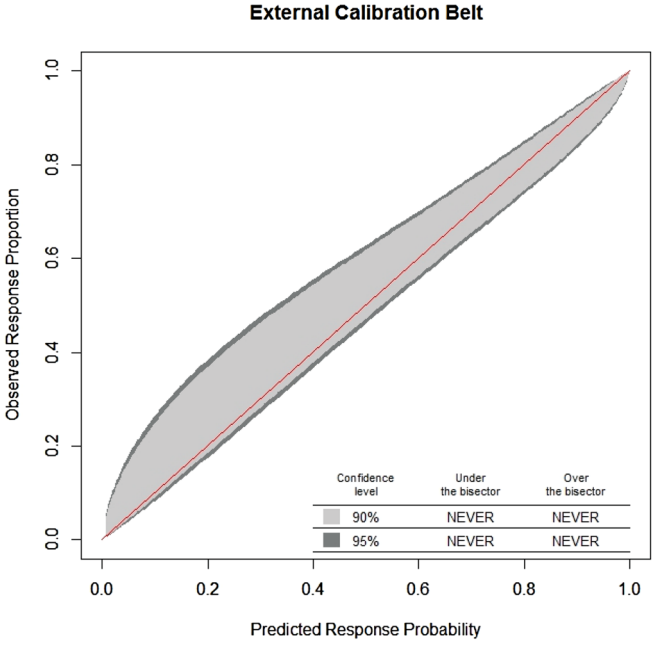
Email: mc767@medschl.cam.ac.uk

Background and Aims: PBC guidelines advocate risk-stratification after 12 months of treatment with UDCA to decide whether patients might benefit from addition of second-line agents (OCA or fibrate). In practice, this means that patients in greatest need of second-line therapy (i.e. those with active disease) must wait 12 months to start it. An alternative approach, albeit untested, is to treat high-risk patients with combination therapy from the outset. The aim of this study was to derive and validate a predictive model of UDCA response that will enable selection of patients at high risk of inadequate response to be directed to combination therapy from the outset.
Method: We analysed data on 2,703 patients from the UK-PBC Cohort treated with UDCA. We undertook logistic regression analysis of diverse explanatory variables to derive the best-fitting model. The endpoint was UDCA response, defined as alkaline phosphatase (ALP) <1.67× ULN after ≥12 months of UDCA therapy. The model underwent internal validation using boot-strapping as well as external validation in an independent PBC cohort from Italy (n = 460). We then explored the biological plausibility of the URS by looking at its correlation with several histological features in an independent cohort of patients (n = 20) for whom FFPE liver biopsies were available from the time of diagnosis.
Results: The following pre-treatment conditions were associated with greater probability of inadequate response to UDCA: higher ALP ($p < 0.0001$), higher bilirubin ($p = 0.0003$), lower transaminases (TA, $p = 0.0012$), younger age ($p < 0.0001$), larger interval from diagnosis to starting UDCA (time-lag, $p < 0.0001$) and worsening of ALP from diagnosis to starting UDCA (ΔALP, $p < 0.0001$). Based on these variables we derived a predictive score of UDCA response:

$$\text{UDCA response score (URS)}: 0.77 + 0.60 \times (\sqrt{TBdiag})^{-1} - 2.73 \times log(ALPdiag) + 0.35 \times log(TAdiag) + 0.03 \times age - 0.15 \times (time - lag) - 0.56 \times \Delta ALP$$

In external validation, the AUROC was 0.84 (0.80, 0.88) with a good calibration (Figure). In liver biopsies, the URS was inversely correlated with the extent of ductular reaction (DR) ($r = -0.777$, $p < 0.0001$) and extent of fibrosis ($r = -0.709$, $p < 0.0001$).
Conclusion: We derived and validated a model predicting future UDCA treatment response prior to initiation of therapy. Notably, delayed initiation of UDCA reduced the probability of response, emphasizing the importance of prompt initiation of therapy. Furthermore, the URS correlated with the extent of DR and fibrosis indicating that the score reflects the underlying pathologic process. A potential use for the URS is for pre-treatment selection of high-risk PBC patients for a clinical trial of primary vs sequential combination therapy. If primary combination therapy is shown to achieve higher rates of remission and faster times to remission, the model may then be used for pre-treatment risk stratification in clinical practice.



THU-219
Sustained biochemical response to oral antibiotics in pediatric PSC and ASC are correlated to changes in gut microbiota during therapy

P. Sambon[1,2], E. Amandine[2], V. Sharat[1], X. Stephenne[1,2], F. Smets[1,2], I. Scheers[1,2], M. Komuta[1,2], P. Cani[2], E. Sokal[1,2]. *[1]Cliniques Universitaires Saint-Luc, Woluwe-Saint-Lambert, Belgium; [2]Université catholique de Louvain, Louvain-la-Neuve, Belgium*
Email: etienne.sokal@uclouvain.be

Background and Aims: Concomitant presence of autoimmune hepatitis and primary sclerosing cholangitis (PSC) is labelled as autoimmune sclerosing cholangitis (ASC) in children. Based upon the possible implication of microbiota in the pathogenesis of PSC, oral antibiotics are increasingly being used as a novel therapeutic approach and shown to have benefit in PSC but their role in pediatric ASC is not well evaluated. We prospectively analysed the gut microflora before and after antibiotic therapy in children with ASC or PSC alone, and evaluated whether changes in gut microflora correlated with response to treatment.
Method: Patients diagnosed with ASC or PSC on basis of biochemical, liver biopsy and radiology findings were included. They prospectively received metronidazole (MTZ) for 14 days as induction or rescue therapy. Antibiotics were administrated in addition to the standard treatment of UDCA for PSC patients and azathioprine, UDCA and/or steroids for ASC patients. Stool samples were collected before and after antibiotic therapy. DNA isolation, amplification and Illumina sequencing to profile the microbiota composition were performed using the bacterial 16s rRNA. The beta-diversity measured the dissimilarity between each paired stool samples. The outcome parameters to assess the efficacy of antibiotics were reduction liver enzymes and subsequently achievement of sustained biochemical remission.
Results: Seven children (4 ASC, 3 PSC) were included, of which 5 have a concomitant ulcerative colitis (UC). All patients showed a significant decrease in their AST (–44%, $p < 0.025$), ALT (–56%, $p < 0.025$) and GGT (–41%, $p < 0.025$) under MTZ. Three children relapsed after stopping MTZ while the four others children showed a sustained

biochemical remission (liver enzymes below 1.5 times upper limit of normal) after a median follow-up of 375 days. Among these four patients, three exhibited a wide different microbial composition before and after MTZ as expressed by the beta-diversity variation. On the contrary, the microbiota of patients who relapsed remained unchanged pre- and post-MTZ.
Conclusion: Our study suggests that oral antibiotic could be an effective treatment of ASC and PSC, especially those with a concomitant UC, and that intestinal microflora play a major role in these diseases as sustained biochemical remission is associated with wide changes in gut microbiota communities after taking antibiotics.

THU-220

Primary biliary cholangitis specific T cell receptors on N-Ras high CD4+ T cells

R. Nakagawa[1,2], R. Muroyama[1], C. Saeki[2], M. Zeniya[3], N. Kato[4]. [1]*The Institute of Medical Science, The University of Tokyo, Division of Advanced Genome Medicine, Tokyo, Japan;* [2]*The Jikei University School of Medicine, Department of Gastroenterology and Hepatology, Tokyo, Japan;* [3]*International University of Health and Welfare, Clinical Research Center, Sanno Hospital, Tokyo, Japan;* [4]*Graduate School of Medicine, Chiba University, Department of Gastroenterology, Chiba, Japan*
Email: lake.vic30@gmail.com

Background and Aims: Primary biliary cholangitis (PBC) is an autoimmune liver disease with unknown pathogenesis. Recently, we have reported activated T cell receptor signaling pathway is associated with the production of inflammatory cytokines via N-Ras upregulation in PBC CD4+ T cells (J Hepatol 2017). Although TCR repertoires of CD4+ T cells are supposed to be concerned with PBC pathogenesis, those in PBC have never been analyzed. Moreover, next generation sequencer (NGS) enabled comprehensive expressional and structural analysis of TCR repertoires, thus we analyzed CD4+ T cell repertoires.
Method: In this study, 1 naïve PBC patient, 3 PBC patients receiving ursodeoxycholic acid (UDCA), and 3 healthy controls, who agreed to provide samples with written informed consent, were enrolled. N-Ras expression in CD4+ T cells from subjects was assessed by qRT-PCR. The repertoires of TCR α chain (TRA) and β chain (TRB) on CD4+ T cells were analysed by the NGS. Hierarchical analysis profiled the expression pattern of TCR repertoires. Motif analysis was performed to elucidate the structure of PBC specific TCR repertoires.
Results: N-Ras was upregulated in PBC CD4+ T cells compared to control ($P < 0.05$). Among 2,668 TRA repertoires, 6 TRA repertoires were significantly upregulated in PBC compared to control ($P < 0.05$, Fold change >1.8). Among 841 TRB repertoires, 8 TRB repertoires were significantly upregulated in PBC compared to control ($P < 0.05$, Fold change >1.8). No repertoire of TRA and TRB was downregulated in PBC compared to control. The expression of 6 TRA and 8 TRB was not significantly different between naïve and treated PBC. Among differentially expressed 6 TRA and 8 TRB, TRAV29/J22, TRBV6-5/J6-2, and TRBV10-1/J2-1 were expressed on PBC CD4+ T cells, however hardly expressed on CD4+ T cells of control. Moreover, the structure of TRAV29/J22, TRBV6-5/J6-2, and TRBV10-1/J2-1 was obviously different between PBC and control. In PBC, those structures were formed mature and longer compared to control.
Conclusion: The expression and structure of TCR repertories on N-Ras high CD4+ T cells of PBC were significantly different from those of control. Then TRAV29/J22, TRBV6-5/J6-2, and TRBV10-1/J2-1 was unique in PBC both expressionally and structurally. Thus, PBC specific TCR repertories might be associated with activating TCR signalling pathway via N-Ras expression.

THU-221

Validation of various prognostic models in primary biliary cholangitis in Korean patients

J.-J. Yoo[1], E.J. Cho[2], S.G. Kim[1], Y.S. Kim[1]. [1]*Soonchunhyang University Bucheon Hospital, Department of Internal Medicine, Bucheon, Republic of South Korea;* [2]*Seoul National University Hospital, Department of Internal Medicine, Seoul, Republic of South Korea*
Email: creatioex@gmail.com

Background and Aims: For primary biliary cholangitis (PBC), various prognostic models have shown good performance in predicting outcomes in Western countries, but have not been validated in Asian population. This study aimed to compare the prognostic performance of suggested models in an independent cohort of PBC patients.
Method: This retrospective study included consecutive 289 patients diagnosed as PBC from 2006 to 2016 by liver biopsy in a tertiary hospital, Korea. Decompensated PBC was defined as presence of ascites, variceal hemorrhage, or jaundice. Event-free survival (EFS) was defined as time until development of decompensation, liver transplantation or death during follow-up. Time-dependent ROC curve analysis was performed to compare the performance of each model.
Results: Mean age of the patients was 57.3 ± 11.9 years and 87.9% were female. Fifteen patients (5.2%) had decompensated PBC at initial diagnosis. During a median follow-up of 76.5 months (range, 4–212), 35 patients (12.1%) died, and 8 (2.8%) underwent liver transplantation. For the prediction of transplant or liver-related death, PARIS-II,

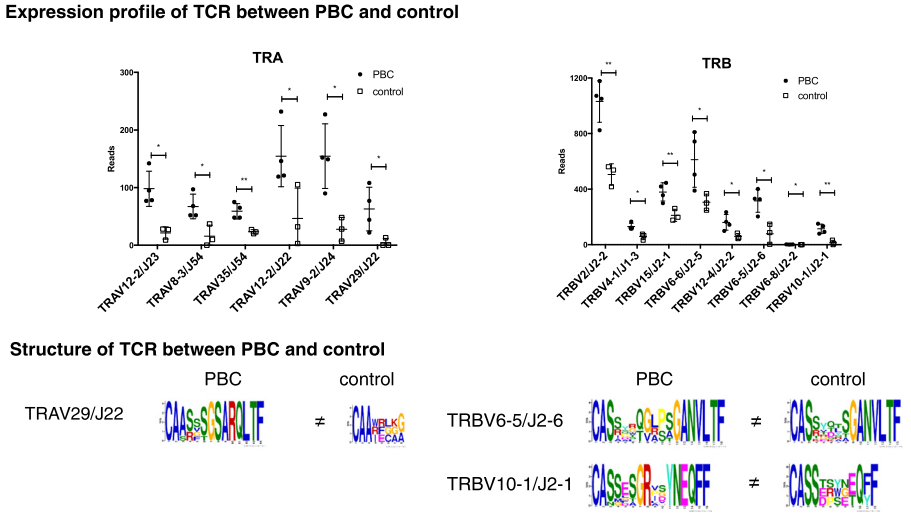


Figure: (abstract: THU-220)

PARIS-I and UK-PBC model showed moderate performance (area under the curves (AUCs), 0.74, 0.74 and 0.72, respectively), whereas GLOBE score and Barcelona model showed poor performance (AUCs, 0.6 and 0.57, respectively). When considering patients with compensated PBC, similar trends were observed. In addition, PARIS-II, PARIS-I and UK-PBC model showed moderate performance in the prediction of decompensation (AUCs, 0.71, 0.74 and 0.73, respectively), and the performance of GLOBE score and Barcelona model were poor (AUCs, 0.63 and 0.6, respectively). None of the models showed reliable performance in the prediction of EFS (all AUCs < 0.7).
Conclusion: Although most of the published prognostic models for PBC show moderate prediction, their prediction accuracies are relatively low in Korea. So it is necessary to develop new prediction model in PBC defined to Korean patients.

THU-222
Imaging features of macroregenerative nodules (MRN) in primary sclerosing cholangitis: MR imaging characteristics
A. Morgado[1], L. Pisani[2], C. Levy[1], B. Madrazo[1]. [1]*University of Miami, Department of Radiology, Miami, United States;* [2]*Pontifical Catholic University of Rio Grande do Sul, School of Medicine, Porto Alegre, Brazil*
Email: andres.morgado@jhsmiami.org

Background and Aims: Primary sclerosing cholangitis (PSC) is a rare cholestatic liver disease without available medical therapy. PSC is associated with increased risk of cholangiocarcinoma and imaging tests are frequently obtained for this patient population. Our aim was to delineate the spectrum of magnetic resonance (MR) imaging characteristics of macroregenerative nodules (MRN) of the liver in patients with PSC.
Method: We conducted a retrospective study of patients with PSC who had at least one hepatic MR imaging of the abdomen performed in a single institution between 2009 and 2017. The presence or absence of cirrhosis was determined by imaging findings. One abdominal radiologist retrospectively reviewed all images for the presence and imaging pattern of MRNs, specifically on diffusion weighted imaging. We used descriptive statistics to characterize study patients and MRI findings, and student t-test or chi-square test to evaluate for associations between patients' characteristics and the presence/absence of MRN on MRI.
Results: Forty-eight patients (26 male; mean age 48 years; age range, 77–20 years) with confirmed diagnosis of PSC underwent hepatic MR imaging. Of 48 patients, 20 (41%) had imaging findings of MRNs. MRNs were present in 11/13 patients with cirrhosis and 9/35 patients without cirrhosis (84.6% vs. 25.7%, $p < 0.001$), and in 14/26 males compared to 6/22 females (55% vs. 27%, $p = 0.06$). Age was not associated with presence of MRN's. These lesions showed absence of restricted diffusion on DWI/ADC imaging in all 20 (100%) cases, were not perceptible on T1 sequences, were low signal on T2 sequences, had no findings on opposed-phase imaging, did not enhance on post-gadolinium sequences and did not retained contrast on delayed images to suggest fibrosis. Another characteristic finding is that of a vascular bundle within the MRN's.
Conclusion: Macroregenerative Nodules (MRN) are lesions that have specific characteristic patterns on MRI imaging of the liver in patients with PSC and should not be confused with malignancy. These nodules are more frequent in males and in cirrhotic patients, although their presence cannot imply cirrhosis. Further studies are needed for better prognostic characterization of MRNs in PSC.

THU-223
Effect of nalfurafine hydrochloride for refractory pruritus in patients with primary biliary cholangitis: a multicenter, post-marketing, single-arm, prospective study
M. Yagi[1], A. Tanaka[1], T. Namisaki[2], M. Abe[3], A. Takahashi[4], A. Honda[5], Y. Matsuzaki[5], H. Ohira[4], H. Yoshiji[6], H. Takikawa[1]. [1]*Teikyo University School of Medicine, Department of Medicine;* [2]*Nara Medical University, The Third Department of Internal Medicine;* [3]*Ehime University Graduate School of Medicine, Department of Gastroenterology and Metabology;* [4]*Fukushima Medical University, Department of Gastroenterology;* [5]*Tokyo Medical University Ibaraki Medical Center, Department of Gastroenterology;* [6]*Nara Medical University, Third Department of Internal Medicine, Kashihara, Japan*
Email: a-tanaka@med.teikyo-u.ac.jp

Background and Aims: Patients with primary biliary cholangitis (PBC) frequently suffer from pruritus, which could severely impair health-related quality of life (HrQOL). In 2015, nalfurafine hydrochloride (NH), a selective κ-opioid receptor agonist, was officially approved in Japan for refractory pruritus of patients with chronic liver diseases (Hepatol Res 2017:47:972), but it still remains unclear whether NH is effective for refractory pruritus in PBC. Herein, we conducted a multicentre, post-marketing, single-arm prospective study.
Method: As screening, we consecutively asked patients with PBC at out-patient clinic to fill out PBC-40, and also to evaluate their pruritus with the visual analogue scale (VAS). Then we administered NH at 2.5 μg daily for three months for patients who were assessed to have moderate to severe pruritus by PBC-40 itch score, and asked patients to fill the questionnaires at 3 months of NH treatment. Blood chemistries and serum autotaxin levels were also measured both at baseline and at 3 months.
Results: Four-hundred and ninety-six Japanese PBC patients (male/female = 52/444, 66.1 ± 9.9 yo) participated in the screening. Moderate to severe pruritus, defined as more than 4 out of 12 points in PBC-40 itch score, were present in 141 (29%) patients with PBC. The VAS was 1.94 ± 2.48, and strongly correlated with the itch score.
Among 141 patients with moderate-severe pruritus, 48 patients participated in this study. All patients completed 3 months' treatment with NH. The VAS was significantly decreased from 4.34 ± 2.23 at baseline to 2.89 ± 2.41 ($p = 0.001$) at 3 months of NH treatment. Overall PBC-40 itch score was declined from 5.56 ± 3.34 to 4.67 ± 2.89 ($p = 0.056$), and the score of #3 question of itch domain ("I felt embarrassed because of the itching") was significantly decreased from 5.56 ± 3.34 to 4.67 ± 2.89 ($p = 0.013$) at 3 months of NH treatment. The effect of NH change was not associated with age, sex, serum ALP and other biomarkers, and not observed in patients with advanced stage. No remarkable adverse effects of HN was observed. Serum autotaxin levels were not associated with the VAS and PBC-40 itch scores at baseline, and with effect of NH.
Conclusion: This study demonstrated that NH was safe and effective for moderate to severe pruritus in patients with PBC, while the effect of NH might be diminished in PBC patients with advanced stage.

Email: kdeane@targetpharmasolutions.com

Background and Aims: PBC is a rare cholestatic liver disease. Obeticholic acid (OCA) was FDA approved in 2016 for patients not responding or intolerant to ursodeoxycholic acid (UDCA). The aim is to evaluate safety and effectiveness of OCA as used in clinical practice.
Method: TARGET-PBC is a longitudinal observational study of PBC patients at 25 U.S. sites (19 academic/6 community). Enrollment after May 2017 was enriched to include only those with elevated alkaline phosphatase (ALP) despite UDCA therapy, those on OCA, or on fenofibrate. Data from consented patients is captured from redacted medical records within a database utilizing centralized data abstraction. Treatment of PBC and initiation of OCA is at the discretion of the treating physician.
Results: To date, 311 PBC patients have been enrolled. Among 32 (10%) OCA-treated patients, median age was 56 years, 94% were female, 91% Caucasian and 86% AMA positive. Cirrhosis was present in 56% and autoimmune hepatitis overlap in 16%. Mean Child Pugh score was 5.8 (range 5–8). Median duration of OCA treatment was 8 months (range 1 to 32). Current OCA dose was 5 mg/day in 57% and 10 mg/day in 18% of patients. All continued UDCA with a mean dose of 14.9 mg/kg/day. Last available pre-OCA lab values were compared to the last available values while on OCA. Reduction in ALP occurred in 19/23 (83%) patients (mean-25.6%, range –8.2% to –54.6%) compared to baseline. ALP decreased >15% in 16 patients (70%). Similarly, alanine aminotransferase decreased in 20/23 (87%) patients (mean –30.6%, range –4% to –70.5%). Most patients (19/23, 83%) had normal total bilirubin (TB) prior to OCA start and remained essentially unchanged during treatment. Four patients had elevated TB prior to OCA (range 2.0–10.6 mg/dL); 1 had progressive hepatic decompensation, with OCA dose reduction to twice weekly, and is undergoing transplant evaluation, while 3 remain stable on OCA without substantial TB change. Adverse events described during OCA therapy included pruritus (25%), fatigue (9.4%), gastroesophageal reflux (9.4%) and urinary tract infection (9.4%). Four patients (13%) discontinued OCA due to pruritus and 1 (3%) discontinued OCA after 3 weeks due to hepatic decompensation, concurrent with chemotherapy for colon cancer.
Conclusion: Consistent with data from the randomized trial, use of OCA has had a beneficial effect on liver biochemistries. Longitudinal follow-up of this expanding, real-world cohort will continue for 5 years.

THU-225
Primary biliary cholangitis (PBC) in the U.S.: clinical characteristics of patients enrolled in TARGET-PBC

C. Bowlus[2], E. Carey[3], G. Demuth[4], K. Deane[4], M.J. Mayo[5], W. Ray Kim[6], B. Bacon[7], D. Bernstein[8], P.J. Thuluvath[9], L. Michael Weiss[10], M.W. Fried[11]. *[1]University of Miami, Miami, United States; [2]University of California Davis, Sacramento, United States; [3]Mayo Clinic, Phoenix, United States; [4]TARGET PharmaSolutions, Chapel Hill, United States; [5]University of Texas Southwestern, Dallas, United States; [6]Stanford University Medical Center, Stanford, United States; [7]Saint Louis University, St. Louis, United States; [8]Northwell Health, Manhasset, United States; [9]Mercy Medical Center, Baltimore, United States; [10]Gastro Florida, Clearwater, United States; [11]University of North Carolina Chapel Hill, Chapel Hill*
Email: kdeane@targetpharmasolutions.com

Background and Aims: Primary biliary cholangitis (PBC) is an uncommon autoimmune cholestatic liver disease. The majority of PBC patients achieve a complete biochemical response with ursodeoxycholic acid (UDCA). Obeticholic acid (OCA) was approved by the FDA in 2016 for PBC patients not responding or intolerant to UDCA. The aim of this study is to determine the natural history of PBC and evaluate treatment regimens used in usual clinical practice.
Method: TARGET-PBC is a longitudinal observational study of PBC patients managed at 25 U.S. sites (19 academic and 6 community). Detailed information from consented patients is captured from redacted medical records within a common database utilizing centralized data abstraction. Optional biospecimens for biomarker and other translational studies are collected, along with patient reported outcomes.
Results: Total enrollment to date is 311 with evaluable data from 251 patients currently available. Enrollment after May 2017 was enriched to include only those with elevated serum alkaline phosphatase (ALP) despite UDCA therapy or those treated with OCA or fenofibrate (33% of current enrollment). Median age was 63 years, 89% were female, 85% Caucasian, 14% Hispanic and 84% were AMA positive. Mean duration of disease is 6 years (0–35 years). Cirrhosis (defined by biopsy and/or by clinical algorithm including non-invasive measures and clinical outcomes) was present in 34% of the cohort and autoimmune hepatitis overlap was identified in 16% of all patients. Other features included pruritus (39%), fatigue (41%), sicca syndrome (26%), hypothyroidism (25%) and hyperlipidaemia (21%). Sixty-one patients had a DEXA scan; 71% had osteopenia and 10% had osteoporosis. At the time of study entry, 63% had serum ALP above the site specific upper limit of normal (ULN): 30% (74/251) with ALP > 1.5× ULN and 22% (54/251) with ALP > 1.67× ULN. Total bilirubin was abnormal in 14% and albumin in 16%. Eighty-seven percent of patients were prescribed UDCA; 9% were prescribed OCA + UDCA and 4% were prescribed fenofibrate + UDCA.
Conclusion: Patients enrolled in TARGET-PBC include populations underrepresented in clinical trials and their characteristics are consistent with published data on PBC. More than half of patients still had abnormal ALP despite being on UDCA, with 30% having ALP >1.50× ULN. Increased awareness about the role of adjuvant therapies is needed. Longitudinal follow-up of this expanding, real-world cohort is ongoing.

Email: w.lammers@erasmusmc.nl

Background and Aims: Earlier studies indicate that 12-month biochemical non-response according to Paris-I, Rotterdam, Barcelona and Toronto criteria, confer an increased risk of hepatocellular carcinoma (HCC) development in primary biliary cholangitis (PBC). Recently, a new score was developed, the GLOBE score, that identifies ursodeoxycholic-acid (UDCA) treated patients with a diminished transplant-free survival. However, no data is available on its ability to stratify HCC risk in PBC.
Method: Patients were derived from the Global PBC Study Group database. Risk factor analyses were performed using univariate and multivariate cox regression models and Kaplan-Meier estimates. Response according to the GLOBE score was defined as a GLOBE score after one year of UDCA therapy below the following age-specific thresholds: <45 yr: −0.52, 45–52 yr: 0.01, 52–58 yr: 0.60, 58–66 yr: 1.01 and ≥66 yr: 1.69.
Results: 4851 PBC patients were included in this study. Within this cohort 155 patients developed HCC; and after excluding those with cancers that manifest early (<6 months from PBC diagnosis) 4820 patients and 124 HCC cases remained. The majority of female sex (n = 4317, 89.6%) with a mean age at diagnosis of 53.6 years (IQR 45.2–62.0) and most with an early histological stage of disease (1400/1917, 73.0%).
Of 4820 patients 85% (n = 4095) were UDCA treated of whom 28.5% (n = 1123 of 3938) had insufficient biochemical response after one year of treatment according to age-specific GLOBE thresholds. The incidence of HCC at 5- and 10-years for patients with an insufficient response versus those with adequate response was 32/705 (4.5%) versus 9/2010 (0.4%) and 43/376 (11.4%) versus 21/1119 (1.9%) respectively (P < 0.000).
On univariate analysis the earlier described factors late histological stage (HR 2.83, 95% CI 1.09–7.35, P < 0.0001), biochemical advanced stage (HR 2.57, 95% CI 1.32–4.98, P < 0.0001), male sex (HR 2.55, 95% CI 1.63–3.99, P < 0.0001) and thrombocytopenia (HR 7.14, 95% CI 4.35–12.5, P < 0.0001) retained association with HCC risk. Furthermore, higher GLOBE scores were associated with increased risk of HCC development, both as a continuous (HR 2.58, 95% CI 2.01–3.31, P <0.0001) and dichotomized variable according to age-specific thresholds (HR 7.72, 95% CI 2.75–21.71, P < 0.0001). When adjusting for aforementioned variables, elevated GLOBE scores retained association with increased risk of HCC (adjusted HR 1.96, 95% CI 1.46–2.62, P < 0.0001).
Conclusion: GLOBE scores after one year of UDCA treatment indicative of an insufficient response to treatment are associated with increased risk of HCC.

THU-227

A dose-response relationship in the association between ursodeoxycholic acid treatment and prolonged transplant-free survival in primary biliary cholangitis

Email: m.h.harms@erasmusmc.nl

Background and Aims: Although the clinical efficacy of ursodeoxycholic acid (UDCA) in primary biliary cholangitis (PBC) has been questioned due to a lack of adequate RCTs, this treatment was recently shown to be independently associated with a prolonged liver transplantation (LT)-free survival among all patients with PBC. In this study, we aimed to assess the dose-response relationship between UDCA and both biochemical response and LT-free survival in PBC.
Method: In 10 Global PBC Study Group centers, data on the baseline dosages of UDCA in milligram (mg) per kilogram (kg) were collected. The associations between UDCA and biochemical response – classified by the GLOBE score- and LT-free survival were assessed with logistic regression and Cox survival analyses respectively, adjusting for sex, age, year of diagnosis, and baseline biochemistry including alkaline phosphatase, total bilirubin, albumin, platelet count, aspartate aminotransferase, and alanine aminotransferase.
Results: We included 2710 patients, who were followed for a median of 8.4 (IQR 4.7–13.1) years. Mean age was 54.4 (SD 11.9) years, 2363 (90.5%) were female and 2337 (86.2%) received UDCA. For 1585 out of 2337 UDCA-treated patients (67.8%), the baseline treatment dosage was available in mg/kg. In this group, treatment with UDCA was associated with an higher rate of biochemical response after 1 year (OR 3.55, 95%CI 1.89–6.67, p = 0.0006) as opposed to no treatment. In comparison to UDCA-untreated patients, those treated with an inadequate dosage of <13 mg/kg UDCA (n = 914, 57.7%) were more likely to have a biochemical response (OR 3.08, 95%CI 1.89–5.03, p = 0.0002). However, among those with an adequate dosage of ≥13 mg/kg UDCA (n = 671, 42.3%), the odds of a biochemical response were higher (OR 4.73, 95%CI 1.95–11.5, p = 0.0018). In the 1585 UDCA-treated patients with known dosages the risk of LT/death was lower than in untreated patients (HR 0.39, 95%CI 0.32–0.47, p < 0.0001). While this association was also significant in inadequately dosed patients (HR 0.40, 95%CI 0.34–0.47, p < 0.0001), it was stronger in those dosed with ≥13 mg/kg (HR 0.27, 95%CI 0.20–0.37).
Conclusion: Among patients with PBC, the association between UDCA treatment and both biochemical response and LT-free survival is dependent on the dosage of UDCA. These findings not only reinforce current guidelines recommending at least 13 mg/kg of UDCA for the treatment of PBC, but also support the causal relationship between UDCA and prolonged LT-free survival.

THU-228

Incidence of autoimmune hepatitis is increasing, while primary biliary cholangitis and primary sclerosing cholangitis have remain unchanged: a population-based study

M. Lamba[1], C. Stedman[1,2], J. Ngu[1]. [1]*Christchurch Hospital, Department of Gastroenterology, Christchurch, New Zealand;* [2]*University of Otaago, Christchurch, New Zealand*
Email: Mehullamba@gmail.com

Background and Aims: Autoimmune diseases arise from a complex interplay of environmental factors in genetically predisposed individuals, leading to a differential increase in the incidence of various autoimmune conditions. We aimed to investigate the incidence of autoimmune hepatitis (AIH), primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC) in a population-based prospective study in Canterbury, New Zealand.
Method: All patients diagnosed with AIH, PBC and PSC in Canterbury were prospectively enrolled from 01/01/2008 until 31/12/2016. This included all paediatric and adult patients seen in out-patient clinic and in-patient admissions, in both public and private hospital. Diagnosis of AIH was based on score ≥6 on simplified criteria or score ≥10 on revised original criteria. PBC was diagnosed if at least 2 of the following were present: positive anti-mitochondrial antibody, raised alkaline phosphatase for > 6 months or compatible liver biopsy. PSC was diagnosed either radiologically or histologically. Change in incidence during the prospective study period was assessed by comparing the average incidence for predefined three 3-year blocks: 2008–2010, 2011–2013, 2014–2016.
Results: During 2008 to 2016, 99 patients were diagnosed with AIH, 25 patients with PBC and 44 patients with PSC. The annual incidence of AIH, PBC and PSC for the last year of study (2016) were 2.17 (95%CI 1.26–3.73), 0.67 (95%CI 0.25–1.78) and 0.33 (95%CI 0.08–1.33) cases per 100,000 respectively. The average annual incidence of AIH increased from 1.37 in 2008–2010 to 2.39 in 2014–2016 (p = 0.06). On the contrary, the average annual incidence of PBC and PSC remained unchanged during the same period. Point-prevalence of AIH on 31st December 2016 was 27.5 per 100,000 (95%CI 23.61–32.04), while that of PBC and PSC were 9.33 (95%CI 7.18–12.13) and 13.17 (95%CI 10.56–16.42) respectively.
Conclusion: In this population-based prospective study, we demonstrate that there is a trend towards an increase in the incidence of AIH, while the incidence of PBC and PSC have remain unchanged. As shown previously by our group, the incidence of PBC in Canterbury has remained lower than PSC or AIH. Since the population at-risk and the environmental factors have remained similar, the divergent trends in the incidence of autoimmune liver conditions suggests that these diseases likely have distinct etiopathogenesis rather than representing spectra of the same disease entity.

THU-229

Autoantibody-negative autoimmune hepatitis presents more commonly with advanced fibrosis or cirrhosis

M. Lamba[1], C. Stedman[1,2], J. Ngu[1]. [1]*Christchurch Hospital, Department of Gastroenterology, Christchurch, New Zealand;* [2]*University of Otago, Christchurch, New Zealand*
Email: Mehullamba@gmail.com

Background and Aims: Some patients with autoimmune hepatitis (AIH) do not have detectable typical autoantibodies. Clinical characteristics of this subgroup of AIH are not well-defined. We aimed to investigate the differences between phenotypes of autoantibody-negative AIH (Abneg-AIH) and autoantibody-positive AIH (Abpos-AIH) in a population-based prospective cohort study in Canterbury, New Zealand.
Method: All patients diagnosed with AIH based on either the simplified scoring system (score ≥ 6) or the revised original scoring system (score ≥ 10) were prospectively enrolled from 01/01/2008 to 31/12/2016. Typical autoantibodies were considered absent if all of following were negative: liver kidney microsomal antibody (LKM), anti-soluble liver antigen/liver-pancreas antibody (SLA/LP), anti-nuclear antibody (ANA) titre ≤ 1:20 and smooth muscle antibody (SMA) titre ≤1:20. Patients were followed-up till 31/07/2017.
Results: Ninety-nine patients were diagnosed with AIH based on the standardised criteria (62 definite AIH and 37 probable AIH). Liver biopsy was obtained in 98% of patients. Of the patients diagnosed with AIH, 15.15% met the inclusion criteria for Abneg-AIH. Only 40% of Abneg-AIH patients were diagnosed using the simplified scoring system, while the remaining patients met the diagnostic criteria when the revised original scoring system was applied. Immunoglobulin G was raised in only 60% of patients with Abneg-AIH compared to 86.9% in Abpos-AIH (p = 0.01). More patients with Abneg-AIH (73.33%) had advanced fibrosis or cirrhosis at the time of first biopsy compared to patients with Abpos-AIH (39.29%) (p = 0.01). During a median follow-up of 4 years, overall survival in Abneg-AIH was 91.67% (95%CI 53.9–98.78), which was not significantly different from Abpos-AIH – 87.45% (95%CI 76.78–93.42).
Conclusion: Fifteen percent of patients with AIH did not have detectable typical autoantibodies. Caution needs to be exercised when using simplified scoring system, as the diagnosis of Abneg-AIH can be missed. Most of the patients with Abneg-AIH had progressed to advanced fibrosis at the time of diagnosis. This may be due to a delay in diagnosis or may represent a more aggressive phenotype of the disease.

THU-230

Prognosis in patients with primary biliary cholangitis based on histological stage at diagnosis. A nationwide population-based study

L. Bossen[1], H. Grønbæk[1], P. Ott[1], P. Jepsen[1,2]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus C, Denmark;* [2]*Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus N, Denmark*
Email: larsbossen@clin.au.dk

Background and Aims: Primary biliary cholangitis (PBC) is a chronic cholestatic liver disease characterized by destruction of intrahepatic bile ducts, ultimately resulting in fibrosis and cirrhosis of the liver. Most patients are diagnosed with PBC before they develop cirrhosis. The aim of this study was to describe the prognosis of PBC patients diagnosed in the non-cirrhotic and cirrhotic stages, compared with age- and gender-matched controls without PBC.
Method: We included all Danish citizens 1997–2014 with a hospital discharge diagnosis of PBC and a histological diagnosis of PBC based on a liver biopsy. For every patient, we included five age- and gender-matched controls from the general Danish population. Patients and controls were followed until death, HCC, transplantation (LT), or 31 December 2014. We used the cumulative incidence function to calculate 10-year cumulative risk of death before requiring LT. Similarly we calculated the 10-year cumulative risk of HCC and LT before death or LT/HCC.
Results: 121 patients presented with PBC in the cirrhotic stage at diagnosis. Of those patients, 84.3% were women and their median age was 63 years (IQR 56.1–70.8). Their 10-year cumulative risk of death before requiring LT was 53.7% (95% CI 43.2–63.1%) compared with 23.7% (95% CI 19.6–28.0%) in age- and gender-matched controls (Figure 1). Of the 553 patients presenting with PBC in the non-cirrhotic stages at diagnosis, 87.7% were women who had a median age at PBC diagnosis of 58.5 years (IQR 48.9–66.4). Their 10-year cumulative risk of death before requiring LT was 28.7% (95% CI 23.9–33.7%) compared with 17.5% (95% CI 15.7–19.5%) in age- and gender-matched controls (Figure 1). Likewise, PBC patients with and without cirrhosis had a higher 10-year risk of HCC and LT compared with their matching controls.

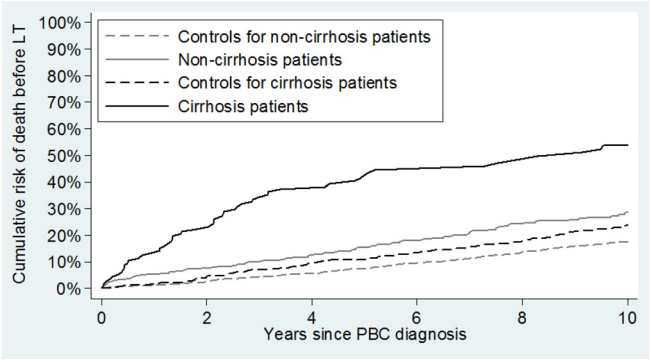

Figure 1: 10-year cumulative risk of death before requiring liver transplantation in PBC patients (solid) diagnosed with cirrhosis (black) and without cirrhosis (grey), and controls (dashed).

Conclusion: All patients with PBC were found to have worse prognosis than age- and gender-matched controls without PBC, and the prognosis was particularly poorer for those who were diagnosed after cirrhosis had developed.

THU-231

Change in bilirubin with obeticholic acid treatment in primary biliary cholangitis patients with high baseline bilirubin: a retrospective analysis of POISE, 201, and 202

G. Hirschfield[1], M. Shiffman[2], A. Pares[3], E.S. Malecha[4], R. Pencek[4], L. Macconell[4], D. Shapiro[4]. *[1]University of Birmingham, Centre for Liver Research, Birmingham, United Kingdom; [2]Liver Institute of Virginia, Newport News, United States; [3]University of Barcelona, Hospital Clinic, Barcelona, Spain; [4]Intercept Pharmaceuticals, Inc., San Diego, United States*
Email: g.hirschfield@bham.ac.uk

Background and Aims: In patients with primary biliary cholangitis (PBC), bilirubin (BILI) is a recognized marker of disease progression and a strong predictor of survival. Recently, the Global PBC Study Group reported the risk with elevated BILI extends into the normal range with a cutoff of 0.67× ULN identifying patients at risk. Obeticholic acid (OCA) is indicated for treatment of PBC in patients with an inadequate response or intolerability to ursodeoxycholic acid. The aim of this retrospective analysis was to evaluate the effect of OCA on BILI in this patient subpopulation.
Method: OCA has been evaluated in patients with PBC in one 12-month Phase 3 double-blind (DB) placebo (PBO)-controlled trial (POISE) and two 3-month Phase 2 PBO-controlled trials (201 and 202). Patients were eligible to continue treatment in open-label extensions (OLE) with all patients receiving OCA. Patients from the Phase 2 and 3 studies with baseline (BL) total BILI (TBILI) ≥0.67× ULN were evaluated for change in TBILI over 12 months in the following manner: 1) DB comparison of OCA vs PBO at 12 months in POISE and 2) DB + OLE OCA use totaling 1 year of treatment (POISE randomized to PBO, evaluated at 12 months OLE; Phase 2 randomized to OCA for 3 months, evaluated at 9 months OLE; and Phase 2 randomized to PBO, evaluated at 12 months OLE).
Results: The analysis included patients with TBILI ≥0.67x ULN at their OCA BL: POISE, n = 51; 201, n = 7; and 202, n = 7. In patients with BL TBILI ≥0.67x ULN, TBILI increased after 12 months of PBO treatment, and decreased after 12 months of OCA (Table 1). In the DB phase of POISE, of the 7 PBO-treated and 9 OCA-treated patients with abnormal TBILI at BL, 14% of PBO-treated and 78% of OCA-treated patients attained normal TBILI levels after 12 months. Further, of 10 PBO-treated and 20 OCA-treated patients with normal TBILI at BL, 60% of PBO-treated and 15% of OCA-treated patients worsened to abnormal TBILI after 12 months.

Table 1: Mean (SD) Change From BL in TBILI (μmol/L) in Patients with BL TBILI ≥0.67x ULN

12 Month Treatment	PBO	OCA				
Phase	DB			OLE		
Study	POISE			201	202	POISE
Dose (mg)	—	5–10	10	10 or 50	10, 25, or 50	5 to 10
n	17	15	14	7	7	17
Mean (SD) change from BL in TBILI	2.6 (6.5)	−3.3 (3.6)	−4.0 (7.8)	−8.1 (6.4)	−10.1 (8.1)	−1.6 (7.9)

OCA BL is defined as:

- OCA-randomized patients: if time from last visit in DB to first visit in OLE ≤30 days, mean of evaluations prior to first DB dose is used; if >30 days, last assessment prior to first dose in OLE is used; the initial OLE visit is included as a BL evaluation.
- PBO-randomized patients: last assessment prior to first dose in OLE is used; initial OLE visit is included as a baseline evaluation.

Conclusion: Patients treated with OCA had a trend toward reduction of TBILI compared with those treated with PBO. These data suggest that OCA may reduce progression of patients with more advanced liver disease.

THU-232

Chloroquine in monotherapy is safe and effective for induction of remission in anti-SLA/LP positive patients with autoimmune hepatitis

D. Terrabuio[1], A.S. Evangelista[2], A.L.V. Guedes[2], A.R. de Moreto Longo Galvão[3], F.J. Carrilho[3], E. Cancado[4]. *[1]Division of Gastroenterology and Hepatology, Gastroenterology, São Paulo, Brazil; [2]Division of Gastroenterology and Hepatology, Gastroenterology, Sao Paulo, Brazil; [3]Division of Gastroenterology and Hepatology, Gastroenterology, Sao Paulo, Brazil; [4]Division of Gastroenterology and Hepatology, Gastroenterology, Brazil*
Email: debora.terrabuio@hc.fm.usp.br

Background and Aims: The combination of azathioprine and prednisone (AZA/PD) is the standard treatment (ST) of autoimmune hepatitis (AIH); second-line treatment regimens are expensive, with few studies in literature, which justifies the search for new therapeutic options. In previous study antimalarials were effective in the maintenance of remission of AIH after treatment withdrawal. Our aim was to describe a series of 4 patients who relapsed AIH and achieved therapeutic response after the use of antimalarials in monotherapy.
Method: Four patients with AIH anti-SLA/LP (+) received chloroquine diphosphate (DFC) 250 mg/d or hydroxychloroquine (HCQ) 400–800 mg/d in monotherapy for induction of biochemical remission after relapse of the disease. Their treatment occurred as described next: histological remission with ST → ST withdrawal and antimalarial use for maintenance of remission for 1–3y → antimalarial withdrawal → relapse of AIH → re-introduction of antimalarial. Patients requested re-introduction of the drug in monotherapy instead of the ST, due to side effects related to corticosteroid use. Clinical and laboratory evaluations were made every 7–15 days until normalization of liver enzymes, thereafter every 2–3 months. 2/4 completed 18 months of biochemical remission and underwent liver biopsy to evaluate histological remission.
Results: Mean age at diagnosis of AIH was 30.5 ± 19.6 y. Anti-SLA/LP was the sole marker of disease in 2; 1 type 1 and 1 type 2 AIH. 2 had liver cirrhosis at diagnosis. Mean doses of AZA/PD in histological remission were, respectively, 93.7 ± 12.5 mg/d and 8.12 ± 2.4 mg/d. The mean interval between antimalarial withdrawal and relapse of AIH was 144.2 ± 54 days. The mean ALT at relapse was 118.5 ± 21 U/L. 2 patients took chloroquine DFC and 2 HCQ. During HCQ intake 1 patient needed further adjustment of drug to 800 mg/d for 15 days because of worsening of ALT from 130 to 246 U/L, which resulted in laboratory improvement, with subsequent reduction to the initial dose. 4/4 achieved biochemical remission, in a mean time of 88 ± 45.7

days. 2/4 patients had histological remission, the other 2 still do not have enough time of biochemical remission. The drug was well tolerated and there were no serious side effects.
Conclusion: Chloroquine monotherapy was safe and effective for induction of remission in a specific subgroup of AIH. This finding is unpublished and raises the possibility of including this drug as an option for initial treatment of AIH, not necessarily in monotherapy.

Email: junior@fmu.ac.jp

Background and Aims: Health-Related Quality of Life (HrQoL) in patients with autoimmune hepatitis (AIH) is impaired, but has not been previously fully assessed, and the association between HrQoL and patient background remains unknown. We aimed to assess HrQoL in patients with AIH and identify factors associated with HrQoL impairment.
Method: We assessed HrQoL in patients with AIH, patients with chronic hepatitis C (CHC), and healthy subjects by using the Japanese version of the Chronic Liver Disease Questionnaire (CLDQ) and the 36-Item Short Form Survey (SF-36). We compared HrQoL in patients with AIH with that of patients with CHC and healthy subjects.
Results: Two-hundred sixty-five patients with AIH were enrolled in the study, of whom 88% were women, with a median age of 65 years. Of these patients, 10.6% and 57.0% had cirrhosis and complications, respectively. The overall CLDQ scores (5.5 vs. 6.2, $p < 0.001$) and physical (48.1 vs 54.2, $p < 0.001$) and mental (51.8 vs. 55.0, $p = 0.004$) component summaries of SF-36 were lower in the AIH patients than in the healthy subjects, but similar to those of the CHC patients. Having cirrhosis, complications, and treatment were associated with impaired HrQoL among patients with AIH. Particularly, prednisolone use was associated with lower scores in the worry domain in the CLDQ.
Conclusion: Patients with AIH showed HrQoL impairment, which was associated with not only disease progression, but also complications and treatment. Ways to improve HrQoL should be considered when disease outcome is not favorable and when using prednisolone.

Email: llovet@clinic.cat

Background and Aims: There is a strong association between pregnancy and the outcome of autoimmune hepatitis (AIH). However, the information about this special situation is scarce. The outcome of the disease that has its onset in the postpartum period and the risk factors related to an adverse outcome or flares in pregnant patients who are already diagnosed of an AIH are currently unknown. Therefore, the aims of the study were: (1) To describe the outcomes of an AIH diagnosed in the postpartum period, and (2) To identify the risk factors associated to disease flares in pregnant patients with a previous diagnosis of AIH.
Method: This is a retrospective and multicentre cohort study. The clinical and laboratory characteristics of patients diagnosed of AIH in the postpartum and patients with AIH who presented at least a pregnancy during their follow-up were collected.
Results: Thirty-eight patients were included: 8 women diagnosed of AIH in the postpartum with a median age of 33 years-old (26–36), AST 648 UI/L (48–1815), ALT 814 UI/L (146–2398), bilirubin 9,3 mg/dL (0,9–12,7), INR 1,48 (1–1,7) and IgG 18 g/L (14–20). In all cases, the liver biopsy was compatible with the disease. After a median follow-up of 50 months (21–79), immunosuppression (IS) was successfully withdrawn in 4 patients (50%) and the rest maintained remission with monotherapy. Thirty patients with diagnosis of AIH (6 of whom had cirrhosis) and a median age of 34 years-old (27–35) had a total of 39 pregnancies. Nine (30%) had a postpartum flare. In these cases, the median time from AIH diagnosis and pregnancy was inferior (21 vs. 45 months; $p = 0.05$), and there was a tendency towards higher IgG levels (30 g/L vs. 24 g/L; $p = 0.43$). In addition, these patients had more flares unrelated to pregnancy (44% vs. 28%; $p = 0.03$), and required combined therapy (89% vs. 30%; $p = 0.03$) and second line therapies (33% vs. 3%; $p = 0.01$) to maintain remission more frequently. The success of immunosuppression withdrawal was inferior in patients who had a postpartum flare (22% vs. 43%; $p = 0.25$).
Conclusion: The acute onset of AIH in the postpartum is rare but the outcome of the disease seems to be excellent, requiring long-term minimal or non-immunosuppression. In patients with a previous diagnosis of AIH, postpartum flares are frequent, particularly in those patients with an inferior time after the diagnosis. The presence of postpartum flares appears to indicate a more aggressive form of the disease.

THU-235
Efficacy and safety of calcineurin inhibitors as salvage therapy in patients with autoimmune hepatitis

S. Strasser[1,2], R. Lim[3], J. Mitchell[4], A. Nicoll[5,6], K. Stuart[7], P. Gow[8], G. Macquillan[9], J. George[10,11], J. Mitchell[12], W. Kemp[4,6], G. Mccaughan[2,13], S. Roberts[4]. *[1]University of Sydney, Central Clinical School, Sydney, Australia; [2]Royal Prince Alfred Hospital, AV Morrow Gastroenterology and Liver Centre, Camperdown, Australia; [3]Royal Prince Alfred Hospital, AV Morrow Gastroenterology and Liver Centre, Sydney, Australia; [4]The Alfred, Gastroenterology, Melbourne, Australia;*

Email: robertss@bigpond.net.au

Background and Aims: There is limited data on the outcomes of calcineurin inhibitors (CI) as salvage therapy in patients with autoimmune hepatitis (AIH) who fail to respond to standard therapy. This, we evaluated the efficacy and safety of cyclosporine A (CyA) and tacrolimus (TAC) in AIH patients who failed or were intolerant of corticosteroids with or without thiopurines.
Method: A retrospective study was performed of AIH patients who received either CyA or TAC after failure or intolerance of standard therapy. Patients were recruited from 7 major liver centres across Australia via the ALA Clinical Research Network. Records were reviewed for baseline demographics and liver disease characteristic, initial therapy, indications for CI initiation, treatment outcome and complications.
Results: A total of 28 patients with AIH (Type 1 96%, mean age 33 [range13–63 yrs], females 86%, Caucasian 96%, cirrhosis 54%) received CI therapy across the seven sites with 16 receiving CyA and 16 TAC, four of whom received TAC after failure/intolerance of CyA. The majority (89%) had received prior combination therapy with corticosteroids plus azathioprine/6-mercaptopurine; 17 (61%) had also received mycophenolate mofetil (MMF). The indication for CI was inefficacy of standard therapy with/without MMF in 22 (79%) and intolerance to treatment(s) in 6 (21%) patients. The median starting and maximal doses of CyA and TAC were 100 and 163, and 2 and 4 mg respectively. The overall biochemical remission rate on CI was 50% (16/32) including 10/23 (43%) patients receiving CI for treatment inefficacy and 6/9 (67%) with prior treatment intolerance. Treatment with CyA achieved remission in 10/16 (63%) patients including 6/11 (55%) in prior non-responders. In comparison TAC achieved remission in 6/16 (38%) patients (42% in CI naïve) including 4/12 (33%) in prior non-responders. Three patients experienced treatment failure on CI while one required liver transplantation. Eleven (73%) patients with cirrhosis achieved biochemical remission on CI therapy. 7 patients (TAC = 5) required dose-reduction due to side effects with 8 (50%) discontinuing CyA and 4 (33%) TAC mainly due to side-effects (50% for both) or treatment inefficacy. Fourteen patients (TAC = 9) reported significant side effects that mainly involved renal toxicity (n = 5), and neurologic (n = 10), dermatologic (n = 5), and musculoskeletal (n = 2) disorders. Three deaths occurred during follow up none of which were treatment related.
Conclusion: Salvage therapy with CyA and TAC in AIH patients who fail standard therapy is moderately effective achieving an overall remission rate of 50% including 43% in non-responders and 67% in those with prior treatment intolerance. Both CI appear relatively safe and reasonably well tolerated with the main side-effects being renal, neurologic and dermatologic in nature.

THU-236
Risk stratification using transient elastography and the new scoring systems for patients with primary biliary cholangitis

L. Perini[1], N. Cazzagon[1], F.P. Russo[2], G. Leardini[1], V. Baldo[3], M.F. Secchi[1], N. Perin[1], C. Mangini[1], A. Zago[1], A. Floreani[1]. [1]University of Padova, Dept of Surgery, Oncology and Gastroenterology, Padova, Italy; [2]University Hospital Padua, Gastroenterology, Padua, Italy; [3]University of Padova, Dept of Hygiene and Public Health, Padova, Italy
Email: annarosa.floreani@unipd.it

Background and Aims: The recent EASL guidelines recommend the use of transient elastography (TE) to monitor PBC progression and the risk scores to better define the individual risk of development of complications.
Method: 154 PBC patients prospectically seen between January 2009 and July 2017 were enrolled into the study. TE was performed at baseline and every 2 years thereafter (in the follow-up 111 pts had 2 measurements, and 52 pts 3 measurements). A cut-off of ≥9.6 kPa was chosen to determine the risk of decompensation. Globe score and UK-PBC scores were calculated at each interval. Risk factors were assessed using Cox proportional hazard models. Longitudinal variations of liver stiffness (LS) were assessed with the following formula: $\Delta LS/\delta t = (LS_2 - LS_1)/(t_2 - t_1)$.
Results: At baseline LS was positively correlated with the Globe score ($r = 0.395$, $p = 0.01$). UK-PBC score provided a survival outcome at 5, 10, and 15 years significantly correlated with the LS ($p < 0.001$). Survival at 15 years was 93.2 ± 5.4% in pts with LS ≤ 9.6 kPa, and 85.4 ± 11% in those with LS >9.6. The increase in LS/year was 0.15 ± 0.38 and 0.63 ± 1.6 kPa respectively ($p < 0.05$).
Conclusion: LS measurements and risk stratification scores are useful tools in the follow-up of PBC patients to establish prognosis and for decision-making for second line therapy.

THU-237
Independent predictors of primary biliary cholangitis (PBC) at high risk for progressive course in the United States: data from a large-real world database

Z. Younossi[1], M. Stepanova[2], R. Epstein[3], M. Strauss[4], P. Globai[5], F. Nader[2], A. Racila[5]. [1]Inova Fairfax Hospital, Department of Medicine, Falls Church, United States; [2]Center for Outcomes Research in Liver Disease; [3]Epstein Health; [4]Intercept Pharmaceuticals; [5]Center for Liver Disease, Inova Fairfax Hospital
Email: zobair.younossi@inova.org

Background and Aims: Primary biliary cholangitis (PBC) is a chronic autoimmune liver disease that can lead to cirrhosis and its complications. Treatment options for PBC include ursodeoxycholic acid (UDCA, first line) and obeticholic acid (OCA). PBC patients with ALP levels ≥1.5×Upper Limit of Norm (ULN) tend to have high risk for a more progressive course. The real-world data regarding factors associated with biochemically uncontrolled/potentially progressive PBC is not available. The aim of the study was to use a large real-world electronic medical record/claims (EMR) database from the United States (US) to assess factors independently associated with high risk for progressive PBC.
Method: We used Owned Outcomes (O2) database containing comprehensive and continuous EMR/claims data from 500+ healthcare systems in the US. The database utilizes a proprietary computing platform to store HIPAA-compliant data. For this study, we selected patients ≥18 years old with an ICD-9/10 code for PBC who had continuous enrollment during 2014–2016 with a 1-year lookback period. Patients with ALP levels <1.5×ULN (regardless of treatment) were considered Low Risk (LR) and patients with ALP levels ≥1.5xULN who had received UDCA for at least 1 year were considered High Risk (HR). ALP levels came from the most current PBC-related visit during the enrollment period; duration of UDCA reflected cumulative exposure over entire enrollment history.
Results: Of 195 million patients comprising this real-world database, 36,317 adults had PBC. After applying inclusion and exclusion criteria, 13,843 patients comprised our final PBC cohort (n = 9,792 LR and n = 4,051 HR). The HR PBC patients were older, more female, more white, had more metabolic and autoimmune comorbidities, and had more compensated cirrhosis ($p < 0.05$). In multivariate analysis, older age, female gender, living in Midwest, presence of other autoimmune diseases and compensated cirrhosis were independently associated with HR PBC (Table).

Table: Independent predictors of uncontrolled PBC

Predictor	odds ratio (95% CI)	p
Age, per year	1.006 (1.003–1.009)	<0.0001
Male gender	0.48 (0.43–0.54)	<0.0001
Midwest region	2.86 (2.59–3.15)	<0.0001
West region	0.64 (0.58–0.70)	<0.0001
Medicaid payer	0.66 (0.54–0.80)	<0.0001
Autoimmune hepatitis	1.18 (1.03–1.35)	0.0173
Peripheral neuropathy	1.11 (1.01–1.23)	0.0359
Autoimmune dermatitis	1.17 (1.01–1.36)	0.0416
Sjogren's syndrome	1.38 (1.16–1.64)	0.0004
Compensated cirrhosis	1.46 (1.31–1.62)	<0.0001

Conclusion: Numerous clinical and sociodemographic factors predict high risk for potentially progressive PBC. These data should inform clinicians to implement strategies to optimize care of these patients.

THU-238

Pharmacokinetics and pharmacodynamics of seladelpar, a potent and selective PPAR-delta, in patients with primary biliary cholangitis

P. Boudes[1], G. Michael[2], C. Bowlus[3], G. Hirschfield[4], D. Jones[5], J. Odin[6], D. Sheridan[7], N. Gitlin[8], S. Harrison[9], T. Hassanein[10], C. Levy[11], M. Shiffman[12], D. Thorburn[13], P.J. Thuluvath[14], J. Vierling[15], Y.-J. Choi[1], M. Varga[1], A.(Sasha) Steinberg[1], C. Mcwherter[1], R. Martin[1]. *[1]CymaBay Therapeutics, Newark, United States; [2]Digestive Healthcare of Georgia, Atlanta, United States; [3]University of California Davis, Sacramento, United States; [4]University of Birmingham, Birmingham, United Kingdom; [5]University of Newcastle, Newcastle upon Tyne, United Kingdom; [6]Icahn School of Medicine at Mount Sinai, New York, United States; [7]Plymouth Hospitals NHS Trust & Plymouth University, Peninsula School of Medicine and Dentistry, Plymouth, United Kingdom; [8]Atlanta Gastoenterology Associates, Atlanta, United States; [9]Pinnacle Clinical Research, San Antonio, United States; [10]Southern California Research Center, Coronado, United States; [11]University Of Miami, University Of Miami, Miami, United States; [12]Institute of Virginia, Richmond, United States; [13]Royal Free London, London, United Kingdom; [14]The Institute for Digestive Health & Liver Diseases at Mercy, Baltimore, United States; [15]Advanced Liver Therapies, Baylor College of Medicine, Houston, United States*
Email: pboudes@cymabay.com

Background and Aims: Seladelpar, a selective agonist of the PPAR-δ receptor, is a potent anti-cholestatic agent that in rats is predominantly eliminated by the bile. We evaluated the plasma exposure of seladelpar in patients with primary biliary cholangitis (PBC) and compared it to healthy volunteers. We also explored the relationship between the exposure of seladelpar and its anti-cholestatic activity.
Method: Plasma drug profiles were obtained from a phase 2 study in PBC patients who were inadequate responders to or intolerant to ursodeoxycholic acid (UDCA) (EudraCT 2016-002996-91). Seladelpar was formulated in capsules and dosed at 2, 5, and 10 mg daily. Plasma concentration vs time profiles (seladelpar and its metabolites) were obtained on the first day of treatment and after 2 weeks of treatment. Markers of cholestasis, including serum alkaline phosphatase (AP), were collected at regular intervals up to 12 weeks. The relationship between seladelpar AUCs and alkaline phosphatase changes was analyzed with linear regression.
Results: Data from 3, 6, and 6 patients were available for the 2, 5, and 10 mg doses, respectively. The mean (SD) C_{max} at Day 1 were 19 (7), 59 (34), 169 (100) ng/mL and the mean (SD) $AUC_{(0-24)}$ were 175 (57), 606 (282), 1285 (406) ng·hr/mL for the 2, 5, and 10 mg, respectively. The mean (SD) C_{max} at Week 2 were 29 (12), 68 (21), 142 (53) ng/mL and the mean (SD) $AUC_{(0-24)}$ were 267 (120), 831 (246), 1387 (257) ng·hr/mL for the 2, 5, and 10 mg, respectively. There was no apparent difference in exposure to seladelpar between the first day of treatment and after two weeks of treatment and exposure appeared dose proportional. Seladelpar exposure after two weeks of treatment correlated with the anti-cholestatic activity (Figure).

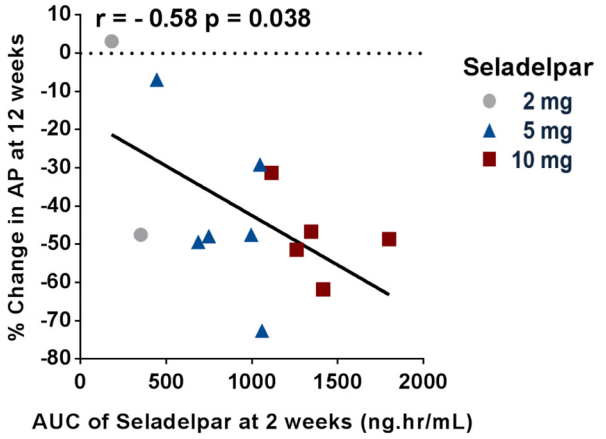

Figure: Correlation between seladelpar exposure and changes in AP.

Conclusion: Seladelpar anti-cholestatic activity correlates with plasma drug exposure after two weeks of treatment. The study is ongoing and has been modified to evaluate seladelpar exposure after 12 weeks of treatment, a time point when the anti-cholestatic activity is further established.

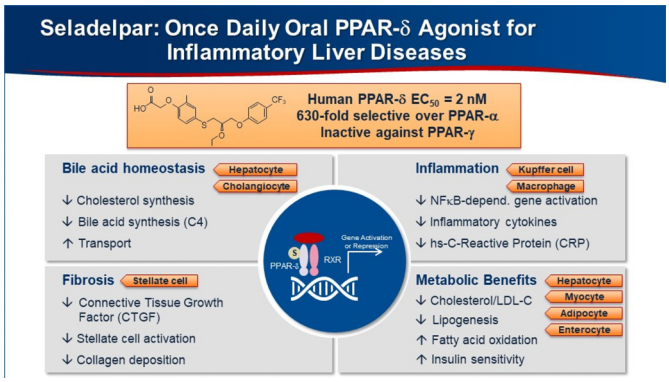
THU-239

Seladelpar's mechanism of action as a potential treatment for primary biliary cholangitis and non-alcoholic steato-hepatitis

P. Boudes[1], Y.-J. Choi[1], A.(Sasha) Steinberg[1], S. Bergheanu[2], C. Mcwherter[1]. *[1]CymaBay Therapeutics, Newark, United States; [2]Saberg Clinical Research, Rotterdam, Netherlands*
Email: pboudes@cymabay.com

Background and Aims: Seladelpar, a potent and selective agonist of the peroxisome-proliferator activated receptor (PPAR)-delta, is being developed for primary biliary cholangitis (PBC) and non-alcoholic steatohepatitis (NASH). PPARs are intra-nuclear receptors that form dimers with the retinoid X receptor (RXR) and regulate specific genes transcription. PPAR-delta is activated by lipids and controls metabolic and inflammatory pathways in the liver, inflammatory cells, muscle, and fat and intestinal tissues. It differs from PPAR-alpha and gamma because of its broad tissue distribution and its unique set of target genes. In the liver, the delta receptor differs from the other isotypes by its broad activity in hepatocytes, cholangiocytes, Kupffer cells and stellate cells. We present data supporting the mechanism of action of seladelpar for PBC and NASH.
Methods: Seladelpar was evaluated in a multiple dose ascending study in healthy volunteers; in two phase-2 studies in dyslipidemia (NCT00701883 and 02472535) and in two phase-2 studies in PBC (NCT02609048 and 02955602). Supportive data were obtained from preclinical in vivo models of metabolic diseases and from culture studies with hepatocytes, intestinal cells and macrophages.
Results: In hepatocytes, seladelpar suppressed CYP7A1, the key enzyme in bile acid (BA) synthesis, and decreased plasma C4, a marker of BA synthesis. It also decreased the synthesis and absorption of cholesterol, the substrate for BA synthesis. This results in potent anti-cholestatic activity. Seladelpar targets liver Kupffer cells, infiltrating macrophages, and stellate cells, responsible for liver fibrosis. The resulting anti-inflammatory effect is manifested clinically by decreases in transaminases and high-sensitivity C-reactive protein. In a mice model of NASH, this resulted in abrogation of hepatocyte ballooning, lymphocytic infiltrates and decreased fibrosis. Seladelpar inhibits lipogenesis and increases fatty acid oxidation which clinically is manifested by decreases in LDL-C, serum triglycerides and free fatty acids, and improved insulin sensitivity. Contrary to FXR agonists,

which also target PBC and NASH, seladelpar does not increase FGF19 or LDL-C and is not associated with drug-induced pruritus.



Conclusion: Seladelpar results in a profound anti-cholestatic and anti-inflammatory effects in PBC patients with no drug-induced pruritus. Seladelpar targets all mechanisms at play in NASH and may constitute a backbone therapy.

Cirrhosis: ACLF and Critical illness

THU-245

Class III (morbid) obesity is an independent risk factor for the development of acute on chronic liver failure in patients with decompensated cirrhosis

V. Sundaram[1], R. Jalan[2], J. Ahn[1], M. Charlton[3], D. Goldberg[4], C. Karvellas[5], M. Noureddin[1], R. Wong[6]. [1]*Cedars-Sinai Medical Center, Los Angeles, United States;* [2]*University College London Hospital, United Kingdom;* [3]*University Of Chicago Medical Center, Chicago, United States;* [4]*Perelman School of Medicine at the University of Pennsylvania, Philadelphia, United States;* [5]*University of Alberta Hospital, Edmonton, Canada;* [6]*Alameda Health System, Oakland, United States*
Email: vinaysundaram@yahoo.com

Background and Aims: Acute on chronic liver failure (ACLF) is a syndrome precipitated by systemic inflammation. Obesity, particularly class III (morbid) obesity, is a risk factor in cirrhosis for decompensation, infection, and mortality, possibly from a chronic inflammatory state. We aim to evaluate the association between obesity and ACLF, using two United States (US) registries.
Method: We first examined the United Network for Organ Sharing (UNOS) database, years 2005–2016, characterizing patients at wait-listing as non-obese (BMI < 30), obese class I-II (BMI 30–39.9) and obese class III (BMI >= 40). ACLF was determined based on the CANONIC study definition. We used Cox proportional hazards regression to assess the association between obesity and ACLF development at transplantation. We then validated our findings using the Nationwide Inpatient Sample (NIS), years 2009–2013, a database representing 20% of US hospital discharges. Obesity category, hepatic decompensation, and organ system failure was identified using validated diagnostic codes. Non-hepatic comorbidities were assessed using Deyo modification of the Charlson index. Logistic regression evaluated the association between obesity and ACLF development.
Results: Among 100,380 patients in the UNOS database, 63,712 (63.5%) were non-obese, 32,603 (32.5%) were obese class I-II, and 4,065 (4.0%) were obese class III. ACLF at time of transplantation was more prevalent among class III obesity patients (23.1%, $p < 0.001$), compared to non-obese (15.9%) and obesity class I-II (16.5%). In the NIS registry, 287,202 patient records with decompensated cirrhosis were studied, of which 258,402 (89.9%) were non-obese, 15,108 (5.3%) had class I-II obesity and 13,692 (4.7%) had class III obesity. ACLF was more prevalent among class III obesity patients (45.1%, $p < 0.001$), compared to non-obese (37.6%) and class I–II obesity (38.8%). Modeling from both databases revealed class III obesity to be independently associated with ACLF (Table 1). Furthermore, class III obesity patients had greater prevalence of renal failure in both analyses. Other organ failures and multi-organ system failure was similar among the three groups.

Table 1: Multivariable modeling regarding association with obesity category and ACLF

	Reference	Odds Ratio	95% CI
UNOS database*			
Obesity Class I–II	Non-obese	1.12	1.05–1.19
Obesity Class III		1.24	1.09–1.41
NIS database**			
Obesity Class I–II	Non-obese	0.987	0.95–1.03
Obesity Class III		1.28	1.23–1.32

*Adjusted for age, gender, ethnicity, etiology of liver disease, presence of ascites, presence of encephalopathy, diabetes, serum sodium, serum albumin, and MELD score at listing.
**Adjusted for age, gender, ethnicity, Charlson index category.

Conclusion: Class III obesity is a newly identified risk factor for ACLF. Development of renal failure is of particularly greater risk in this population.

THU-246

Regional variations in the development of acute-on-chronic liver failure (ACLF) in patients with cirrhosis and bacterial infections

Email: pangeli@unipd.it

Background and Aims: Bacterial infections, by inducing an inflammatory state and by further perturbing the already abnormal hemodynamics of advanced cirrhosis, can potentially precipitate ACLF. Patterns of bacterial infections and antibiotic resistance vary in different regions of the world. These could possibly contribute to variations in the types of organ failure or severity of ACLF around the world. The aim was to evaluate the regional differences in the development of ACLF as a result of bacterial infections in cirrhosis.
Method: The International Club of Ascites (ICA) enrolled 1302 cirrhotic patients admitted for complications of cirrhosis with a concomitant bacterial infection worldwide from Oct 2015 to Sept 2016. All patients had baseline clinical, laboratory and microbiological data collected from the time of diagnosis of infection. Information on antibiotic given, antibiotic resistance, further complications, patient and infection outcomes were also collected. All patients were followed till liver transplant, or death, or discharge.
Results: Patients were divided into 6 regions worldwide (table). Patients were mostly middle aged (57 ± 13 years) men (69%) with alcoholic cirrhosis (52%). ACLF as defined by the EASL-Chronic Liver Failure (CLIF) Consortium was already present in 35% of patients at infection diagnosis, being significantly more prevalent (60%) and more severe in the Indian subcontinent (table) when compared to the rest of the world, possibly related to the high prevalence of multidrug resistant organisms in India (73% vs. 29%, p < 0.0001). Renal failure was the most common organ failure with ACLF across the world (17–34% of all organ failures). In patients without ACLF at infection diagnosis, further ACLF episodes occurred more frequently in Indian patients than in the other patients (44% vs. 25%, p = 0.0072). The severity of ACLF following treatment of infection was similar across the world (p = 0.078).

	South Europe (n= 428)	North Europe (n= 137)	South America (n = 252)	North America (n = 69)	Indian hospitals (n= 250)	Other Asian hospitals (n= 166)	P
ACLF – n (%)	111 (26)	39 (29)	93 (37)	24 (35)	151 (60)	42 (25)	<0.001
ACLF grade – n (%)							
Grade 1	53 (48)	24 (62)	44 (47)	9 (38)	41 (27)	19 (45)	<0.001
Grade 2	42 (38)	8 (21)	35 (38)	6 (25)	59 (39)	14 (33)	
Grade 3	16 (14)	7 (18)	14 (15)	9 (38)	51 (34)	9 (21)	

Conclusion: ACLF is common with bacterial infections in cirrhosis, and can occur even after infection is treated. Efforts should be made to prevent infection so to reduce the likelihood of ACLF.

THU-247

Number of organ failures is a better predictor of waitlist mortality in those who die within 30 days of listing for liver transplantation

P.J. Thuluvath[1], A. Thuluvath[2], Y. Savva[3]. [1]*Mercy Medical Center & University of Maryland School of Medicine, Medicine, Baltimore, United States;* [2]*Johns Hopkins University, Medicine, Baltimore, United States;* [3]*Mercy Medical Center, Institute of Digestive Health & Liver Diseases, Baltimore, United States*
Email: thuluvath@gmail.com

Background and Aims: It is possible that many patients with cirrhosis who died or transplanted within 30-days of listing have ACLF. The independent effect of organ failures (OF) on waitlist mortality is not well defined.
Method: We analyzed UNOS data from 2002 to 2016 of all adults who died within 30 days of listing for LT. We defined OF if patients had bilirubin ≥12 mg/dL, INR ≥2.5, serum creatinine ≥2 mg/dL or on dialysis, on ventilator, on life support or had stage 3 or 4 HE. Based on this, patients can have no OF or between 1 and 6 OF. The cumulative incidence of death based on the number of OF was estimated using a cumulative incidence competing risk (competing risk being liver transplantation) approach (CICR). For the models of the associations with risk factors, the Fine and Gray competing risk regressions were used and the goodness of fit was evaluated. We examined 3 models: Model 1 with age and organ failures, Model 2 with age and 6 MELD groups (see table), and Model 3 with age and MELD as a continuous variable.
Results: During the study period, 5,577 (5%; 1198 no OF, 2018 1-2 OF, 1430 3-4 OF, 679 5-6 OF) patients died and 21,580 (18%) patients were transplanted within 30 days of listing. For patients who died, mean MELD score was 31.1 ± 10.7, and 40.2% had MELD ≥35. 30-day mortality increased with increasing number of organ failures in those who were not transplanted (Figure); the incidence of mortality (%) was 1,8,16, 25, 33, 37 and 48 for the 7 groups respectively for OF 0 to OF 6. Additionally, the interval between listing and death or transplantation decreased with increase in organ failures. The median interval for death after listing was only 3–4 days for OF 4–6, 7–9 days for OF 2–3, and 14–18 days for OF 0-1. After adjusting for age, Model 1 using the number of organ failures fit 30-day mortality best (lowest AIC) compared to the other 2 models using MELD scores. Moreover, the likelihood ratio test confirmed that Model 1 fits the 30-day mortality better than the other 2 models (MELD categorical, Chi-square statistic 1441, P < 0.0001; MELD continuous Chi-square statistic 1712, P < 0.0001).

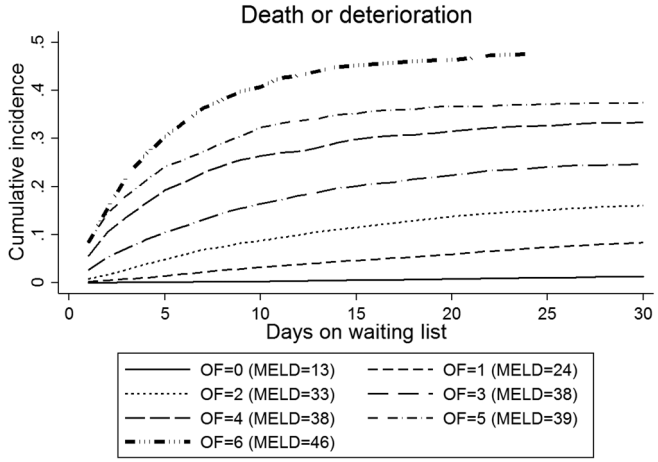

Table (abstract: THU-247).

Sub-distribution Hazard Ratio (HR) (*** = P <0.0001)

Model 1 (AIC = 118,242)		Model 2 (AIC = 119,680)		Model 3 (AIC = 119,943)	
Age	1.02 (1.02–1.02)***	Age	1.02 (1.01–1.02)***	Age	1.02 (1.02–1.02)***
OF		MELD		MELD score continuous	1.12 (1.12–1.12)***
0	1.00	≤20	1.00		
1	7.02 (6.47–7.61)***	21–25	5.85 (5.32–6.40)***		
2	15.16 (13.96–16.46)***	26–30	13.06 (11.94–14.27)***		
3	25.94 (23.71–28.39)***	31–35	19.15 (17.50–20.96)***		
4	41.65 (37.61–46.14)***	36–40	27.36 (24.98–29.96)***		
5	53.44 (47.79–59.75)***	≥41	43.25 (39.65–47.17)***		
6	65.41 (54.79–78.09)***				

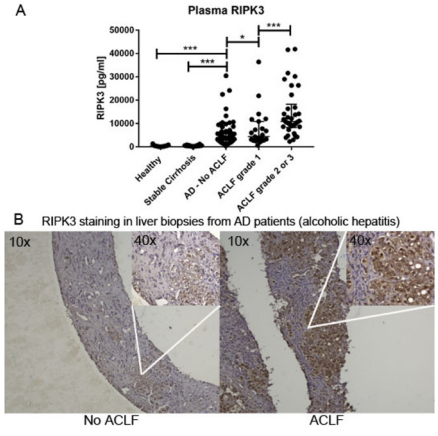
Conclusion: Waitlist mortality, within 30 days of listing, increases with an increase in the number of OF, and the median interval between listing and death is 3–7 days with 3 or more OF. Number of organ failures is a better predictor of mortality within 30 days of listing than MELD scores.

THU-248

Impact of receptor interacting protein kinase 3 levels on acute on chronic liver failure progression

T. Kondo, S. Macdonald, Y. Zheng, R. Mookerjee, F. Andreola, R. Jalan.
Institute for Liver and Digestive Health, University College London, London
Email: takakondonaika@yahoo.co.jp

Background and Aims: In cirrhotic patients with acute decompensation (AD), the occurrence of organ failures defines acute on chronic liver failure (ACLF); a condition characterized by liver cell death and high risk of short-term mortality. With progression from AD to ACLF the mode of cell death evolves from predominantly apoptotic to other non-apoptotic forms. Necroptosis is a newly described form of programmed cell death and results in a release of potentially pro-inflammatory cell contents that could drive further cell death, and organ failure. Receptor Interacting Protein Kinase 3 (RIPK3) is the key player in the necroptosis signaling pathway but its role in ACLF is unclear. We therefore, evaluated plasma and hepatic RIPK3 levels in patients with no ACLF and those with ACLF.
Method: One hundred forty cirrhotic patients from DASIMAR study cohort (NCT01071746) with AD were enrolled (83 with no ACLF, 23 with ACLF grade 1 and 34 with ACLF grade 2 or 3). Twenty-four of the no ACLF patients progressed to ACLF. Additional 42 patients with stable cirrhosis (SC) and 21 healthy volunteers (HV) were also studied. RIPK3 plasma levels and liver tissue expression were assessed by ELISA and immunohistochemistry, respectively.
Results: Plasma RIPK3 levels rose progressively with the severity of liver injury (HV: 322.1 pg/ml [51.18–1294], SC: 445.4 [28.83–1196], no ACLF: 3247 [371.9–30489], ACLF grade 1: 4383 [589.5–36383], ACLF grades 2 or 3: 10909 [2300–41878]) which demonstrated statistical significance between HV vs. AD ($p < 0.001$), SC vs. no ACLF ($p < 0.001$), no ACLF vs. ACLF grade1 ($p = 0.022$), ACLF grade1 vs. grade2 or 3 ($p < 0.001$) (Fig. 1A). Furthermore, plasma RIPK3 levels were a significant predictive factor for 90-day mortality ($p = 0.041$) (HR = 1.0001 [95%CI 1.0000–1.0001]).



Prediction of progression from AD to ACLF: Plasma RIPK3 levels were significantly higher in the patients who progressed from no ACLF to ACLF than those who did not (2658 [371.9–30489] vs. 4968 [1401–24159]) ($p = 0.002$) and significant predictive factor for progression from no ACLF to ACLF ($p = 0.023$).
Liver immunohistochemistry: Liver biopsies of ACLF patients showed a stronger RIPK3 staining compared to no ACLF patients (Fig. 1B).

Conclusion: These data demonstrate for the first time the importance of necroptosis, as measured by plasma and hepatic RIPK3 in ACLF and, its prognostic value in the risk of progression from no ACLF to ACLF and, mortality.

THU-249

NASH/NAFLD patients with end stage liver disease experienced high inpatient hospitalization costs and substantial disease progression: Results of a French national database on hospital care analysis

J. Boursier[1], C. Fabron[2], A. Lafuma[2], I. Bureau[2]. [1]*Angers Hospital University, France;* [2]*CEMKA, Bourg La Reine, France*
Email: jeboursier@chu-angers.fr

Background and Aims: Disease progression and inpatients costs have not been well characterized in NAFLD/NASH patients. This study examined mortality, healthcare resource utilization, and inpatient costs in NAFLD/NASH patients with end stage liver disease (ESLD) (decompensated cirrhosis, hepatocellular carcinoma or liver transplant) with and without type 2 diabetes mellitus (T2DM).
Method: Patients ≥18 years of age with NAFLD/NASH (ICD-10: K76.0, K75.8) were identified from the French National Database on hospital care (PMSI) between 2009 and 2015. Patients with other causes of liver disease were excluded. All hospital stays with ESLD were extracted. The index dates were first dates of ESLD diagnosis.
Results: 131,898 NAFLD/NASH patients were hospitalized during the study period, with 11.2% (n = 14,822) experiencing CC, ESLD, and/or death. The total percent of ESLD patients in the study population was 6.3% (n = 8,288) (2,810 progressed to ESLD and 5,478 diagnosed with ESLD at index). ESLD patients' mean age was 64.8 ± 16.1 years and 46.8% female. For the subset of patients (n = 2,559) who progressed directly from NAFLD/NASH at baseline study period to ESLD, mean time of progression was 21.4 months. 20% (n = 1,654) of ESLD patients progressed to death and mean time of progression was 14.4 months. ESLD patients had a high prevalence of comorbidities at ESLD index date: hypertension was 65%, hyperlipidemia was 34%, obesity was 42%, and T2DM was 46%. In subgroup analysis, the prevalence of comorbidities was significantly higher in T2DM than no T2DM patients. The mean number of hospitalizations and length of stay per hospitalization increased from 0.5 ± 1.2 to 2.8 ± 10.7 and from 2.2 ± 6.3 to 10.8 ± 13.2 days following ESLD diagnosis, respectively (both $P < 0.0001$). Additionally, following ESLD diagnosis, mean cost per stay increased from €1,119 ± 2,743 to €5,970 ± 6,318 and mean annual hospitalization costs increased from €3,474 ± 15,212 to €13,291 ± 27,225 (both $P < 0.0001$) (Figure).

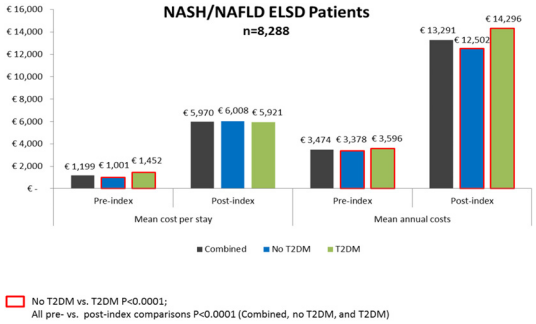


Figure: NASH/NAFLD ESLD patients mean cost per hospital stay and mean annual hospitalization costs pre- and post-index and stratified by T2DM and no T2DM patients.

Conclusion: NAFLD/NASH hospitalized ESLD patients had a high mortality rate. During the study period of 7 years, 20% of ESLD patients died in a mean time of 14.4 months. ESLD patients experienced an over 400% increase in mean annual number of hospitalizations, 400% increase in length of stay, and an almost 300% increase in annual hospitalization costs following ESLD diagnosis.

New treatments are urgently needed to prevent progression of NAFLD/NASH patients to ESLD and to reduce medical costs.

THU-250

Combinations of inflammatory markers, soluble (s)CD163, mannose receptor (sMR) and neutrophil gelatinase associated lipocalin (NGAL), predicts mortality in patients with acute-on-chronic liver failure

H. Grønbæk[1], H.J. Møller[2], D. Benten[3], R. Jalan[4], C. Moreno[5], A. Alex[6], P. Marco[6], P. Ginès[7], V. Arroyo[6]. [1]*Aarhus University Hospital, Department of Hepatology & Gastroenterology, Aarhus C, Denmark;* [2]*Aarhus University Hospital, Department of Clinical Biochemistry, Århus C;* [3]*University Hospital Hamburg-Eppendorf, Department of Gastroenterology and Hepatology, Hamburg, Germany;* [4]*University College London, Royal Free Hospital, Liver Failure Group, Institute for Liver Disease Health, London, United Kingdom;* [5]*Erasme Hospital, Universite Libre de Bruxelles, Department of Gastroenterology and Hepato-Pancreatology, Brussels, Belgium;* [6]*European Foundation for the study of Chronic Liver Failure (EF-CLIF), Barcelona, Spain;* [7]*University de Barcelona, Liver Unit, Hospital Clínic de Barcelona, Barcelona, Spain*
Email: henngroe@rm.dk

Background and Aims: Acute-on-chronic liver failure (ACLF) has a sinister prognosis and there is a need for precise biomarkers and scoring systems to better characterize ACLF patients and predict prognosis. Systemic inflammation and renal failure are hallmarks in ACLF disease development and progression. We hypothesized that the combination of specific inflammatory markers in combination with clinical scores are better predictors of survival than the originally developed CLIF-C acute decompensation (AD) and CLIF-C ACLF scores.
Method: We re-evaluated all measured inflammatory markers in 522 patients from the CANONIC study, 342 *without* and 180 *with* ACLF. We used the Harrell's C-index to determine the best marker alone or in combination with the original scores, and calculated new scores for prediction of mortality in the original CANONIC cohort.
Results: The best markers to predict 90-day mortality in patients *without* ACLF were macrophage activation markers soluble (s)CD163 and mannose receptor (sMR). Urinary neutrophil gelatinase associated lipocalin (UNGAL) and sCD163 were predictors for 28-day mortality in patients *with* ACLF. The new developed CLIF-C AD + sMR score in patients *without* ACLF improved 90-days mortality prediction compared to the original CLIF-C AD score (C-index 0.82(0.78–0.86) vs. 0.74(0.70–0.78, P = 0.004). Further, the new CLIF-C ACLF + UNGAL + sCD163 improved the original CLIF-C ACLF score for 28-days mortality (0.85(0.79–0.91) vs. 0.75(0.70–0.80), P = 0.039).
Conclusion: The capability of these inflammatory markers to improve the original prognostic scores in cirrhosis patienst *without* and *with* ACLF points to a key role of macrophage activation and inflammation in the development and progression of AD and ACLF.

THU-251

The outcome of acute-on-chronic liver failure in the intensive care is similar to a propensity matched ICU population without liver disease

S. van der Merwe[1], P. Meersseman[2], L. Langouche[3], H. Korf[4], J.D. Plessis[5], M. Mekeirele[2], D. Cassiman[6], W. Laleman[5,7], F. Nevens[5,7], A. Wilmer[2], G. Van den Berghe[2,3]. [1]*UZ Leuven, Department of Gastroenterology and Hepatology, Belgium;* [2]*UZ Leuven, Department of Internal Medicine, Leuven, Belgium;* [3]*KU Leuven, Clinical Division and Laboratory of Intensive Care Medicine, Department of Cellular and Molecular Medicine, Leuven, Belgium;* [4]*KULeuven, Laboratory of Hepatology, Leuven, Belgium;* [5]*KU Leuven, Laboratory of Hepatology, Leuven, Belgium;* [6]*University hospitals leuven, Gastroenterology and Hepatology, Leuven, Belgium;* [7]*UZ Leuven, Gastroenterology and Hepatology, Leuven, Belgium*
Email: hannelie.korf@kuleuven.be

Background and Aims: Acute-on-chronic liver failure (ACLF) is characterized by acute decompensation of cirrhosis, development of organ failure and high short-term mortality. It is unclear whether the ICU outcome in ACLF is different from other ICU populations. We compared the clinical course and host response in critically ill ICU patients with or without ACLF matched for baseline severity of illness scores.
Method: A post-hoc analysis was performed of the large EPaNic ICU study (n = 4640): 133 patients were identified with cirrhosis of whom 71 patients fulfilled the Canonic criteria for ACLF. These patients were matched for type and severity of illness and demographics to 71 septic and 71 medical ICU patients without liver disease. The clinical, biochemical and outcome parameters were compared and, in a subset of 100 patients, day 1 serum cytokines were quantified.
Results: The outcome of ACLF when compared to septic or medical ICU patients, matched for baseline parameters of illness severity, was similar regarding length of ICU stay, development of new infections, organ failure and septic shock, ICU hospital and 90 day mortality. CRP and platelets levels were lower in ACLF patients throughout the first week in ICU. Baseline cytokines IL-10, IL-1β, IL-6, and IL-8 were similarly elevated in ACLF and septic ICU patients, whereas serum TNF-α was higher and CCL13 lower in ACLF.
Conclusion: ACLF patients admitted to the ICU showed comparable clinical and ICU outcomes compared to non-ACLF patients without liver disease with similar baseline severity of illness characteristics. This suggest that admission criteria to the ICU should not be different in ACLF compared to other populations. Furthermore, ACLF patients that are liver transplant candidates should be identified early in their ICU course.

THU-252

Early management of critically ill cirrhotic patients admitted in ICU for gastrointestinal bleeding: wait day 3 to avoid taking a bad decision

L. Meunier[1], A. De Jong[1], L. Caillo[2], J.U. Bedoya[1], S. Faure[1], S. Jaber[1], G.-P. Pageaux[3]. [1]*CHU St Eloi Montpellier;* [2]*CHU Caremeau Nimes;* [3]*CHU Montpellier, Montpellier, France*
Email: lucymeunier66@gmail.com

Background and Aims: Gastrointestinal bleeding is a serious complication of portal hypertension and a leading cause of death in cirrhotic patients. The main objective of this study was to determine the risk factors for hospital mortality of cirrhotic patients admitted to intensive care unit (ICU) for gastrointestinal bleeding related to portal hypertension.
Method: It was an observational retrospective study of prospectively collected data in the ICU at Montpellier University Hospital. Risk factors for hospital mortality were analyzed in univariate and multivariate analysis after logistic regression.
Results: Between November 1998 and March 2016, 200 cirrhotic patients with a gastrointestinal bleeding (219 admissions) admitted to the ICU were included. The median age was 55 ± 10.5 years, 78% were men and the cirrhosis was most frequently alcohol-related (64%) and advanced (78% of patients Child-Pugh B or C). Mortality rate in ICU was 29.5% and hospital mortality rate was 38.5%. On day 3 (D_3), AUROC for the prognosis scores were 0.73 (95% CI 0.64–0.82) for Chronic Liver Failure Sequential Organ Failure Assessment (CLIF SOFA) and 0.75 (95% CI 0.65–0.84) for grade of acute-on-chronic liver failure (ACLF). The independent risk factors for hospital mortality were, on D_3: Model for End-stage Liver Disease (MELD) score >20 on D_0 (OR: 2.78 (1.14–6.75), p = 0.0243), increase of bilirubin > 13% µmol/L between D_0 and D_3 (OR: 6.18 (2.33–16.38), p= 0.0003), mechanical ventilation until D_3 (OR: 3.51 (1.34–9.18), p = 0.0105), Extracorporeal Renal Replacement Therapy (ERRT) (OR: 5.06 (1.30–19.68), p = *0.0193)* and vasopressor therapy on D_3 (OR: 2.62 (1.05–6.59), p= 0.0401). AUROC curve obtained on D_3 from this risk factors was 0.86 (95% IC 0.78–0.91) (Figure).

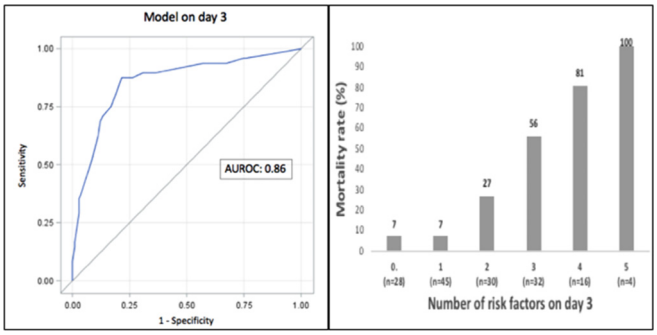

Figure: Model on D_3 obtained by multivariate analysis: AUROC curve and percentages of mortality according to number of items.

Conclusion: This is a large cohort specifically dedicated to cirrhotic patients admitted in ICU for gastrointestinal bleeding related to portal hypertension, in order to determine the risk factors for hospital mortality. On D3, we identified hepatic and non-hepatic risk factors that were independently associated with ICU mortality. The association of these risk factors on D_3 could help to discuss the futility or utility of the ICU management in these patients.

THU-253

Dynamic assessment is superior to baseline assessment in prognostication of patients with acute on chronic liver failure

S. Rathi[1], S. Taneja[1], A. Duseja[1], V. Gautam[2], Y. Chawla[1], R.K. Dhiman[1].
[1]PGIMER, Hepatology, Chandigarh, India; [2]PGIMER, Microbiology, Chandigarh
Email: rkpsdhiman@hotmail.com

Background and Aims: Acute on Chronic Liver Failure (ACLF) is a dynamic syndrome that leads to high risk of mortality in patients with cirrhosis. While the definitions of both acute events and underlying chronic liver disease are debated by different groups, the prognostic scoring models in all definitions are based on variables at presentation. We studied a dynamic model of prognosis assessment and compared it with the static models.

Method: We prospectively evaluated 160 patients who presented with acute decompensation of cirrhosis, which included development of ascites, hepatic encephalopathy, variceal bleeding or sepsis. These patients were assessed at baseline and at day 5–6 of admission in terms of prognostic scores like Model for End stage Liver Disease (MELD), Chronic Liver Failure-Sequential Organ Failure Assessment (CLIF-SOFA), ACLF Grade, and Simple Organ Failure Count (SOFC), and followed up till 90 days or until death.

Results: Of the total, 126 patients were analysed. The mean age was 47.8 ± 12.4 yrs, and 104(82%) were males. Alcohol was the most common etiology of cirrhosis (52%), followed by non-alcoholic steatohepatitis/cryptogenic. Ascites was the most common acute decompensation (81%), and infections were the most common acute precipitating event. A total of 70 (55.6%) survived at 4 weeks, and 32 (25.4%) at 3 months. The prognostic scores at day 5–6 fared better than baseline scores in predicting 28-day mortality. SOFC and CLIF-SOFA score at day 5–6 were the best predictors of mortality with an AUROC of 0.88 and 0.87 respectively. For 90-day mortality, CLIF-C ACLF at day 5–6 fared the best (AUROC 0.79). Patients who showed worsening of organ failure were less likely to survive as compared to those who either remained stable or improved (28-day survival OR-0.36, 95% CI 0.16–0.79, P= 0.017; 90-day -day survival OR-0.34, 95% CI 0.13–0.87, P = 0.03). Moreover, patients with 3 or more organ failures

Table 1: (abstract: THU-253)

		Day 5-6 Grade							
Initial Grade		No ACLF		ACLF 1		ACLF 2		ACLF 3	
No ACLF	N	N	%	N	%	N	%	N	%
Prevalence	68	41		8		12		7	
28day mortality	19	5	12	3	38	5	42	6	86
90day mortality	37	17*	41	4	50	9	75	7	100
ACLF 1									
Prevalence	9	3		1		2		3	
28day mortality	6	1	33	1	100	1	50	3	100
90day mortality	7	1	33	1*	100	2	100	3	100
ACLF 2									
Prevalence	25	8		1		11		5	
28day mortality	15	3	38	0	0	7	64	5	100
90day mortality	20	5	62	0	0	10	91	5	100
ACLF 3									
Prevalence	24	5		2		2		15	
28day mortality	16	0	0	0	0	1	50	15	100
90day mortality	19	1	20	1	50	2	100	15	100

**one patient each in these groups underwent liver transplantation*

at day 5–6 had a uniformly poor survival irrespective of the severity at presentation.
Conclusion: ACLF is a dynamic process with a potential for reversibility. However, most prognostic models based on a single baseline assessment, which may not be adequate. A dynamic assessment at day 4–5 after initial stabilization in-hospital gives a much better measure of the severity of the disease and risk-stratification. Moreover, patients who fail to improve or deteriorate at day 4–5 have a uniformly poor prognosis, and an argument may be made for futility of care.

THU-254
Acute on chronic liver failure-comparison of patients identified by the European association for the study of the liver and the North American consortium for study of end-stage liver diseases
Z. Galvin, E.N.S. Fong, N. Selzner, F. Wong. *Universit Health Network, Toronto General Hospital, Toronto, Canada*
Email: zita.galvin@uhn.ca

Background and Aims: Acute-on-chronic liver failure (ACLF) is characterized by acute clinical deterioration, multiorgan failure and high-mortality in patients with established chronic liver disease. Current ACLF scoring systems have not been compared in liver transplant (LT) patients.
To compare the relevance of the NACSELD (North American Consortium for Study of End-Stage Liver Diseases) and the EASL-Chronic Liver Failure (CLIF) Consortium scoring systems for ACLF in determining post LT renal function and patient survival outcomes.
Method: This was a retrospective single center study of patients, excluding those who received MELD exception points, fulminant liver failure or evidence of intrinsic kidney disease, who received a LT between 2007 & 2014. Patients were screened for ACLF according to both sets of criteria during their last hospital admission prior to LT. Patient demographics, at time of listing and LT, and post LT renal outcome and overall survival were compared between groups.
Results: 581 (66% male, mean age at listing 51 years, 21% alcoholic) met the inclusion criteria. Of these, 175 (30%) met the EASL-CLIF criteria for ACLF, 61 of whom (11%) also met the NACSELD criteria. Both ACLF groups had significantly higher baseline serum creatinine (SCr), bilirubin, INR and MELD scores at listing compared with the no-ACLF group ($p < 0.01$). Significantly more patients with ACLF required renal replacement therapy post LT, had higher SCr during follow-up and significantly lower survival, especially in the NACSELD-group (Table 1).

Table 1: Listing, transplant and outcome data for LT recipients

	No ACLF	EASL-CLIF ACLF	NACSELD ACLF	P value
n	406	175	61	
Listing SCr (μmol/L)	75 (62–96)	108 (72–195)	117 (69–239)	<0.0001
MELD				
Listing	17 (14–20)	23 (17–34)	27 (18–36)	<0.0001
At LT	19 (14–23)	29 (23–36)	31 (24–38)	<0.0001
Post LT SCr (μmol/L)				
3M	92 (74–110)	96 (76–127)	96 (73–133)	0.114
6M	95 (78–115)	104 (88–135)	98 (82–134)	<0.0001
12M	95 (81–117)	108 (86–132)	111 (81–137)	0.001
Post LT RRT [n(%)]	6 (1.5)	19 (10.9)	14 (23.0)	<0.0001
Survival (%)				
6M	95.1	88.6	82.0	<0.0001
12M	93.6	86.9	80.3	<0.0001
24M	91.4	84.6	78.7	0.002

Conclusion: ACLF patients have worse post LT renal function and overall survival outcomes compared to non-ACLF. The NACSELD score identifies sicker patients and is easier to use in the LT setting since the presence of 2 organ failures is sufficient to meet the criteria.

THU-255
Liver transplantation in patients admitted to intensive care with acute-on-chronic liver failure
E. Theocharidou, T. Pirani, M. Heneghan, N. Heaton, W. Bernal, M. Mcphail. *King's College Hospital, Institute of Liver Studies, London, United Kingdom*
Email: eltheocharidou@hotmail.com

Background and Aims: Acute-on-chronic liver failure (ACLF) is characterized by acute decompensation of cirrhosis with organ failure(s) and is associated with high short-term mortality. Recent studies suggest a significant transplant benefit with liver transplantation (LT) in patients with ACLF-3 after admission to intensive care units (ICU) but with a high complication rate. This study assessed outcomes in patients with ACLF who underwent LT either from ICU (Group A), or after discharge from ICU to the ward (Group B), or shortly after discharge from hospital (group C).
Method: 736 patients with cirrhosis were admitted to a dedicated liver ICU at King's College Hospital between 2012–2016, 64 of which (8.7%) received LT within the year of ICU admission. Disease severity scores, outcomes, length of ICU and hospital stay were recorded.
Results: 18 patients were in group A, 24 in group B, and 18 in group C. Median time from ICU admission to LT was 9, 21 and 86 days, respectively. The admission MELD score (32, 29 and 25, $p = 0.023$), the CLIF-organ failure score (12, 11 and 10, $p = 0.018$) and the SOFA score (11, 9 and 8, $p = 0.023$) were significantly higher in group A compared to other groups. ACLF staging at admission to ICU was significantly different in the three groups ($p = 0.037$): group A – ACLF1 4 (22.2%), ACLF2 6 (33.3%), ACLF3 8 (44.4%); group B – ACLF0 4 (17.4%), ACLF1 2 (8.7%), ACLF2 10 (43.5%), ACLF3 8 (30.4%); group C – ACLF0 6 (40%), ACLF1 4 (26.7%), ACLF2 2 (13.3%), ACLF3 3 (20). Two patients in group B died (in-hospital mortality 8.3%) both with ACLF1 at ICU admission. All patients in group A and C survived. In-hospital mortality in the remaining 672 patients who did not receive LT was 42.7%. Length of ICU stay was significantly higher in group A (16, 4 and 2 days, $p < 0.0005$) compared with the other two groups. Length of hospital stay was significantly higher in groups A and B (50, 45 and 16 days, $p = 0.046$).
Conclusion: Survival rates with LT in patients with ACLF requiring ICU admission are high in those transplanted directly from ICU or shortly after transfer to the ward, although LT rates are lower than in other cohorts. These patients require a prolonged post-LT hospital stay. A significant number of patients with ACLF will survive ICU stay and can be transplanted from the ward and the optimal timing requires further investigation.

THU-256
Impact of the non-hepatic surgery on the survival of patients with viral cirrhosis: prospective study from the CirVir cohort
C. Zylberfajn[1], P. Nahon[2], L. Richard[3], C. Carole[4], R. Francoise[3], E. Audureau[3], R. Amathieu[1]. *[1]Hopital Jean Verdier, Intensive Care Unit, Bondy, France; [2]Hopital Jean Verdier, Hépatologie, Bondy, France; [3]Hopital Henri Mondor, Santé publique, Creteil, France; [4]Hopital Beaujon, Hépatologie, Clichy, France*
Email: cecile.zylberfajn@gmail.com

Background and Aims: Surgery in decompensated cirrhotic patient is associated with a high postoperative morbidity and mortality. Nevertheless, outcome after surgery in compensated cirrhotic patients are not well known.
The main objective of this study is to assess mortality and risk of death in compensated cirrhotic patients after surgery in the ANRS CO12 CirVIr cohort.
Method: Data were collected prospectively between 2006 and 2012 in 35 French centers from 1671 patients with histologically proven cirrhosis due to hepatitis B or C virus Patients were free of any decompensation episode before inclusion.
Patients with at least one surgical procedure during the follow-up were included in the study. Data were collected at the time of the

inclusion in the cohort for all patients and at the time of surgery for the patients who underwent surgery. The surgery was classified in hepatic or non-hepatic surgery, in minor and major surgery and in surgery for cancer or not.

Results: 1671 patients were included in the analysis. 19.4% (n = 324) underwent surgery, of witch 268 non-hepatic surgeries (82.7%), 137 minor surgeries (51.1%) and 130 major surgeries (48.5%).

Liver function tests were not statistically different in operated and non-operated patients: total bilirubin was 11.0 [8.0–16.0] vs 11.6 [8.0–16.0] μmol/l (p = 0.69), Prothrombin Time was 89% [80–98] vs 87.5% [78–97] (p = 0.056); and albuminemia was 42.0 [38.9–45.1] vs 41.8 [38.5–45.0] g/L (p = 0.17).

Patients with surgery during the follow-up, according to the type of surgery, had an increased risk of death compared to patients who did not require surgery (HR = 2.33 [1.74, 3.12], p < 0.001).

With the exception of cancer-related deaths, the causes of death were similar in both groups, including deaths from end-stage liver failure (13.6% vs. 12.7%).

However, patients with surgery had a greater risk of having decompensation of the cirrhosis than patients without surgery (HR = 2.35 [1.74; 3.17], p < 0.001).

In our model, in multivariate analysis, major non-digestive surgery had a significant mortality risk with a HR of 3.39 (1.79–6.44), p < 0.001

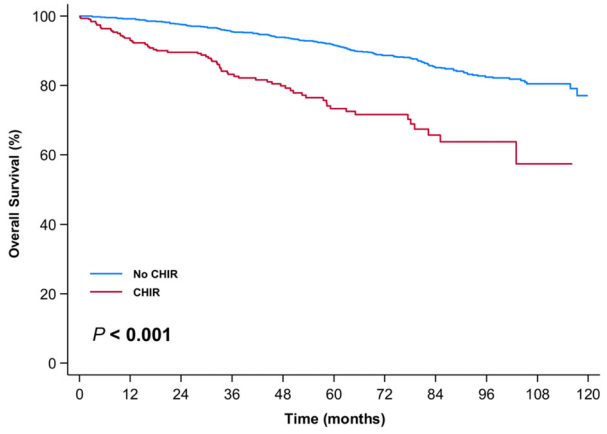

Figure: Survival curve according to the absence or the presence of a surgical act.

Conclusion: In patients with compensated viral cirrhosis, without prior decompensation history, surgery, seems to be an independent risk factor of mortality.

THU-257

Clinical phase 1b study results for safety, pharmacokinetics and efficacy of ND-L02-s0201, a novel targeted lipid nanoparticle delivering HSP47 SIRNA for the treatment of Japanese patients with advanced liver fibrosis

N. Sakamoto[1], K. Ogawa[1], G. Suda[1], K. Morikawa[1], T. Sho[1], M. Nakai[1], H. Suzuki[2], N. Yamagata[2], Y. Tanaka[2], W. Ying[3], Y. Tamura[4], Y. Niitsu[5], K. Maruyama[2]. *[1]Hokkaido University, Department of Gastroenterology and Hepatology, Graduate School of Medicine, Sapporo, Japan; [2]Nitto Denko, Tokyo, Japan; [3]Nitto BioPharma Inc., San Diego, United States; [4]Hokkaido University, Department of Molecular Therapeutics, Institute for the Business-Regional Collaboration, Center for Food & Medical Innovation, Sapporo, Japan; [5]Sapporo Medical University, Sapporo, Japan*

Email: sakamoto@med.hokudai.ac.jp

Background and Aims: ND-L02-s0201* is an injectable lipid nanoparticle that encapsulates a chemically-modified siRNA targeting HSP47, a collagen-specific chaperone, in hepatic stellate cells. In the US and European portion of a Phase 1b study, ND-L02-s0201, administered for 5 weeks, was associated with improvements in fibrosis, as assessed by biopsy, in subjects with advanced fibrosis due to nonalcoholic steatohepatitis (NASH) or hepatitis C virus (HCV) infection (The Liver Meeting 2017). Here we report results from the Japanese portion of the Phase 1b study.

Method: This study was an open label, multiple-dose escalation study to evaluate safety, pharmacokinetics (PK), and biological activity of ND-L02-s0201 in Japanese subjects with advanced fibrosis (METAVIR F3-4). ND-L02-s0201 was intravenously infused once weekly for 5 weeks to 3 cohorts (0.2, 0.4, and 0.6 mg/kg). Subjects had a baseline biopsy within 6 weeks. In Cohort 1, subject who had biopsy within 12 months before screening was eligible. A post-therapy biopsy was done at Week 6. Open biopsy reading was performed by pathologist at the site.

Results: The study included 10 subjects across 3 cohorts, previously diagnosed with NASH (n = 5), HCV-SVR (n = 3), hepatitis B virus (n = 1; sAg (-)) or alcoholic hepatitis (AH) (n = 1). 8 subjects completed 5-week dosing. 5 out of 10 subjects had adverse events (AEs), possibly related to the study drug. 1 subject had a serious AE of *Staphylococcus aureus* infection in the right shoulder and lumbus. Other AEs were observed during infusion and were all mild and transient. The HSP47 siRNA had a linear PK profile. Improvement in Ishak and METAVIR scores were observed in 3 out of 8 evaluable subjects (Table), including 1 subject showing reduction of METAVIR score from F4 to F2 (Cohort 1), and 2 subjects (1 each in Cohort 2 and 3) from F3 to F2. An increase in Ishak score was noted in 1 subject, but no increase in METAVIR score. The subjects who showed improvement in Ishak and METAVIR scores were diagnosed with NASH- (n = 2) and AH-related fibrosis (n = 1).

Table Fibrosis Change at Week 6 (Compared to Baseline)

	Improved	No Change	Worsened
Ishak	3/8 (37.5%)	4/8 (50%)	1/8 (12.5%)
METAVIR	3/8 (37.5%)	5/8 (62.5%)	0/8 (0%)

Conclusion: ND-L02-s0201 was well tolerated in Japanese subjects with advanced liver fibrosis, with no dose-limiting toxicities up to 0.6 mg/kg for 5 weeks, and an acceptable PK profile. Histological improvement was observed at all tested doses. Given the unmet medical need for advanced liver fibrosis, these results support further evaluation of the efficacy and safety of ND-L02-s0201.

*Further clinical development as BMS-986263

THU-258

Acute kidney injury in patients with hepatitis B virus related acute-on-chronic liver failure is different from in decompensated cirrhosis

Q. Jiang, M. Han, K. Ma, G. Chen, W. Wu, Y. Wang, J. You, W. Yan, D. Xi, Q. Ning. *Tongji Hospital Tongji Medical College, University of Science and Technology*

Email: qning@vip.sina.com

Background and Aims: Acute kidney injury (AKI) is a common complication of acute-on-chronic liver failure (ACLF) and decompensated cirrhosis(DC). However, the differences of AKI between these two diseases are little known. To clarify it, we evaluated the biomarkers levels of tubular damage including neutrophil gelatinase-associated lipocalin (NGAL), interleukin-18 (IL-18), kidney injury molecule-1 (KIM-1),liver-type fatty acid binding protein (L-FABP), and cystatin C (cysC), clinical response to terlipressin and prognosis in patients of AKI with ACLF or DC in chronic hepatitis B (CHB) patients.

Methods: Total 280 patients with HBV-ACLF and 132 with HBV-DC consecutively admitted to Tongji hospital between December 2015 and July 2017 were enrolled in a prospective study, and 24 patients with chronic hepatitis B(CHB) and 20 healthy controls(HC) at the

same period were also investigated. Patients' plasma and/or urine specimens from these patients were collected. The correlation between the levels of biomarkers of AKI representing kidney injury and clinical features of AKI in CHB patients with ACLF and DC were analyzed.

Results: 71(25.4%) and 28(21.2%) patients developed AKI in CHB patients with ACLF and DC, named ACLF-AKI group and DC-AKI, respectively (p = 0.358). Compared with DC-AKI patients, the rate of AKI progression was higher [39(54.9%) vs 5(17.9%), p = 0.002] and clinical response rate to terlipressin was lower in ACLF-AKI patients [14(32.6%) vs 11(57.9%), p = 0.018]. Most of the biomarkers (NGAL,L-FABP,CysC, and IL-18) levels representing kidney tubular injury in urine were significantly higher in ACLF-AKI patients than in DC-AKI patients as well as CHB patients and healthy control. While there were no significant difference between DC-AKI patients and CHB patients as well as healthy control. Two plasma biomarkers levels (NGAL,CysC) were higher in patients with AKI than patients without AKI, but there was no significant difference between ACLF-AKI group and DC-AKI group. Moreover, the survival rates at 28-day and 90-day were markedly decreased in ACLF-AKI group than DC-AKI group (both p < 0.001).

Conclusions: The degrees of structural kidney injury in ACLF-AKI group were severer than that in DC-AKI group. ACLF-AKI group displayed greater possibility to progression, less response to terlipressin treatment as well as with poorer prognosis compare with DC-AKI group.

THU-259

Invasive fungal infections in Acute on chronic liver failure – An Asia Pacific experience from the AARC consortium

Email: drsuniltaneja@hotmail.com

Background & Aims: Invasive fungal infections (IFI) have been associated with higher morbidity and mortality in critically ill cirrhosis patients. Emerging evidence suggests similar trends in patients with acute on chronic liver failure (ACLF).

Aims: To compare the clinical and laboratory profiles of ACLF patients with bacterial and fungal infections and their impact on outcome.

Methods: All patients with proven IFI (culture positive) as per EORTC/MSG guidelines from the APASL-ACLF research consortium prospectively collected database were analysed. Age, gender, and etiology-matched patients of ACLF with bacterial infections were taken as controls. Baseline clinical and laboratory variables, prognostic scores and length of hospital stay were compared in both groups.

Results: A total of 74 patients with ACLF had evidence of IFI. 101 matched ACLF controls with bacterial infections were randomly selected from the database with bacterial infections. There were no differences in the demographic parameters, acute precipitating events and etiology of chronic liver disease between the groups. The baseline Child-Pugh (Mean ± SD- 12.2 ± 1.7 vs 12.1 ± 1.4; p = 0.75), MELD (32.1 ± 7.9 vs 30.4 ± 7.8; p = 0.16), APACHE II (20.0 ± 6.2 vs 17.9 ± 6.4; p = 0.18) and CLIF-SOFA (12.3 ± 3.1 vs 12.5 ± 2.9; p = 0.7) scores were similar in both groups.

Duration of hospital stay (16.7 ± 14.3 vs 13.9 ± 10; p = 0.2) and ICU stay (7.1 ± 7.8 vs 5.8 ± 5.3; p = 0.33) were similar for both groups. The 30-day mortality too was similar in both groups (OR 1.3, 95% CI 0.7–2.4; p = 0.43), however, in the 90-day mortality; there was a trend towards higher mortality in the bacterial infection group (OR 1.9, 95%CI 1.0–3.8, p = 0.07).

Among the patients with IFI, urinary tract involvement was the most common (n = 54, 73%), followed by pulmonary (n = 15, 20%) and fungemia (n = 8, 11%). There was no difference in the duration of hospital stay or ICU stay between patients with different foci of fungal infection.

		FUNGAL N = 74		BACTERIAL N = 101		p-value
		MEAN	SD	MEAN	SD	
Age		44.6	11.0	45.9	12.2	0.47
Gender (Males, %)		74 (89%)		88 (87%)		0.68
Acute	Alcohol	40		47		0.9
	HBV reactivation	10		15		
	Other Hepatotropic viruses	8		12		
	DILI	8		13		
	Others	8		14		
Chronic	Alcohol	41		56		0.65
	Viral	13		22		
	NASH	9		9		
	Others	10		20		
CTP		12.2	1.7	12.1	1.4	0.75
MELD		32.1	7.9	30.4	7.8	0.16
CLIF-SOFA		12.3	3.1	12.5	2.9	0.7
APACHE II		20.0	6.2	17.9	6.4	0.18
Organ Failures		2.1	1.2	2.0	1.3	0.69
Hospital Stay		16.7	14.3	13.9	10	0.2
ICU stay		7.1	7.8	5.8	5.3	0.33
30-d mortality		43, (58%)		48, (65%)		0.43
90-d mortality		65, (64%)		79, (78%)		0.07

Conclusion: Patients with Acute on Chronic Liver Failure with IFIs have similar poor outcomes as those with bacterial infections. The diagnosis and treatment of IFI at baseline in most patients in this study may be responsible for the attenuation of the outcome difference between bacterial and fungal infections. Thus, a high index of suspicion and early diagnosis and treatment may improve the outcome in this group.

THU-260

Albumin function in acute-on-chronic liver failure (ACLF): Effect of plasma exchange with albumin 5% (PE-A5%)

M. Torres[1], R. Horrillo[2], N. Afonso[1], L. Núñez[1], A.M. Ortiz[2], A. Pérez[2], M. Costa[2], V. Arroyo[3], J. Fernández[3], S. Grancha[2], A. Páez[1]. *[1]Grifols, Clinical, Barcelona, Spain; [2]Grifols, R+D, Barcelona, Spain; [3]Hospital Clinic, Hepatology, Barcelona, Spain*
Email: mireia.torres@grifols.com

Background and Aims: Non-oncotic albumin function relays on its capacity to bind and transport endogenous and exogenous biologically active free molecules, including fatty acid and aminoacid-derived inflammatory mediators as well as reactive oxygen species (due to albumin antioxidant scavenger capacity), thus modulating their biological effects. Since severe systemic inflammation and organ failure are the main differential characteristics of ACLF, it is suggested that PE-A 5% may be an effective treatment for ACLF patients. In this study we assessed the effect of PE-A 5% on albumin functional

capacity in ACLF patients (*study 1*) and we characterized the albumin functionality in ACLF patients at baseline compared to healthy controls (*study 2*).
Method: *Study 1* was a phase II, open-label, single arm, pilot clinical trial (EudraCT: 2010-021360-15) in 10 patients with ACLF treated with 6 PE-A 5% sessions of 1.1 plasma volumes for 11 days. Albumin functional capacity was assessed. *Study 2* used plasma samples of ACLF patients at baseline from study 1 and age-matched healthy controls (n = 19). Albumin binding capacity of fatty acid and aminoacid derivatives were measured by Electronic Paramagnetic Resonance and by specific fluorescence with dansylsarcosine, respectively. The albumin Cys34 thiol antioxidant capacity was analyzed by anionic-exchange chromatography and expressed as total amount of the reduced albumin (HMA). Results are expressed as lsmean ± SEM.
Results: *Study 1:* 10 ACLF patients were enrolled (12 screened): age 55.0 ± 9.3 years old. PE-A 5% increased serum albumin concentration (29.5 ± 1.3 to 32.5 ± 1.3 g/l, $p < 0.01$), albumin binding capacity to fatty acids (Kd: 8.2 ± 1.4 to 3.1 ± 1.5 μM; $p < 0.005$) and to dansylsarcosine (15.3 ± 1.6 to 18.9 ± 1.7 vs. normalized ABiC/mL; $p < 0.005$), and antioxidant capacity (9.5 ± 1.5 vs. 14.6 ± 1.6 HMA mg/dl; $p < 0.005$). *Study 2:* The albumin function in ACLF patients was significantly lower than in age-matched controls: fatty acids Kd increased 6.8-fold ($p < 0.001$), binding to dansylsarcosine was 2.1-fold lower ($p < 0.001$) and antioxidant capacity decreased 2.5-fold ($p < 0.001$).
Conclusion: Albumin binding capacity to fatty acids and aminoacid derivatives as well as albumin antioxidant capacity are markedly decreased in advanced cirrhosis, which may contribute to the pathogenesis of systemic inflammation and ACLF. PE-A 5% improved non-oncotic albumin functions in ACLF patients.

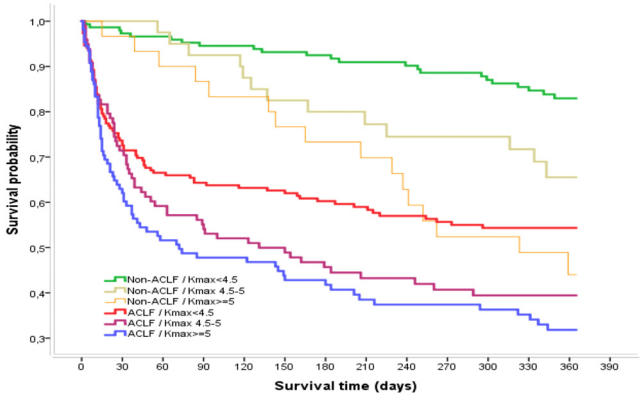
Email: acardena@clinic.cat

Background and Aims: Hyperkalemia is considered a risk factor of mortality in different clinical scenarios such as heart failure, chronic kidney disease and diabetes mellitus. The aim of this study was to investigate whether hyperkalemia is a risk factor for mortality in patients with cirrhosis and acute decompensation (AD) with and without ACLF
Method: We performed an analysis of the Chronic Liver Failure Consortium CANONIC database in 1,314 consecutive patients admitted to 29 European centers with AD both with and without associated ACLF (294 and 1,020 respectively). Hyperkalemia was defined as serum potassium above 5.0 mEq/L. For the analysis, we considered all patients with presence of at least one valid measure of serum potassium from admission through hospitalization.
Results: Of the 1314 patients admitted with AD, 294 presented ACLF at admission. Prevalence of hyperkalemia in the whole cohort was 11.7% with a mean serum potassium of 5.47 mEq/L. The prevalence of hyperkalemia was significantly higher in patients with ACLF versus those with AD (22.4% and 8.6% respectively, $p < 0.001$). Presence of hyperkalemia was associated with an increased 90, 180 and 360-day mortality risk with higher hazard ratio (HR) in ACLF than in acute decompensation (10 vs 2.3 at 90-day $p < 0.001$, 8.9 vs 3.1 at 180-day, $p < 0.001$ and 5.8 vs 3.8 at 360-day, $p < 0.001$). In a multivariate analysis development of hyperkalemia during admission was independently associated with 90-day mortality [HR 2.4 (1.7–3.4)]. To assess further the prognostic value in the whole cohort, we compared the ROC curves of the MELD score with and without hyperkalemia during admission; this showed an increase of the AUC for MELD score from 0.74 to 0.76 $p < 0.001$. This MELD-K model resulted in a higher diagnostic accuracy to predict 90-day mortality on the whole cohort.



Conclusion: The presence of hyperkalemia is an independent predictive factor of survival in patients with cirrhosis AD and ACLF. The addition of hyperkalemia to the MELD score improves the diagnostic accuracy to predict 90-day mortality in patients with AD and ACLF.

Email: pandeap@gmail.com

Background and Aims: Acute hepatic insult leading to liver failure with or without extra-hepatic organ failure leads to a high short-term mortality. However, the impact of organ failure(s) on long- term, i.e. beyond 90 days survival is unknown. We studied the impact of organ failures and on survival beyond 90 days in ACLF patients.
Method: The patients diagnosed to have ACLF (APASL definition) were recruited from 52 centres across Asia Pacific. The data was prospectively collected in this observational study cohort on a predefined format in the database from October 2012 to September 2017. Clinical and laboratory parameters, severity score, organ failures were analysed at baseline and their dynamic changes at D4 and D7 to predict the survival beyond 90 days. Liver failure (serum bilirubin 12.0 mg/dl or more), Kidney failure (2.0 mg/dl or more, or on renal replacement therapy), Cerebral failure (Grade III or IV hepatic encephalopathy), Coagulation failure (INR >2.5 and/or platelet <20.000/cc).
Results: A total of 3037 prospectively enrolled patients, 2553 (84%) males and 484 (15.4%) females with a mean age of 45 ± 12.7 years were analyzed. Baseline characteristics in all the groups were comparable. The most common acute insult was alcohol (43%) reflecting a change akin to the West, and followed by viral etiologies (23.3%). The mean baseline MELD score was 28 ± 7.6; SOFA score was 8.9 ± 3.2; CLIF-SOFA-11.47 ± 2.74 and AARC score was 9.89 ± 2.15. There were 395 (15.8%), 984(39.5%) and 1115 (44.7%) patients with no; one and two organ failures respectively. Mortality at the end of 1 year and 5 year was 955/1855 (51.5%) and 982/1855 (52.5%) respectively. Presence of organ failure increased short-term mortality [HR = 1.99 (95CI 1.53–2.26); HR = 4.41(95 CI 3.38–5.75) and 10.33(95 CI 7.64–13.18)] for 1.2 and >2 organ failures respectively. AARC Score was better than other scores in predicting the 90 day survival outcome.

	AUC	p value	95%CI	Cut off	Sensitivity	Specificity
ARRC Score	0.721	<0.002	0.68–0.78	10	69.6	61
MELD	0.708	<0.002	0.672–0.72	30	67.1	65
CTP	0.646	<0.002	0.608–0.76	30	70	50
Organ failure ≥2	0.698	<0.002	0.68–0.72	30	70.4	61

Conclusion: The organ failure has an impact in predicting the short-term outcome i.e. 3 months in patients of ACLF. Recently defined AARC Score i.e. a liver failure better predict the outcome than the existing disease severity score.

THU-263

Tenofovir is more potent over entecavir in reducing the viral load in patients of hepatitis B reactivation presenting as Acute on Chronic Liver Failure (ACLF)-Results of multination study from APASL-ACLF Research Consortium (AARC)

Email: ahmadjuned43.jk@gmail.com

Background and Aims: Reactivation of hepatitis B is a well-characterized syndrome marked by abrupt reappearance or rise of HBV DNA in the serum of a patient with previously inactive or resolved HBV infection. A significant number of patients of spontaneous acute exacerbation of CHB may present with, high HBV DNA, jaundice, liver failure (bilirubin >5 mg/dl), INR >1.5). The presentation, response to therapy and outcome were analyzed.
Method: The patients diagnosed to have ACLF (APASL definition) were recruited from 52 centres across Asia Pacific. The data was prospectively collected in this observational study cohort on a predefined format in the database from October 2012 to September 2017. A total of 560 patients of ACLF (ACLF-HBVr), predominantly male (361, 64.5%) with mean age 40.6 ± 10.4 yr those receiving Nucs i. e. tenofovir(Group-A) or enetcavir(Group-B) or combination (Group-C) were analyzed in relation to viral load at presentation, at 90 days and its impact on 90 days survival.
Results: 312 patients received Tenofovir (Gr. A) and 203 patients received entecavir (Gr. B) and 35 patients received combination of tenofovir and entecavir (Gr.C). Baseline characteristics in all the groups were comparable. All had high MELD (Gr. A-23.4 ± 3.1; Gr.B-25.2 ± 2.3; Gr. C-24.1 ± 3.1; p = 0.51),CTP score (Gr.A-11.5 ± 2.3;Gr.B-11.2 ± 1.9 Gr.C-12.4 ± 1.9;p = 0.32) and AARC score (Gr.A-11.6 ± 2.5,Gr. B-11.9 ± 2.1,Gr.C-12.3 ± 2.1) were comparable. Cirrhosis was seen on biopsy in 73% (408/560) of patients. HBsAg inclusion bodies were seen in 67% (375/560). Fever was seen in 91% (509/560) and features of serum sickness in 57/560 (9.8%). Most common cause of reactivation was spontaneous in 88.6% (496 /560) followed by chemotherapy in 7.67% (43/560), HCV therapy (21/560). Baseline DNA-Gr.A-$1.2 \times 10^5 \pm 0.8 \times 10^3$ IU/ml,Gr.B-$2.3 \times 10^5 \pm 1.1 \times 10^3$ IU/ml, Gr.C $4.3 \times 10^7 \pm 2.1 \times 10^3$ IU/ml(p = NS),quantitative HBsAg{Gr.A-5.6×10^3,Gr.B-7.8×10^3, Gr.C-8.1×10^3 (p = NS)}. Tenofovir lead to significant decline in HBV DNA at 3 months i.e., log 3.1 ± 0.8 decline in Gr. A compared to log 1.7 ± 0.9 in Gr. B and 3.2 ± 1.02 log in Gr.C.(p = 0.03). There was comparable decline in HBsAg levels in all the groups {Gr.A-log 1.1 ± 0.4; Gr.B log 1.1 ± 0.7; Gr. C – 1.5 ± 0.9(p = 0.2). Mortality at 3 months was comparable among all groups {Gr.A-36.7%; Gr.B-41.5% and Gr.C-38.3%p = NS}. Baseline DNA, HBsAg (q), bilirubin and INR, cirrhosis on biopsy were significant predictors of mortality on univariate analysis whereas bilirubin and INR were predicators of mortality in multivariate as well. Mean MELD/CTP/SOFA/AARC score were predictors of outcome.
Conclusion: Tenofovir is more potent than entecavir in Asian patients with ACLF-HBVr in reducing viral load, though there is no mortality benefit.

THU-264

Serum caspase-1 level as a diagnostic and prognostic biomarker for HBV-related acute-on-chronic liver failure

X. Zhang, H. Shi, Y. Chen, Z. Duan, F. Ren. *Beijing YouAn Hospital, Beijing, China*
Email: renfeng7512@hotmail.com

Background and Aims: Liver inflammation is crucial in the pathogenesis of HBV-related acute-on-chronic liver failure (ACLF). The aim of this study is to investigate the role of Caspase-1 as biomarker of disease progression and prognosis in HBV-related ACLF.

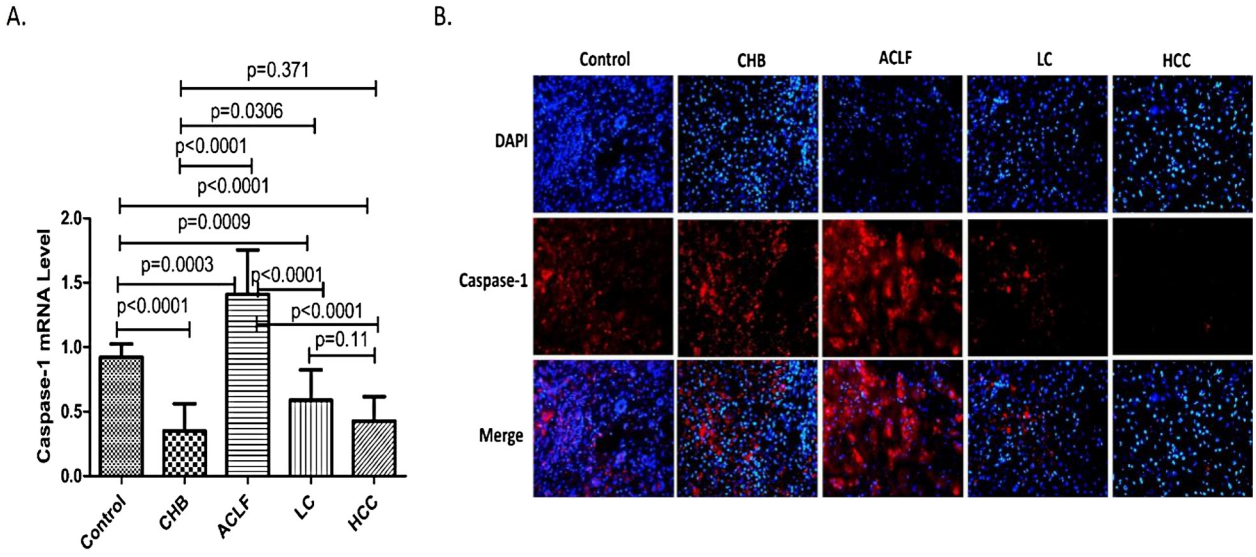

Figure 1: (abstract: THU-264): Altered hepatic mRNA and protein expression of Caspase-1 in the HBV-related liver disease.

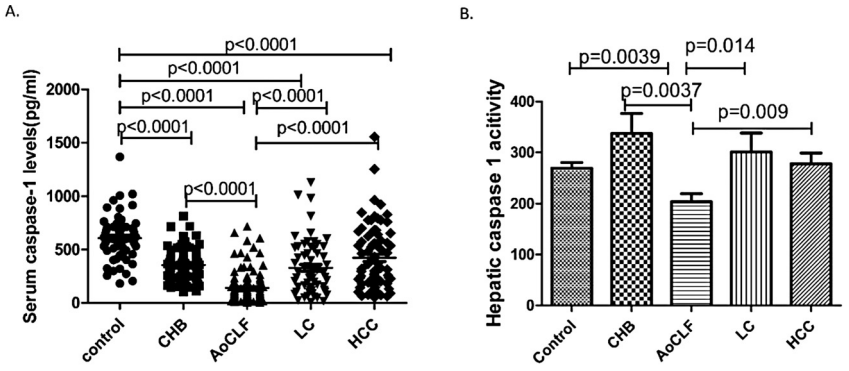

Figure 2: (abstract: THU-264): Altered serum Caspase-1 levels and hepatic Caspase-1 activity in the HBV-related liver disease.

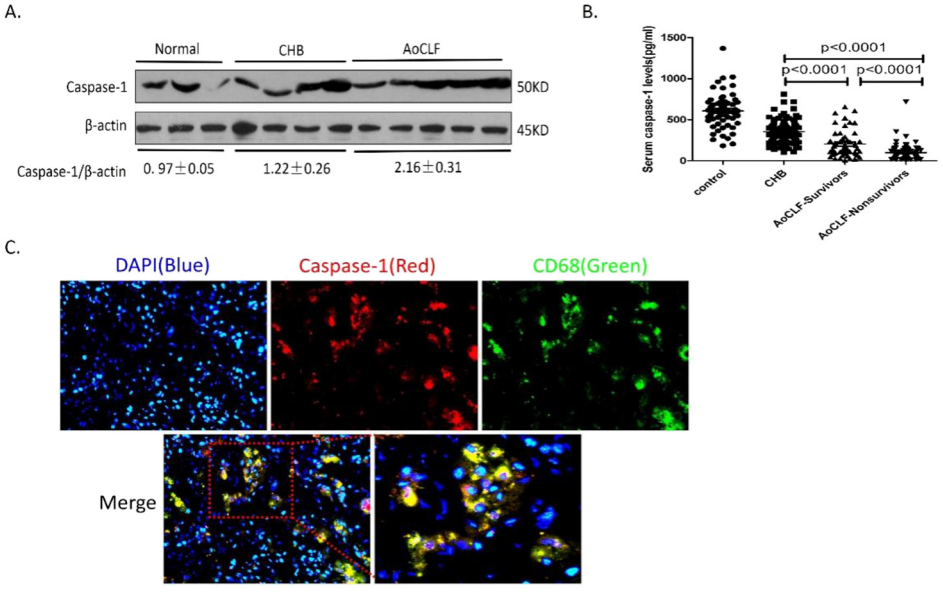

Figure 3: (abstract: THU-264): Expression of serum and hepatic Caspase-1 in ACLF patients.

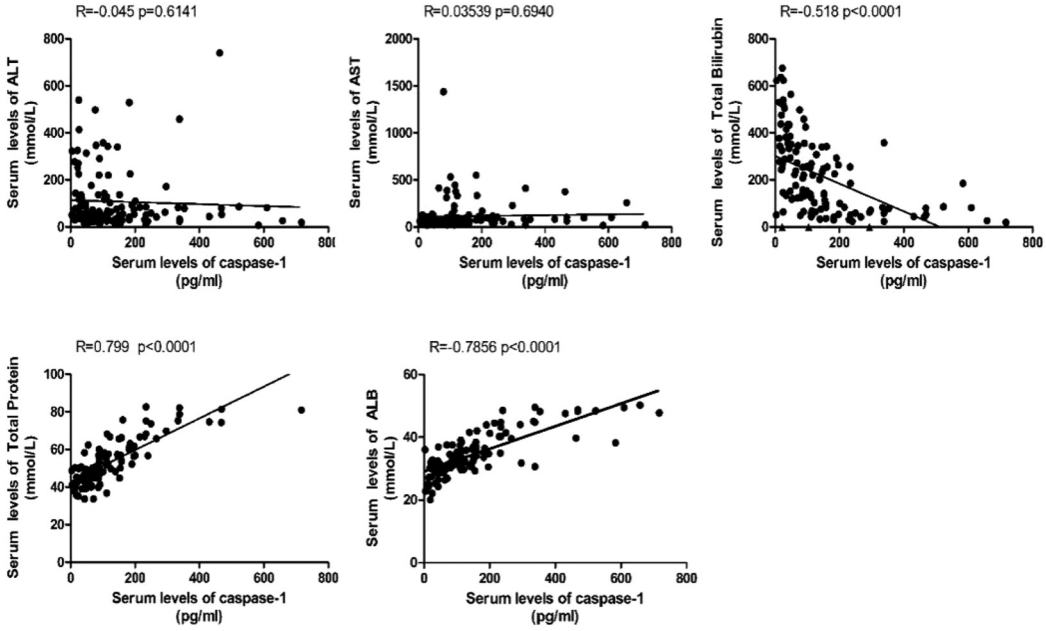

Figure 4: (abstract: THU-264): Association of serum Caspase-1 levels with liver injury in ACLF.

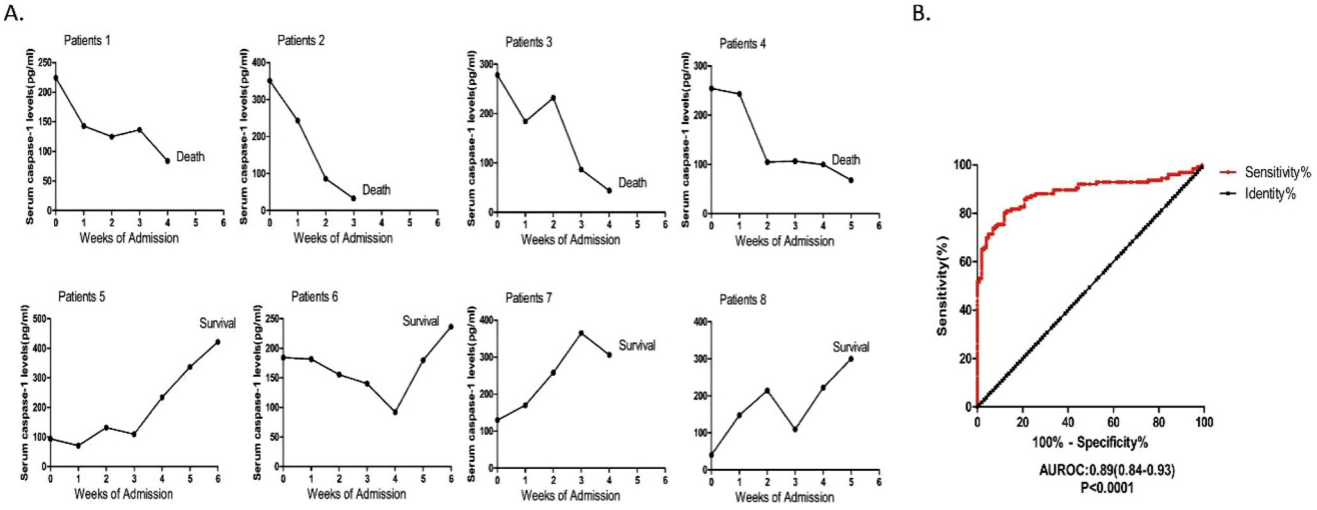

Figure 5: (abstract: THU-264): Diagnostic potential of Caspase-1 for predicting ACLF.

Method: The subjects with HBV-related hepatocellular cancer (HCC, n = 80), subjects with HBV-related liver cirrhosis (LC, n = 62) and subjects HBV-related ACLF (n = 126), to those of chronic hepatitis B (CHB) subjects (n = 101) were selected. The expression of Caspase-1 were measured using liver tissues from normal control subjects (n = 10), CHB patients (n = 12) and HBV-related ACLF patients (n = 19).

Results: Compared with CHB patients, the ACLF patients had distinctly decreased serum levels of Caspase-1, however, the HCC patients and LC patients showed no significant difference; the serum levels of Caspase-1 was showed a negative correlation with serum TBIL and a positive correlation with the serum total protein (TB) and albumin (ALB), although there are no correlation with ALT and AST. The intrahepatic mRNA and protein expressions of Caspase-1 were decreased in CHB subjects compared to healthy individuals and were increased in ACLF subjects compared to CHB subjects; however, the activity of Caspase-1 were gradually decreased in ACLF subjects compared to healthy individuals and CHB subjects. Importantly, the serum Caspase-1 levels in the survival group with ACLF was more significant higher than those of in the dead group patients and analyses of area under the receiver operating characteristic curve (ROC-AUC) indicated that Caspase-1 (0.84) may be useful for independently predicting ACLF patients.

Conclusion: We demonstrate for the first time that Caspase-1 plays a pivotal role in the pathogenesis of in ACLF patients caused by acute exacerbation of CHB, and Caspase-1 maybe a potential non-invasive diagnostic and prognostic biomarker for ACLF patients.

THU-265

Outcome of bacterial infections complicated or not by acute-on-chronic liver failure in patients with cirrhosis admitted to hospital for acute decompensation

M. Bartoletti[1], M. Baldassarre[2], M. Domenicali[2], M. Rinaldi[1], M. Giannella[1], R. Lewis[1], M. Tufoni[3], G. Zaccherini[3], M. Tamé[4], L. Napoli[5], R.M. Pavarin[6], S. Berardi[7], G. Orsola-Malpighi Hospital, Department of Clinical Medicine and Surgery, Section of Infectious Diseases, Bologna, Italy*
Email: michele.bartoletti4@unibo.it

Background and Aims: Bacterial infections (BIs) are a frequent complication in patients with cirrhosis and often trigger the onset of acute-on-chronic liver failure (ACLF). This prospective observational study aims to describe the clinical and microbiological characteristics, risk factors and 1-year survival of patients admitted to hospital for acute decompensation (AD) with or without BIs and the relationship with the onset and outcome of ACLF.

Method: From January 2014 to March 2016 patients with cirrhosis admitted for AD at the S. Orsola-Malpighi University Hospital, Bologna, and at the "Infermi" Hospital, Rimini, were consecutively enrolled. Data were recorded at admission and during hospitalization. Survival was recorded up to 1-year. The diagnosis of BIs was confirmed by an Infectious Disease specialist according the current international guidelines.

Results: Among the 516 patients enrolled, 108 (21%) presented an infection at admission, while additional 61 (12%) developed a nosocomial infection. Overall, 1-year survival was lower in patients with nosocomial (43%) and community acquired/healthcare related (52%) infections as compared to non-infected patients (65%) ($p < 0.001$). ACLF was diagnosed more frequently in infected (either at the time or after the diagnosis of infection) than in non-infected patients (36 vs 26%; $p = 0.002$). Multivariate logistic regression showed that higher MELD-Na score ($p = 0.001$), QuickSOFA score ≥2 points ($p = 0.004$), bacteremic ($p = 0.004$) and multidrug-resistant (MDR) infections ($p = 0.048$) were independent predictors of ACLF.

Kaplan-Meyers curves showed that 1-year survival was similar in infected and non-infected patients without ACLF (71 vs 67%, $p = 0.337$). As expected, 1-year survival was worsened by the presence of ACLF. Interestingly, ACLF related to BIs was associated to a significantly lower survival rate than ACLF precipitated by other events (23 vs 47%, $p = 0.010$). Finally, multivariate Cox regression showed that only BIs complicated by ACLF are associated to an increased risk of death ($p < 0.001$) independently from MELD-Na and Charlson comorbidity index.

Conclusion: This large prospective study indicated that the adverse impact of BIs on long-term survival in decompensated cirrhosis is not universal, but limited to those patients who also develop ACLF. Both disease severity and microbiological factors predispose infected decompensated patients to ACLF.

THU-266

Typing acute-on-chronic liver failure according to World Gastroenterology Organization working party definition in HBV-related patients

X. Tang, T. Qi, B. Li, C. Zhu, J. Gao, G. Lu, M. Xiong, Q. He, Y. Chen, F. Zhou, J. Chen, J. Hou. *Nanfang Hospital, Southern Medical University, Hepatology Unit, Department of Infections Diseases, Guangzhou, China*
Email: chjj@smu.edu.cn

Background and Aims: Acute-on-chronic liver failure (ACLF) can be divided into 3 categories depending on whether or not there is underlying cirrhosis, and in patients with cirrhosis, whether or not there is a history of previous hepatic decompensation. For now, this criterion hasn't been validated and described in HBV-related ACLF patients. Therefore, we aimed to investigate the characteristics and prognosis of the three types of ACLF in patients with hepatitis B virus infection.

Method: Hospitalized patients infected with hepatitis B virus who met European Association for the Study of the Liver (EASL) defined ACLF from January 2012 to June 2016 in hepatology unit, Nanfang hospital were included in this retrospective study, which were subsequently grouped according to WGO criterion: ACLF on non-cirrhotic as type A, on well compensated cirrhosis as type B and on

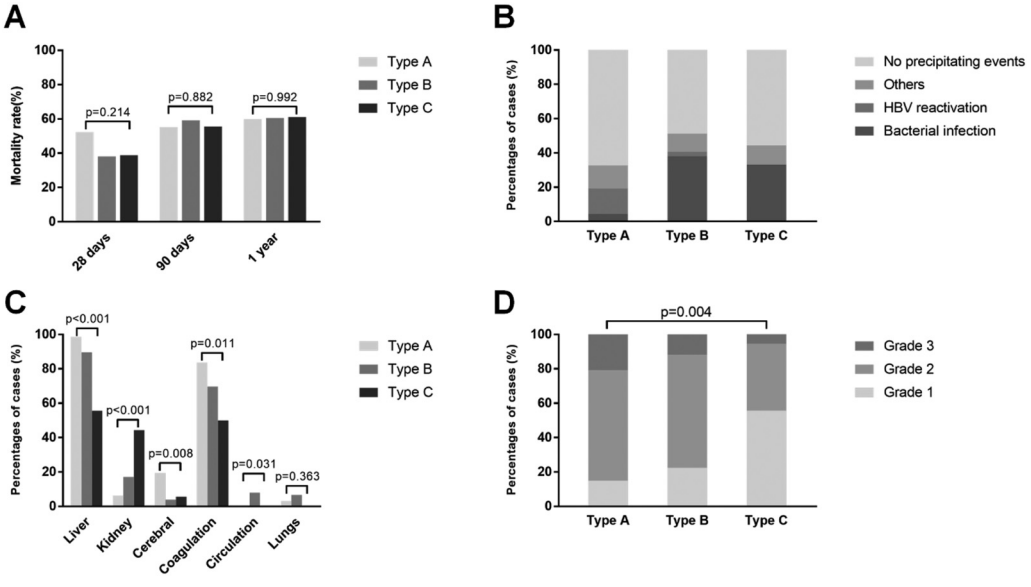

Figure: (abstract: THU-266)

previous hepatic decompensation as type C. The precipitating events, organ failures, laboratory tests and outcomes were compared among these three types of ACLF.

Results: Of the 161 subjects enrolled, 67 (41.6%), 76(47.2%) and 18 (11.2%) had type A, B and C ACLF at enrollment, respectively. Subjects with type A ACLF were the youngest, which had highest leukocytes counts, bilirubin levels, highest Model for End-stage Liver Disease (MELD) score, but lowest C-reactive protein and serum creatinine among the three types (Table). The 28-day, 90-day and 1 -year mortality rates were all comparable among these types (28-day: 52.2% vs. 38.1% vs. 38.9%, p = 0.214; 90-day: 55.2% vs. 59.2% vs. 55.6%, p = 0.882; 1-year: 59.7% vs. 60.5% vs. 61.1%, p = 0.992, Figure A). However, there were several distinct characteristics among the three ACLF types. For precipitating event, HBV reactivation was more common among type A subjects (14.9% vs. 2.6% vs. 0%, p = 0.014), while bacterial infection contributed more among type B and type C subjects (4.5 vs. 38.2% vs. 33.3%, p < 0.001, Figure B). Liver, coagulation and cerebral failure were more frequently seen type A ACLF compared with type B and C (Liver: 98.5% vs. 89.5 vs. 55.6%, p < .001; Coagulation: 83.6% vs. 69.7% vs. 50.0%, p = 0.011, Cerebral: 19.4% vs. 3.9% vs. 5.6%, p = 0.008). On the contrary, the proportion of kidney failure was highest in type C, followed by type B ACLF (44.4% vs. 17.1% vs. 6.0, p < 0.001, Figure C). Furthermore, the distribution of ACLF grades were significantly different among the three types (p = 0.004). Grade 2 ACLF was the most frequent in both type A (65.2%) and B (65.8%) subjects, while 55.6% subjects with type C were grade 1 ACLF (Figure D).

Conclusion: EASL defined HBV-ACLF can be further classified into three types according to WGO criterion, which have similar short and long-term prognosis, but distinct characteristics in precipitating event, organ failures and ACLF grades.

THU-267

Analyzing the Duration Between Acute Insult and ACLF in a Chinese 14 centers, prospective study for natural course of ACLF

Background and Aims: Patients with chronic liver disease who are at high Acute-on-Chronic liver failure (ACLF) risk are characterized by precipitating events (PE), intra- and extrahepatic organ failure(OF) and rapid deterioration to death. Although the time interval between PE and single liver failure(LF) as four weeks has been defined in APASL consensus, however studies on such interval and clinical course of ACLF are scarce. Whether intra- and extrahepatic PE lead to distinct durations remains uncertain. Hereby we analyzed the intervals of PE-to-single LF and PE-to-ACLF in Chinese CANONIC study patients.

Method: A Chinese nationally 14 liver centers representative cohort comprising 2600 chronic liver disease patients (including 70% cirrhotic and 30% non-cirrhotic) with acute decompensation or acute liver injury(defined as ALT > 3NL or TB > 2NL) was recruited. single LF (TB > 12 mg/dl) and ACLF were diagnosed using CLIF-OF score. We evaluated PE-to-single LF interval among cirrhotic patients who developed single LF at admission or within 28-days hospitalization after admission. Next, PE-to-ACLF interval was studied among patients who had defined PE and developed ACLF during hospitalization. The two intervals were then compared in patients with isolated defined intrahepatic PEs (including HBV reactivation, active alcohol intaking, superimposed hepatic virus and drug-induced hepatic injury)and those with infections as only existing extrahepatic PE.

Results: Among 1833 cirrhotic patients, 1070(58.4%) had explicit PE. Among those PE defined patients, 205 patients had single LF, and 76% patients develop single within 4 weeks when PE occurred. 71.5% etiology are HBV related and 20.6% developed ACLF. PE-to-single LF intervals for patients with intra-(n = 94) and extrahepatic PE (n = 111) were 19(7–42) (median and interquartile range) and 4(1–11) days, respectively (p < 0.0001). There was a significant PE-to-ACLF interval difference between intra- (n = 41) and extrahepatic (n = 55) PE(21(8–44) vs 15(9–24) days, p = 0.02). Comparing with bacterial infection as an only existing extrahepatic PE (n = 84), those with intrahepatic PEs (n = 51) had significant longer PE-to-single LF interval (intra:16(7–35) vs extra: 2(1–7) days, p < 0.0001), when PE-to-ACLF interval reached borderline significance(intra:16.5(7–44) days, n = 16 vs extra 15(9–24) days, n = 36; p = 0.05).

Conclusion: Our multicenter, prospective study showed both single LF and extrahepatic OF were most likely to occur within less than 4 weeks after PE presence among eastern type cirrhotic patients. Additionally, Both single LF and ACLF developed more rapidly with the presence of extrahepatic insult, especially in patients with bacterial infection. Exploring the interval from both PE-to-single LF and PE-to-ACLF interval will help to understand the natural course evolution about HBV dominated Eastern type ACLF.

Relative adrenal insufficiency in acute-on chronic liver failure – a new futility marker?

S. Chiriac[1], A. Trifan[1,2], A.-M. Singeap[1,2], C. Cojocariu[1,2], I. Girleanu[1,2], O. Stoica[1], T. Cuciureanu[1,2], L. Huiban[1,2], C.-M. Muzica[1,2], C. Alexandru[1,2], C. Stanciu[2]. *[1]"Grigore T. Popa" University of Medicine and Pharmacy, Gastroenterology, Iasi, Romania; [2]"St. Spiridon" Emergency Hospital, Institute of Gastroenterology and Hepatology, Iasi, Romania*
Email: ancatrifan@yahoo.com

Background and Aims: Acute-on Chronic Liver Failure (ACLF) is a condition characterized by organ failure in the setting of decompensated liver cirrhosis and associating high short-term mortality. Urgent liver transplantation could represent a life-saving intervention but only in selected patients, before the progression to multiple organ failure. Relative adrenal insufficiency (RAI) is frequently diagnosed in patients with severe sepsis, severe burns, after major surgery, and in the case of hemodynamically unstable cirrhotic patients with and without sepsis. Moreover, RAI has been considered another organ failure in the setting of decompensated cirrhosis, further worsening the prognosis of critically-ill patients. We aimed to evaluate the prognosis significance of RAI in patients with ACLF and to

assess the association of RAI as a possible marker of futility in ACLF patients.
Method: We conducted a prospective study of patients with decompensated liver cirrhosis who were hospitalized between March 2015 and September 2016 in the Hepato-Gastroenterology unit of the Clinical Emergency Hospital "St. Spiridon" Iasi, Romania. 153 patients were included. ACLF was defined according to the CANONIC study criteria. The concentration of serum cortisol (SC) was measured at 08:00 hours (baseline cortisol) and 30 minutes after intravenous administration of 250 μg of synacthen (tetracosactide) (peak cortisol). RAI was defined as a baseline cortisol value <5 μg/dl or as a delta cortisol value (the difference between baseline cortisol and peak cortisol) <9 μg/dl.
Results: RAI was diagnosed in 72 patients (47%). 113 patients (74.3%) were diagnosed with ACLF, out of which 62 (55%) had RAI. 30 patients had ACLF grade 1, 32 ACLF grade 2, and 51 ACLF grade 3. Short-term mortality rates were high in ACLF patients (58.44%) and varied progressively according to ACLF grade (7.6% grade 1, 22.7% grade 2, and 69.7% grade 3). The mortality rates were higher among patients with ACLF grade 3 and RAI (39 patients, 81.2%) compared to 7 patients (38.9%) in ACLF grade 3 without RAI. In patients with ACLF, RAI was associated with an increased risk for 28-days mortality [OR = 2.6, CI (1.705–4.059), P < 0.001]. Deceased patients with RAI had a lower median survival time 7 days (5–12), compared to patients without RAI, of 19.5 days (9.75–65.5), P = 0.001. In the ACLF group, univariate analysis identified RAI, alcoholic hepatitis, liver failure, renal failure, coagulation failure, respiratory failure, and cerebral failure as independent risk factors for death.
Conclusion: Patients with ACLF have high short-term mortality rates, which vary according to ACLF grade. The association of RAI represents another risk factor for death and in the case of grade 3 ACLF with RAI the mortality rates are the highest. The association of RAI may thus represent a futility marker for transplantation, particularly in ACLF grade 3 patients.

THU-269
The combination of acute-on-chronic liver failure (ACLF) as defined by EASL-CLIF consortium definition and MELD can predict post-transplant survival in patients with ACLF

U. Agbim[1], A. Sharma[2], S. Karri[2], J. Vanatta[1], H. Gonzalez[1], S. Nair[1], J. Eason[1], B. Maliakkal[1], S. Satapathy[1]. *[1]University of Tennessee Health Science Center, Department of Surgery; [2]University of Tennessee Health Science Center, Department of Medicine*
Email: uagbim@uthsc.edu

Background and Aims: Acute-on-chronic liver failure (ACLF) is an increasingly recognized entity that was recently redefined by European Association for the Study of the Liver-Chronic Liver Failure (EASL-CLIF) consortium. The aim of this study was to characterize post-transplant early survival outcomes based on pre-transplant ACLF severity as defined by the EASL-CLIF consortium definition and Model for End Stage Liver Disease (MELD).
Method: This was a retrospective review of 833 consecutive liver transplant (LT) recipients between April 2006 and March 2013 at Methodist University Hospital Transplant Institute. Patients with no evidence of chronic liver disease, dual-organ transplant, acute liver failure, and re-transplants were excluded. We defined "ACLF" and "no ACLF" using the EASL-CLIF Consortium definition and categorized those with ACLF into Grades 1–3. Further, ACLF Grade 2 and 3 was considered high ACLF and a MELD score ≥30 was considered a high MELD. To analyse the combined effect of MELD and ACLF we divided patients into the following categories: high MELD with high ACLF, high MELD with low ACLF, low MELD with high ACLF, and low MELD with low ACLF. Demographic and clinical variables were collected and patient outcomes were analysed using Kaplan-Meier survival analysis.

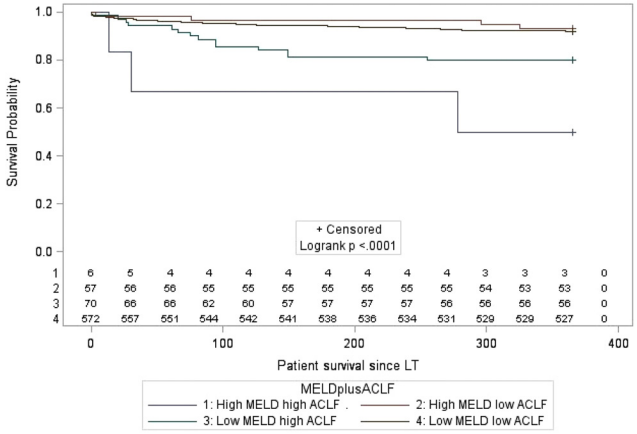

Figure 1: Kaplan-Meier Survival in Days of LT Recipients Stratified by MELD and ACLF.

Results: 582 LT recipients were found to have no ACLF, whereas 123 patients had ACLF. This was further subdivided into ACLF Grade 1 [47 (38.2%)], ACLF Grade 2 [47(38.2%)], and ACLF Grade 3 [29(23.6%)]. The median MELD was 17 (IQR 17–22). There were 6 LT recipients with high MELD with high ACLF, 57 with high MELD with low ACLF, 70 with low MELD with high ACLF, and 572 with low MELD with low ACLF. Using the low MELD with low ACLF group as control we noted an inferior patient survival in the high MELD with high ACLF (P = 0.003) and the low MELD with high ACLF group (P = 0.005) Figure 1.
Conclusion: Using the combined effect of MELD and ACLF, the patient survival of LT recipients with high MELD with high ACLF as well as the low MELD with high ACLF group was markedly inferior do the other groups. This suggests that the presence of extra hepatic organ failures not included in the MELD, but encompassed by ACLF, strongly influences morbidity and mortality in this critically ill group.

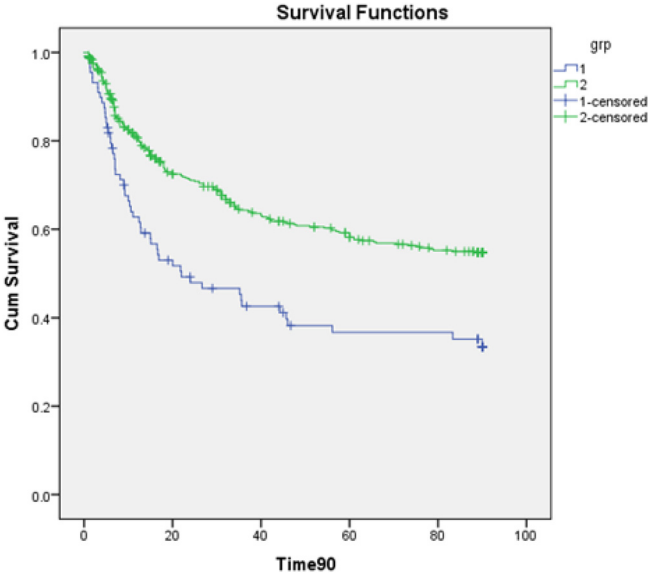
Email: hershey4686@gmail.com

Background and Aims: Activation of macrophages in response to acute hepatic insult in patients with pre-existing chronic liver disease presenting as ACLF is a new entity, HLH. Considered to be result of a cytokine storm, uncontrolled inflammatory response, HLH has a poor survival. We studied patients of ACLF to investigate the spectrum, presentation and influence of HLH syndrome on organ failure, disease severity and short-term survival.
Method: The patients diagnosed to have ACLF (APASL definition) were recruited from 52 centres across Asia Pacific. The data was prospectively collected in this observational study cohort on a

predefined format in the database from October 2012 to September 2017. A total of 615 patients of ACLF with ferritin >500 µg/l, were analyzed among those fulfilling the HLH criteria [5 of 8 criteria i.e. fever, splenomegaly, bicytopenia,hypofibrinogenemia & ferritin >500 µg/l, irrespective of the bone marrow examination).

Results: Out of 615 patients with ferritin above >500 µg/l, the HLH was seen in 90 (14.6%) cases i.e. full-filling 5 criteria. Males were 84.1% and with mean age of 43.31 ± 11.69 yrs. Alcohol was the most common acute and chronic etiology followed by Hepatitis B reactivation. The most common presentation was Jaundice (98.5%), hypofibrinogenemia (93.3%), Spleenomegaly (73.1%) and Fever (61%). Organ failures more than 2, Creatinine >1.49 mg/dl, albumin <2.3 gm/l, INR >2.4, Total Bilirubin >22.3 mg/dl and HE at baseline independently predicted 90 day mortality. Presence of HLH increased mortality ($p < 0.001$) even though various disease severity scores MELD Na [31.49 ± 7.56 vs 28.05 ± 7.38,* p = 0.27], SOFA [10.69 ± 3.20 vs 8.78 ± 3.09, p = 0.84], AARC Score [10.37 ± 2.15 vs 9.85 ± 2.19, p = 0.79] were not different between those dying versus surviving.



Conclusion: Presence of HLH even in absence of bone marrow confirmation is a poor predictor of outcome in patients of ACLF. Diagnosis of HLH predicts worse prognosis. Newer definition and criteria for HLH and its inclusion in liver severity scores is required in ACLF patients.

THU-271

Human beta-defensin-1 is a highly predictive marker of mortality in patients with acute-on-chronic liver failure

I. Mani, L. Vasilieva, A. Alexopoulou, E. Hadziyannis, D. Agiasotelli, T. Alexopoulos, D. Zampetas, S. Ntourakis. *2nd Department of Internal Medicine and Research Laboratory, Medical School, National and Kapodistrian University of Athens, Hippokration Hospital, Athens, Greece*
Email: alexopou@ath.forthnet.gr

Background and Aims: Human beta-defensin-1 (hBD-1) is a natural antimicrobial peptide expressed in the epithelia of multiple tissues including the digestive tract. Acute-on-chronic-liver-failure (ACLF) is defined as an acute deterioration of liver disease with high mortality in patients with cirrhosis. In the current study, hBD-1 levels were determined in different subsets of patients with decompensated cirrhosis including ACLF. In addition, the association of both hBD-1 and C-reactive protein (CRP) values with mortality was assessed.

Method: 125 patients were divided into 3 groups: 39 with ACLF, 46 with acute-decompensation without ACLF (AD) and 40 with decompensated cirrhosis without an acute event (DC). The hBD-1 was evaluated in serum by enzyme-linked-immunosorbent-assay. 15 healthy individuals were used as control group.

Results: Serum hBD-1 levels were higher in ACLF compared to AD ($P < 0.001$) and more elevated in AD compared to DC-group ($P < 0.001$). In contrast, CRP values showed a blunt association with severity of liver disease. Controls demonstrated lower values compared to cirrhotics ($P < 0.001$). Serum hBD-1 levels were not correlated with CRP ($r = 0.224$). In ROC curve, the value of 30.635 ng/ml was associated with the best prediction of 60-day mortality in ACLF-group (c-statistic 0.931, sensitivity 87.5%, specificity 100%). CRP was less accurate in predicting mortality (c-statistic 0.792, sensitivity 87.5%, specificity 66.7%). In AD-group neither serum hBD-1 nor CRP seemed to be associated with poor survival (c-statistics 0.500 and 0.596, respectively). In DC-group serum hBD-1 and CRP were equally accurate markers in predicting mortality (c-statistics 0.800 and 0.808, respectively). In ACLF-group, patients with high hBD-1 (>30.635) had a poor prognosis compared to those with low values (log-rank P = 0.001). In Cox univariate analysis, variables that had at least a trend ($P < 0.10$) for association with survival included age, gender, CLIF-C OF ACLF, MELD, sodium and CRP. In multivariate cox regression analysis only serum hBD-1 [hazard ratio (HR) 13.088, 95% confidence interval (CI) 1.475–116.101, P = 0.021] and liver function as assessed by MELD score (HR 1.106 95%CI 1.012–1.120, P = 0.027) emerged as independent predictors of death in ACLF group.

Conclusion: High serum hBD-1 was detected at presentation in patients with ACLF who died during the 60-day-follow-up period. Serum hBD-1 is an accurate predictor of short-term mortality in patients with ACLF.

THU-272

Thromboelastography parameters in acute on chronic liver failure

S. Goyal[1], Shalimar[1], S.S. Jadaun[1], S. Kedia[1], S.K. Acharya[1], S. Verma[2], B. Nayak[1], B. Thakur[1]. *[1]All India Institute of Medical Sciences, Gastroenterology, New Delhi, India; [2]Max Hospital, Department of Pediatric Hepatology and Gastroenterology, New Delhi, India*
Email: drshalimar@yahoo.com

Background and Aims: Patients with acute on chronic liver failure (ACLF) are assumed to have coagulation abnormalities on the basis of conventional tests (CCTs) – prolonged international normalized ratio (INR) and activated partial thromboplastin time (aPTT) and decreased platelet counts. Thromboelastography (TEG) assesses the global coagulation cascade. We aimed to evaluate TEG parameters in patients with acute on chronic liver failure (ACLF), and their ability to predict complications.

Method: Consecutive patients diagnosed with ACLF were included. We also included patients with chronic liver disease having acute decompensation and no ACLF (AD), and healthy subjects (HC) as controls. CCTs and TEG parameters were assessed within 24 hours of admission, and compared between the 3 groups. Cox-proportional hazard analysis was used to assess predictors of outcome.

Results: In this prospective study (June 2015 to June 2016), 68 ACLF (17-grade1, 20-grade 2, 31-grade 3), 53 AD patients and 58 HC were included. Alcohol consumption was the most common etiology. CCTs were significantly prolonged in patients with ACLF and AD as compared to HC. The mean values of INR in ACLF, AD and HC groups were 2.9 ± 1.4, 1.6 ± 0.4 and 1.1 ± 0.2; $P < 0.001$. Among TEG parameters- maximum amplitude (MA) was low in ACLF and AD patients as compared with HC (52.4 ± 14.3, 58.3 ± 13.7 mm and 66.9 ± 13.3 mm, respectively; $P < 0.001$). Lysis at 30 (LY30) min was high in ACLF patients as compared to AD and HC (8.6 ± 14.1%, 5.0 ± 9.5% and 4.9 ± 9.8%, respectively; P = 0.060). Among ACLF and AD patients, abnormal LY30 (>15 min) was seen in 23.5% and 15.1% patients, respectively. There were no differences in r time, k time, and alpha angle between the 3 groups. There was no difference in TEG parameters between different ACLF grades, whereas CCTs were more deranged with increasing grades. In the ACLF group, on multivariate analysis, MA was an independent predictor of outcome

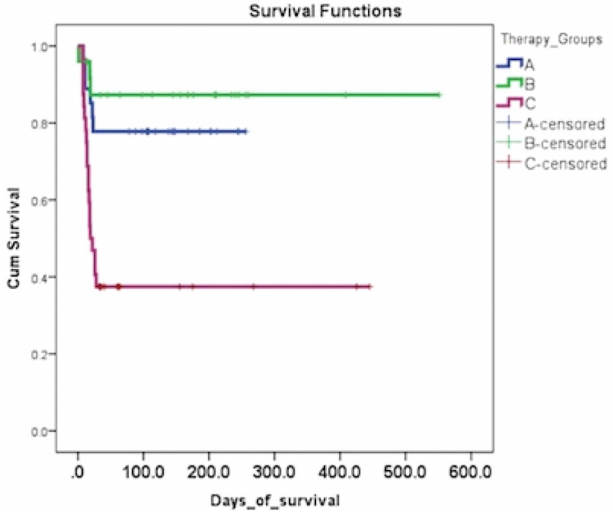
(HR 0.973 (95% CI, 0.948–0.998, P = 0.036) after adjusting for sex, total leucocyte count, hepatic encephalopathy, mean arterial blood pressure, creatinine, INR and LY30.
Conclusion: TEG parameters are abnormal in ACLF. MA may be of benefit in predicting outcome.

THU-273
Features of levels of neurospecific proteins in patients with hepatic encephalopathy
N. Dynnyk[1], E. Manzhalii[2], O. Baka[3], M. Lysianyi[4]. [1]*Bogomolets National Medical University, Internal Medicine, Kyiv, Ukraine;* [2]*Bogomolets National Medical University, Propedeutics of Internal Medicine;* [3]*Hospital for Scientists, Gastroenterology, Kyiv, Ukraine;* [4]*The State Institution Romodanov Neurosurgery Institute National Academy of Medical Sciences of Ukraine*
Email: dynka@ukr.net

Background and Aims: Today role of autoimmune processes in the pathogenesis of hepatic encephalopathy (HE) is not fully established. Many studies concerning damages of the nervous system showed the change of the content of some marker proteins, including myelin basic protein (MBP), cerebral antigen (CA), neuron specific enolase (NSE) and S100 proteins and the increasing of the titer of antibodies to these antigens. These phenomena are underlying the development of autoimmune processes in the conditions of the nervous tissue injury. However, there are no enough data on these proteins changes in the conditions of HE.
The aim was to establish the level of autoantibodies to neuron specific antigens: MBP, CA, NSE and S100 proteins in patients with HE.
Method: The study involved 51 patients aged 34–69 years (average age 49,4 ± 5,8 years) dominated by men (80%) with cirrhosis and hepatitis with the transition to cirrhosis with two or more documented episodes of HE over the last 6 months who were hospitalized and then under nursing. The levels of autoantibodies to MBP, S100, NSE and CA were measured by ELISA using specific antibodies (Sigma) in the serum of patients with HE. We studied the correlation between these autoantibodies and the level of general indicator of neurological status of patients in points. This figure included the assessment of the presence of oral automatism, anisoreflexia, statico-locomotory ataxia, violation of the sensitivity in patients. Each of the symptoms measured in the categorical values: there is either no violation. Accordingly, the overall rate of neurological.
Results: It was found a significant increase in the level of antibodies to CA, protein S100, NSE and MBP in patients with HE. In blood serum of patients CA increased by 33.4% ($p < 0.001$), S100 protein – by 81.1% ($p < 0.001$), NSE – by 39.6% ($p < 0.001$), MBP – by 55.1% ($p < 0.001$) compared with normal level.
Conclusion: The positive correlation between these proteins and the degree of neurological disorders in patients was revealed. Therefore, these indicators can be considered as markers of the degree of severity of HE. Determination of the levels of autoantibodies in patients with HE has a high diagnostic value. This gives us a reason to associate increase in these parameters with the process of destruction of brain tissue, which allows to predict the course of the disease and develop treatment tactics.

THU-274
Non inferiority of combination of slow continuous albumin, furosemide with low dose Terlipressin with Noradrenaaline infusion in ACLF patients in comparison to slow continuous albumin, furosemide and Terlipressin
G. Pandey[1], A. Kumar[2], M. Durgappa[2], A. Singh[2], A. Nehra[2], K. Vp[2], P. Sharma[2], P. Mishra[2], S. Mohindra[2], V. Saraswat[3]. [1]*Sanjay Gandhi Institute of Medical S, Hepatology and Gastroenterology, Lucknow, India;* [2]*Sanjay Gandhi Institute of Medical S, Gastroenterology, Lucknow, India;* [3]*Sanjay Gandhi Postgraduate Institute, Gastroenterology, Lucknow, India*
Email: drgauravpandey@yahoo.com

Background and Aims: Slow continuous albumin,furosemide ± terlipressin(SAFI ± T) infusion mobilizes ascites and significantly improves systemic hemodynamics and intestinal permeability in acute on chronic liver failure (ACLF) patients. Due to potential adverse effects of terlipressin at high doses a combination approach of low doses of 2 vasocosntrictors – Terlipressin and Noradrenaline in-effect causing splanchnic and systemic vasoconstriction synergistically with potentially lower side effects in ACLF patients was studied to look at the side effects and efficacy of the 2 regimen,comparing 28 day mortality with Standard medical treatment(SMT) arm.
Method: A case control prospective study with 3 groups of ACLF. Arm I SAFI ± T, Arm II SAFIT + Noradrenalin (SAFIT ± NA),ArmIII- SMT. In Arm I- Furosemide at 2 mg/ hour and albumin 2 gm/hour (20 g/d) was started(40 g/d). Blood and urine(electrolytes) done 12 hourly and corrected as required. Graded increase of furosemide was done by 1 mg (max 6 mg/hr) if UNa < 80 mmol/d. At 48 hours UNa <80 mmol/d then terlipressin infusion @2 mg/12 hours was started after correcting anemia and response guided increase (1 mg/12th hourly) was done (maximum 6 mg/24 hours). Arm II -the same protocol was followed but Terlipressin at 2 mg/24 hrs low dose was supplemented with Noradrenalin at 0.5 mcg/kg/min and titrated to max 1.5 mcg/kg/min if UNa < 80 mmol/day. Patients were shifted to oral diuretics at discharge maintaining UNa > 80 mmol/24 hours. Arm III received SMT including Albumin, and Terlipressin wherever indicated with oral diuretics.
Results: 84 ACLF patients-27(32%), 25 (30%) and 32(38%) in Arms I, II, III were enrolled. Overall age 47.3 ± 12 yrs and etiology were not significantly different. Baseline characteristics of Arm I, II and III including MELD 31.3 ± 6.7 vs 29.3 ± 4.6 vs 29.7 ± 5.6, Number of Organ failure 1.9 ± 0.8 vs 1.6 ± 0.7 vs 1.4 ± 0.8, Serum Creatinine 1.7 ± 0.8 vs 1.6 ± 0.7 vs 1.3 ± 0.9 mg/dl and CLIF-C-ACLF –49.9 ± 8 vs 47 ± 8 vs 52 ± 8 were not significantly different. Baseline urine sodium in Arm I (37.9 ± 27) and II (31 ± 11.5) increased to 235.8 ± 159 and 246 ± 146 mmol/24 hrs at discharge. 28 day survival in Arm I, II and III were 77% vs 88% vs 37.5% with p = 0.002 and 0.001 between Arm I-III and Arm II-III and p = 0.396 between Arm I and II. There was also significant improvement in systemic hemodynamics and intestinal permeability (NMR based Lactulose Mannitol ratio) in Arm I and II. No major adverse events were noted in Arm II.



Conclusion: Non inferiority of SAFIT ± NA over SAFI ± T in ACLF with no major adverse effects was seen.

THU-275

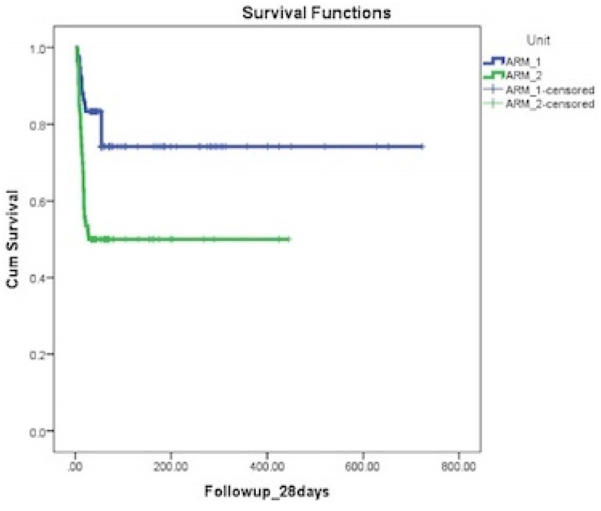
Impact of response guided aggressive pharmacological therapy with slow continuous albumin, furosemide and terlipressin infusion in chronic liver failure consortium acute on chronic liver failure score

G. Pandey, A. Kumar, M. Durgappa, S. Mohindra, A. Singh, V. Saraswat, K. Vp. *SGPGIMS, Gastroenterology, Lucknow, India*
Email: drgauravpandey@yahoo.com

Background and Aims: In Acute on chronic liver failure (ACLF) patients, chronic liver failure-consortium-acute-on-chronic liver failure score (CLIF-C ACLF) 35–65 identifies the sub-group of patients with good response to intervention. This is a prospective case-control study to assess the prognostic performance of ACLF patients with large ascites admitted with CLIF-C ACLF score between 35–65 treated with slow continuous albumin, furosemide ± terlipressin(SAFI ± T) infusion or standard medical therapy(SMT) and compare their 28-d mortality.

Method: Arm I Furosemide infusion at 2 mg/hour and albumin 2 gm/hour (20 g/d) was started. Blood and urine (electrolytes) samples were collected every 12 hours for UNa,UK and graded increase of furosemide was done by 1 mg (max 6 mg/hr) if UNa < 80 mmol/l. Aggressive potassium supplementation (oral/iv) was done in all patients. If after 48 hours UNa was still <80 mmol/l then terlipressin infusion @2 mg/12 hours was started after correcting anemia and baseline ECG (repeated 12th hourly) and response guided increase (1 mg/12th hourly) was done (maximum 6 mg/24 hours). Patients were shifted to oral diuretics at discharge maintaining UNa > 80 mmol/24 hours. Arm II received SMT including Albumin, and Terlipressin wherever indicated with oral dirutics. Central line wasplaced in oliguric/anuric patients.

Results: 211 patients Overall etiology: alcohol (49.5%) cryptogenic (23%), HCV (12.2%), HBV (6%), NASH (5.3%) and autoimmune (4%) was not significantly different. Baseline characteristics of Arm I(80) vs Arm II(14 patients) including mean age 46.7 ± 11.7 years, CTP 11.5 ± 2.7 vs12 ± 0.9, MELD 23 ± 5.7 vs24.3 ± 5.6, CLIF-SOFA-9.8 ± 1.8 vs 10.2 ± 2.1, Number of Organ failure2 ± 1.1 vs 1.6 ± 1, Serum Creatinine 1.52 ± 1.15 vs 1.4 ± 0.9 mg/dland CLIF-C-ACLF –2 ± 12.6 vs 49.6 ± 10.8 (p > 0.05)was not significantly different. Baseline urine sodium in Arm I increased from 32.6 ± 23 to 155 ± 143.8 mmol/24 hrs at discharge. 28 day mortality in Arm I was 75% vs 50% (p < 0.01). There was also significant improvement in systemic hemodynamics and intestinal permeability(NMR based Lactulose Mannitol ratio) in Arm I.



Conclusion: CLIF-C ACLF score ≤ 65 offers a window of opportunity for aggressive therapy in these extremely sick patients having beneficial impact on hemodynamics, intestinal permeability and survival.

THU-276

Impact of Clostridium difficile 027 ribotype in decompensated cirrhotic patients

A. Fernandez, L. Carrion, L. Dieguez, C. Villaseca, A. Conthe, M. Valerio, L. Ibañez, R. García, R. Bañares. *Hospital Gregorio Marañon, Liver Unit, Madrid, Spain*
Email: afyunquera@gmail.com

Background and Aims: Clostridium difficile (CD) constitutes an important cause of morbidity and mortality in hospitalized patients, especially with the emergence of a virulent strain known as BI/NAP1/027. The aim of the study was identify factors predisposing to CD disease and evaluate the impact on outocomes in decompensated cirrhotic patients hospitalized during a CD-027 ribotype outbreak in a terciary center.

Method: A retrospective analysis of cirrhotic patients hospitalized with decompensation and all CD 027 episodes at a terciary center, from November 2014 to January 2016 (CD027 outbreak) was made. Etiology of cirrhosis, decompensation data, comorbid condition, infection data, type of contact and history of hospitalization, use of antibiotics (including norfloxacin or rifaximin) and proton-pump inhibitor were collected. Mortality, length of stay, determinant for CD disease, and outcomes of cirrhosis were analyzed with a logistic regression and Cox model. Patients with CD ribotype 027 were intensified early treated with vancomicina.

Results: Cirrhosis was the most frequent disease associated with CD027 in the hospital (18.5%). 173 cirrothic patients were admitted with complete data in 121 cases. Patients with CD disease were 24% (CI 95% 16.7–32.6) and CD 027 14% (CI 95% 8.36–21.48). No differences in severity and hospital mortality were found (serious disease: CD027 26.7% no CD027 36.4%; p = 0.61; hospital mortality: CD027 17.6% no CD027 8.3%; p = 0.62). Diabetes mellitus, antibiotic in the previous six weeks, rifaximin or norfloxacin use, history of hospitalization in the previous three months, Child B-C were associated with CD in univariate analysis. Child B-C (OR 11.9), rifaximin/norfloxacin (OR 3.72) and antibiotic in the previous six weeks (OR 22.33) were associated with CD and also in CD027 in multivariate analysis. Length of stay was higher in CD than no CD [56.39 days (17.40) Vs 17.10 (11.34) P < 0.001] especially in CD027 [76.64 (27.70) Vs 17.99 (9.86) P < 0.001]. Diabetes mellitus (HR 1.78), female sex (HR 2.28) and CLIF-AD score (HR 1.05) were associated to survival.

Conclusion: Although cirrhosis constitutes a risk factor for CD027 disease, it is not associated with a higher risk of serious disease and mortality if intensified early treatment is applied.

THU-277

Albumin administration in the prevention of hepatorenal syndrome (HRS) and death in patients with advanced cirrhosis and non-SBP infections

J. Fernandez, P. Angeli, J. Trebicka, M. Merli, T. Gustot, C. Alessandria, N.K. Aagaard, A. De Gottardi, S. Zeuzem, A. Gerbes, G. Soriano, V. Vargas, A. Albillos, F. Salerno, F. Durand, R. Bañares, R.E. Stauber, V. Prado, M. Arteaga, F. Morando, C. Jansen, B. Lattanzi, C. Moreno, A. Risso, H. Grønbæk, R. Garcia, M. Pavesi, V. Arroyo. *Hospital Clinic, Liver Unit, Spain*
Email: jfdez@clinic.ub.es

Background: Albumin administration prevents HRS and death in SBP. Previous studies failed to demonstrate a clinically relevant beneficial effect of this treatment in non-SBP infections.

Aims and Method: Open-label, multicenter European RCT aimed to evaluate if albumin administration improves short-term survival in patients with non-SBP infections and advanced cirrhosis (serum creatinine ≥1.2 mg/dl, serum sodium ≤130 mEq/l and/or serum bilirubin ≥ 4 mg/dl). Initial sample size was estimated in 512 patients, 256 per treatment arm.

Results: 119 patients were finally included. The study was prematurely stopped due to low recruitment rate and expiration of the

study drug. Sixty subjects were randomized to receive antibiotics + albumin within the first 72 h after infection diagnosis (1.5 g/kg at inclusion, 1 g/kg on day 3) and 59 to receive antibiotics. Baseline clinical and analytical characteristics were similar between groups with no differences in Child-Pugh, MELD score, type of infection (pneumonia: 28% vs. 37%, UTI: 27% vs. 20%, bacteremia: 23% vs. 19% in the albumin and non-albumin groups, respectively) or severity (nosocomial: 30% vs. 32%; ACLF: 25% vs. 18%). Hospital mortality rate, the main aim of the study, was similar between groups: 13% in patients receiving albumin compared to 10% in the non-albumin group. Seven patients were lost to follow-up after hospital discharge (2 in each group at 28-d and 5 and 2 in the albumin and non-albumin group at 90-d). Twenty-eight day (13% vs. 8.5%) and 90-d (28% vs. 22%) mortality rates were also similar between groups. Two patients in the albumin group and 6 in the non-albumin group were transplanted during follow-up (3% vs. 10%; p = NS). Transplantation was performed within 28 days after inclusion in 1 and 5 patients in the albumin and non-albumin groups, respectively. Four patients receiving albumin (7%) developed pulmonary edema during hospitalization (2 pneumonia, 1 bacteremia, 1 suspected infection) compared to none in the non-albumin group.

Conclusion: Albumin administration does not improve short-term survival in cirrhotic patients with non-SBP infections and liver and/or renal dysfunction.

Viral hepatitis C: Therapy and resistance

THU-281

Emergence and long-term persistence of NS3, NS5A, and NS5B resistance associated substitutions after treatment with direct-acting antivirals

D. Wyles[1], E. Lawitz[2], B. Mcnabb[3], J. Lu[3], S. Chang[3], A. Osinusi[3], E.S. Svarovskaia[3], D. Brainard[4], S. Pianko[5], J. Feld[6], H. Mo[3], H. Dvory-Sobol[3]. *[1]Denver Health Medical Center, Denver, CO, United States; [2]Texas Liver Institute, The University of Texas Health San Antonio, San Antonio, United States; [3]Gilead Sciences, Foster City, United States; [4]Gilead Sciences, Foster City, CA, United States; [5]Monash Health and Monash University, Melbourne, Australia; [6]Toronto Centre for Liver Disease, Toronto, Canada*
Email: hadas.dvory-sobol@gilead.com

Background and Aims: Limited data on the long-term persistence of NS5A and NS3 HCV resistance associated substitutions (RASs) are available after treatment with clinically relevant HCV regimens. The aim of this study was to evaluate the persistence of NS3, NS5A and NS5B nucleotide inhibitor (NI) RASs in patients not achieving SVR in Gilead-sponsored treatment studies who were enrolled in a follow-up Sequence Registry.

Method: Patients who did not achieve SVR following treatment with a DAA-containing regimen in a Gilead treatment protocol were eligible for enrollment into the Sequence Registry where they were followed for up to an additional 144 weeks. Patients had NS5A, NS3 and/or NS5B regions sequenced if they were exposed to an NSS5A inhibitor (ledipasvir [LDV] or velpatasvir [VEL]), an NS3 inhibitor (vedroprevir [VDV] or voxilaprevir [VOX]), and/or an NS5B NI (sofosbuvir [SOF]), respectively. Patients were discontinued if they received HCV treatment or once RASs were no longer detectable. Results are reported using a 15% cutoff.

Results: Treatment-emergent NS5A and NS3 RASs were observed at the time of virologic failure (VF) in 95% and 93% of registry enrolled patients treated with non-SOF based regimens, respectively. NS5A and NS3 RASs were present at Week 144 in 63% and 25% of non-SOF treated patients, respectively. Treatment-emergent NS5A resistance was observed in 48% of registry enrolled patients at the time of VF with a SOF-based regimen. No treatment-emergent NS3 RASs were detected among the SOF/VEL/VOX failures enrolled in the study (Table). More than 1 NS5A RAS was detected in 47% and 7% of patients treated with non-SOF and SOF-based regimens, respectively. Treatment-emergent NS5B NI RASs were observed in 13/227 (6%) patients treated with a SOF-based regimens at the time of VF. No S282T was observed in any patient.

	Emergent RASs n/N (%)					
		Registry Study				
	Virologic Failure	Baseline	FU 12	FU 48	FU 96	FU 144
	NS5A RASs					
Non SOF-based[1]	138/145 (95)	137/145 (94)	107/115 (93)	92/107 (86)	64/86 (74)	27/43 (63)
SOF-based[2]	32/67 (48)	32/67 (48)	14/31 (45)	5/11 (45)	0/3	–
SOF/VEL/VOX	1/10 (10)	1/10 (10)	1/6 (17)	1/5 (20)	–	–
	NS3 RASs					
Non SOF-based[1]	105/113 (93)	102/113 (90)	68/82 (83)	37/81 (46)	16/63 (25)	8/32 (25)
SOF/VEL/VOX	0/10	0/10	0/6	–	–	–

[1]LDV + VDV + tegobuvir ± ribavirin (RBV) ± pegylated-interferon.
[2]LDV/SOF ± RBV, SOF/VEL ± RBV, SOF/VEL/VOX.

Conclusion: Among patients enrolled in this follow up registry, treatment-emergent RASs at the time of VF as well as long-term persistence of NS5A and NS3 RASs were more common among patients receiving regimens without SOF. NS5A RASs were more likely to persist than NS3 RASs, and NS5B RASs were uncommon. RASs were infrequent among patients failing treatment with SOF/VEL/VOX.

THU-282

Behavioral and clinical factors and Direct Acting Antiviral effectiveness in HCV/HIV co-infection; clinical experience from the TRIO network

G. Huhn[1], D. Jayaweera[2], K. Althoff[3], J. Eron[4], S. Milligan[5], A. Mills[6], G. Moyle[7], S. Santiago[8], P. Sax[9], G. Voskuhl[10], D. Wyles[11], R. Elion[12]. *[1]The Ruth M. Email: ghuhn@cookcountyhhs.org

Background and Aims: Clinical studies of Direct Acting Antivirals (DAA) in patients co-infected with HIV and hepatitis C virus (HCV) have demonstrated comparable efficacy and tolerability to studies with HCV mono-infected individuals. However, many co-infected patients in clinical care have psychosocial issues (e.g. active drug or alcohol use) excluded or not well represented in clinical trials. This study assesses DAA effectiveness in HIV/HCV co-infected patients.

Method: Data were extracted from the electronic medical records of 450 HIV/HCV co-infected patients who initiated DAAs between Jan 2014 and Mar 2017 and were in care at 5 US-based HIV treatment centers. The primary outcome was sustained virologic HCV response at ≥12 weeks (SVR12) from the end of DAA therapy.

Results: 6 regimens accounted for 96% (430/450) of treatment: 68% (304/450) ledipasvir-sofosbuvir (LDV-SOF) +/– ribavirin (RBV), 9% (39/450) SOF + RBV, 8% (34/450) simeprevir (SMV) + SOF +/– RBV, 4% (18/450) elbasvir-grazoprevir (EBR-GZR) +/– RBV, 4% (18/450) ombitasvir-paritaprevir-ritonavir and dasabuvir (PrOD) +/– RBV, and 4% (17/450) daclatasvir (DCV) + SOF +/– RBV. Outcomes in the intent to treat (ITT) population were 90% (404/450) achieved SVR12,

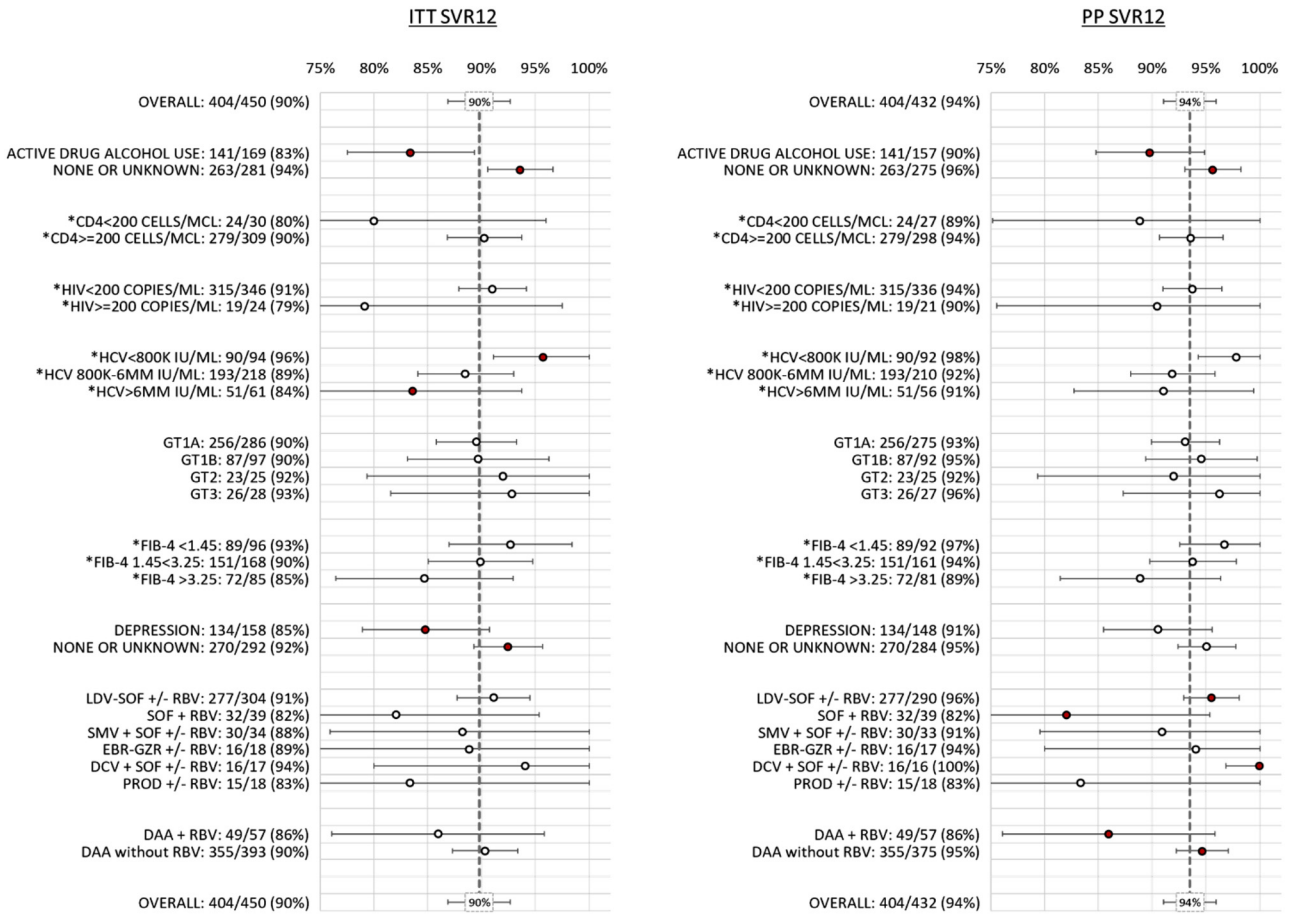

Figure: (abstract: THU-282): Univariate analyses of variable association with ITT SVR12 (left) or PP SVR12 (right). Filled circles indicate subgroups that are significantly different for rates ($p<=0.05$) based on chi-square or z-tests for population proportions. * indicates measures at baseline relative to DAA treatment. @ denotes that PP SVR12 rates were significantly different between SOF + RBV and LDV-SOF +/– RBV or DCV + SOF +/– RBV but not between LDV-SOF +/– RBV and DCV + SOF +/– RBV.

6% (28/450) completed therapy but did not achieve SVR12, 2% (8/450) completed but were lost to follow up, 1% (4/450) discontinued, and 1% (6/450) died. The per protocol (PP) SVR12 rate, limited to patients who completed therapy and an SVR assessment, was 94% (404/432). By regimen, SVR12 rates were highest for LDV-SOF +/– RBV (ITT 91%, 277/304; PP 96%, 277/290) and DCV + SOF +/– RBV (ITT 94%, 16/17; PP 100%, 16/16) and lowest for SOF + RBV (ITT 82%, 32/39; PP 82%, 32/39) and PrOD +/– RBV (ITT 83%, 15/18; PP 83%, 15/18). Characteristics significantly associated with failure to achieve HCV SVR12 were active drug or alcohol use, HCV > 6MM IU/ml, depression, use of SOF + RBV, and use of DAA containing RBV (Figure).

Conclusion: In this analysis of co-infected patients in US clinical care, effectiveness of anti-HCV regimens was 90% (ITT SVR12) with 6% having virologic failure. Discontinuation and lost to follow up rates were low compared to HCV mono-infection in TRIO real-life studies. Variables significantly associated with failure to achieve SVR primarily include those likely to predict poor medication adherence and follow-up, highlighting a need for improved patient engagement in conjunction with highly effective DAAs.

THU-283

HCV-FiS (HEpatitis C Virus Finger-stick Study): HCV RNA point-of-care testing by GeneXpert in the setting of DAA therapy

V. Calvaruso[1], F. Bronte[1], D. Ferraro[2], M.G. Bavetta[1], S. Petta[1], V.D. Marco[1], A. Craxi[1]. [1]*University of Palermo, Gastroenterology and Hepatology Unit, DIBIMIS, Palermo;* [2]*University of Palermo, Virologia Dip.PRO.SA.M.I., Palermo*
Email: vincenza.calvaruso@unipa.it

Background and Aims: DAA regimens have simplified HCV patient care and provide the opportunity to cure patients of the disease, but HCV RNA assessment at baseline, during and after therapy still relies on assays requiring blood collection and transport to a specialized laboratory, all of which compromise linkage to care. GeneXpert HCV Viral Load (GXHVL, Cepheid, Sunnyvale, CA, USA) is a plasma-based assay and results are available within 2 hours of sampling. In HCV-FiS we evaluated the performance of GXHVL with a modified protocol for point-of-care testing using finger-stick capillary whole-blood samples in the setting of a hospital-based outpatient clinic caring for HCV patients (1).

Methods: 59 consecutive chronic HCV patients (F3 24:40.7%; F4 35:59.3%) were enrolled in HCV-FiS. HCV genotype was 1a in 7 patients, 1b in 41, 2 in 8, 3 in 1, and 4 in 2. Capillary blood collected by finger-stick was processed on site by a trained nurse on the GeneXpert platform. HCV viral load (VL) was tested on a simultaneous venous blood sample by the Hospital's Virology Lab using a standardized Real Time (RT) PCR (Roche TaqMan). DAA regimens were prescribed according to the current EASL recommendations. The performance of the GXHVL and of the TaqMan assay were compared at baseline (BL), at week 4 (W4) and at end of therapy (EOT) and at week 12 of follow up to evaluate the sustained virological response (SVR12).

Results: 57 patients (mean age 65.8 ± 12.1 years; 54% males) were tested with both assays, while 2 were excluded due to mishandling of the GXHVL specimen at BL. At BL 56/57 (98.2%) patients were HCV RNA positive. In one patient HCV RNA was undetectable by both methods but had tested positive by TaqMan two months earlier.

Linear regression analysis confirmed the high concordance in HCV RNA quantification between GXHVL test and the RT-PCR HCV VL assay (R = 0.809; R2: 0.654 p < 0.001) at BL (median VL:778,400 vs 123,0000 IU/ml respectively). At W4, 39/56 (69.6%) and 42/56 (75%) patients had undetectable HCV-RNA by GXHVL and RT-PCR test, respectively. Six patients had undetectable HCV RNA by RT-PCR but levels <10 IU/ml by GXHVL test; 5 patients had undetectable HCV RNA by GXHVL but <15 IU/ml by RT-PCR. Both assays demonstrated undetectable HCV-RNA in all 56 patients (100%) at EOT. At SVR12 both assays identified the single case of HCV relapse in the cohort (HCV-RNA: 248,600 vs 822,000 IU/ml by GXHVL and RT-PCR respectively) with a concordance rate, a sensitivity and specificity of 100%.

Conclusion: GeneXpert as a point-of-care assay used in the outpatient setting, provides results fully comparable to the laboratory-based test. Its excellent performance characteristics and ease of use suggest its adoption in non-specialist settings where simplicity of care is paramount to implement HCV eradication campaigns.

Therapy with DAAs in patients with chronic hepatitis C and advanced chronic kidney disease: Real-world experience from the German Hepatitis C-Registry (DHC-R)

J. Wiegand[1], P. Buggisch[2], S. Mauss[3], K. Boeker[4], H. Klinker[5], T. Müller[6], R. Guenther[7], Y. Serfert[8], M.P. Manns[9], S. Zeuzem[10], T. Berg[1], H. Hinrichsen[11], D.H. C-Register[8]. *[1]University Hospital Leipzig, Leipzig, Germany; [2]IFI-Institute for Interdisciplinary Medicine, Hamburg, Germany; [3]Center for HIV and Hepatogastroenterology, Düsseldorf, Germany; [4]Center of Hepatology, Hannover, Germany; [5]University Hospital Würzburg, Würzburg, Germany; [6]Charité Campus Virchow-Klinikum (CVK), Berlin, Germany; [7]Universitätsklinikum Schleswig-Holstein (UKSH), Campus Kiel, Kiel, Germany; [8]Leberstiftungs-GmbH Deutschland, Hannover, Germany; [9]Dept. of Gastroenterology, Hepatology and Endocrinology, Hannover Medical School, Hannover, Germany; [10]University of Frankfurt, Department of Medicine, Frankfurt, Germany; [11]Gastroenterology-Hepatology Center Kiel, Kiel, Germany*
Email: johannes.wiegand@medizin.uni-leipzig.de

Background and Aims: Real-world experience with direct antiviral agents (DAA) in patients with chronic hepatitis C virus (HCV) infection and a glomerular filtration rate (GFR) < 30 ml/min is limited to case series so far. The German Hepatitis C-Registry (DHC-R) is a prospective, multicenter real-world registry study for patients with chronic hepatitis C. We investigated the safety and effectiveness of novel DAAs in patients with impaired kidney function.

Method: The DHC-R comprises approximately 11,000 patients recruited by more than 250 centres. Patients are treated at the discretion of the physician. The present analysis is based on 5,833 patients with treatment initiation between February 2014 and September 2015.

Results: Overall, antiviral therapy was associated with a GFR improvement in 330/4,527 (7.3%) individuals, a deterioration to GFR < 30 ml/min occurred in in 9/4483 (0.2%) patients (Table 1). Only 46/5,833 (0.8%) patients initiated antiviral therapy with a baseline GFR of <30 ml/min (87%/9%/4% HCV-genotype 1/3/4; 26% cirrhosis; 54% treatment-naïve, 43% interferon-experienced). They suffered significantly more frequently from hypertension, coronary heart disease and chronic heart failure than individuals with GFR > 30 ml/min. Treatment regimens were based on sofosbuvir (+ ribavirin n = 2, +simeprevir n = 3, +daclatasvir n = 5, +ledipasvir n = 18; each ± ribavirin) or paritaprevir/r, ombitasvir ± dasabuvir ± ribavirin (n = 18). Adverse events did not occur more often in patients with GFR < 30 vs. >30 ml/min (treatment without ribavirin: 58% vs. 50%; treatment with ribavirin 67% vs. 72%), however, serious adverse events were significantly more frequently in individuals with GFR < 30 ml/min (treatment without ribavirin: 13% vs. 3%, p = 0.02; treatment with ribavirin 33% vs. 5%, p < 0.001). Treatment discontinuation due to (serious) adverse events occurred more often in patients with GFR < 30 ml/min (6.5% vs. 1.1%; p = 0.02) and were associated with the use of ribavirin. Overall sustained virologic response rates (SVR12) did not differ significantly between cases with GFR < 30 vs. >30 ml/min (91% vs. 97%).

Table 1: Comparison of GFR (ml/min/1.73 m^2) between baseline and end of treatment

	End of treatment GFR				
Baseline GFR	**0-15**	**>15-30**	**>30-60**	**>60-90**	**>90**
0-15 (n=26)	92.6% (n=25)	0	0	0.1% (n=1)	0
>15-30 (n=18)	0	58.8% (n=10)	2.6% (n=7)	0.1% (n=1)	0
>30-60 (n=232)	0	29.4% (n=5)	56.8% (n=154)	3.8% (n=61)	0.5% (n=12)
>60-90 (n=1,396)	3.7% (n=1)	0	38.7% (n=105)	65.2% (n=1,042)	9.5% (n=248)
>90 (n=2,855)	3.7% (n=1)	11.8% (n=2)	1.8% (n=5)	30.9% (n=494)	90.0% (n=2,353)

Conclusion: Adherence to treatment guidelines were very high in this large real world cohort as only few patients started sofosbuvir-based therapy with a baseline GFR of <30 ml/min. However, safety and efficacy was good in selected patients with impaired kidney function but RBV was a main cause of treatment discontinuations. RBV-free treatment options like grazoprevir/elbasvir or glecaprevir/pibrentasvir will therefore be of major importance for these patients.

THU-285

Uniform addition of ribavirin to sofosbuvir/velpatasvir for genotype 3 patients with cirrhosis: real world outcomes

A. Boyle[1,2], F. Marra[1,2], E. Reilly[1], C. Fleming[1], M. Heydtmann[3], R. Fox[4], M. Priest[5], J. Morris[6], S. Barclay[7]. *[1]NHS Greater Glasgow and Clyde, Pharmacy Department, United Kingdom; [2]University of Liverpool, Department of Molecular and Clinical Pharmacology; [3]NHS Greater Glasgow and Clyde, Royal Alexandra Hospital, United Kingdom; [4]NHS Greater Glasgow and Clyde, Brownlee Centre for Infectious Diseases; [5]NHS Greater Glasgow and Clyde, Gartnavel General Hospital, United Kingdom; [6]NHS Greater Glasgow and Clyde, Queen Elizabeth University Hospital; [7]NHS Greater Glasgow and Clyde, Glasgow Royal Infirmary, United Kingdom*
Email: alisonboyle2@nhs.net

Background and Aims: In registration trials sofosbuvir/velpatasvir (SOF/VEL) for 12 weeks achieved an SVR rate of 93% in untreated patients with genotype 3 (GT3) HCV and cirrhosis. Treatment-experienced patients, and those with baseline NS5a resistance-associated substitutions, achieved suboptimal SVR rates of <90%. In patients with decompensated cirrhosis, the addition of ribavirin (RBV) to SOF/VEL led to an increased SVR rate. EASL recommends that, where baseline resistance is not performed, RBV be added to SOF/VEL for patients with compensated cirrhosis, however evidence of increased efficacy is lacking. In line with EASL guidance we elected to treat all GT3 cirrhotic patients with SOF/VEL/RBV with a view to maximising SVR. Child's Pugh (CP) A/B patients were treated with weight based RBV, CPC patients received 600 mg with escalation if tolerated. We report initial results.

Method: Patients with cirrhosis and GT3 infection commencing treatment with SOF/VEL/RBV prior to 01/10/2017, in Glasgow treatment centres were identified from the Scottish HCV database. Baseline data on age, gender, liver stiffness (LSM), CP score, end of treatment response (EOTR) and SVR were collected. Significant anaemia (Hb < 10 g/l) and RBV dose reductions were recorded from chart review.

Results: Eighty patients (62 male, mean age 49.3 (± 6.8) years, 2 HIV co-infected, 46 on Methadone) commenced treatment. Eighteen patients were decompensated (12 CPB, 6 CPC). Amongst the CPA patients, median liver stiffness was 21.5 kPa (IQR 14.2). Thirteen

patients (8 CPA, 4 CPB, 1 CPC) were treatment-experienced including 6 interferon/RBV/sofosbuvir failures. To date, 57 patients have completed treatment, 1 (CPC) prematurely due to nausea/vomiting, all achieving an EOTR. Eight (10%) patients developed significant anaemia and 18 (22.5%) required RBV dose reduction (12/62 (19.3%) CPA, 5/12 (41.7%) CPB, 1/6 (16.7%) CPC). Amongst CPA patients reaching SVR12 time point, SVR was achieved by 12/13 (92.3%) of treatment-naïve patients and 5/6 (83%) of treatment-experienced patients. To date, 6/6 (100%) of decompensated patients achieved SVR.

Conclusion: SOF/VEL/RBV was well tolerated in a real-world cohort of patients with compensated and decompensated cirrhosis. RBV frequently required dose reduction, particularly in CPB patients. Despite addition of RBV, early SVR results in compensated patients are not higher than those obtained without RBV in clinical trials. Full SVR12 data will be presented.

Direct Antiviral Agents are safe and efficacious in paediatric patients with chronic hepatitis C; Real world data from the public health perspective

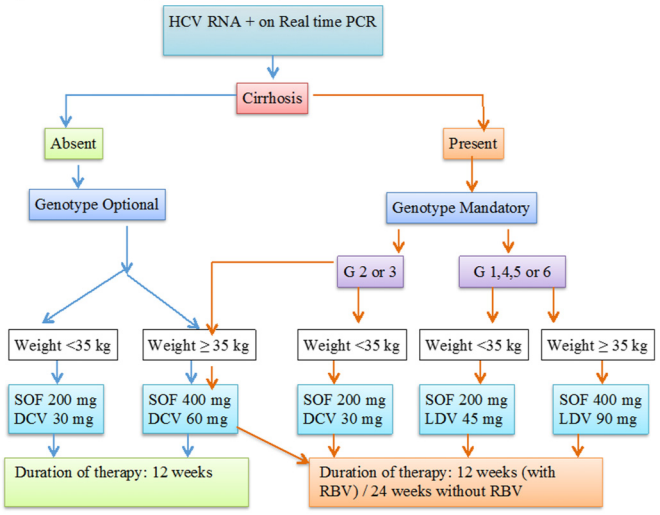
M. Premkumar[1], G. Grover[2], S. Rathi[1], S. Taneja[1], A. Duseja[3], R.K. Dhiman[1]. [1]*PGIMER, Hepatology, Chandigarh, India;* [2]*Program Officer, Hepatitis C Treatment Programme, Chandigarh, India;* [3]*PGIMER, Chandigarh, India*
Email: rkpsdhiman@hotmail.com

Background and Aims: The Mukh-Mantri Punjab Hepatitis C Relief Fund (MMPHCRF) is a public health initiative for prevention and control of hepatitis C (HCV) in Punjab, India. We assessed the efficacy of decentralized public health services and safety of 12 or 24 weeks of sofosbuvir (SOF) + ledipasvir (LDV) or SOF + daclatasvir (DCV) with or without ribavirin (RBV) in the treatment of pediatric HCV patients (aged 12 to <18 years).

Methods: Consecutive chronic HCV infected children [age: 12 to <18 years; both treatment-naïve (TN) and treatment-experienced, (TE)] were enrolled. As per the devised algorithm (see Figure), genotyping was not recommended for patients without cirrhosis of liver/ TN and were treated with SOF + DCV for 12-weeks, while genotyping was recommended for patients with cirrhosis of liver/TE. Patients with liver cirrhosis/TE and genotype (G)3 were treated with SOF + DCV for 24 weeks, while non-G3 patients were treated with SOF + LDV for 24-weeks. SVR-12 was mandatory in all patients.

Results: In the first 16 months (18 June 2016 to 31st October 2017) of the MMPHCRF program, 78 pediatric patients [74.3% male, mean age 15.8 ± 1.86 years, (range 12–17)] were enrolled. Fifty-six (72.3%) were from a rural background. The mean age was 15.8 years (range 12–17 years), mean weight 42 ± 3.8 kg, 74.3% were male, mean baseline HCV RNA $\log_{10}$ IU/ml was 6.0 (range, 4.2–7.5 $\log_{10}$ IU/ml), with 45.6% having HCV RNA >6.0×10^6 IU/ml, 65.5% with G3, 73 (93.5%) as TN, and 2 (2.5%) with cirrhosis. Of the 57 who have completed treatment, SVR-12 was achieved in 56 (96.9%), except one non-cirrhotic G3 patient with poor drug compliance. Unsafe medical practice 30 (48.5%), prior surgery-10 (15.5%), and IV drug abuse-5 (8%) were the main modes of transmission. Genotype was not done in 54 (69.2%) patients as they were non-cirrhotic, and received SOF/DCV therapy for 12 weeks with SVR-12 of 100%. The treated genotypes were G1, 9 (10.2%); G3, 22 (25%); G4, 2 (2.3%), and G5,1 (1.1%). Comparable results were noted in cirrhotic patients (SVR-12, 100%) versus non-cirrhotic (SVR-12, 97%; p = 0.672), and G3 (SVR-12, 94.3%) versus non-G3 (SVR-12, 100%; p = 0.073). No serious adverse effects like anemia, decompensation of liver disease, headache, diarrhea, and fatigue were reported. Transient nausea was noted in 4 (5.1%) patients, which resolved.

Figure 1: Treatment algorithm for pediatric patients in the MMPHCRF



Abbreviations: PCR,polymerase chain reaction; SOF, sofosbuvir; DCV, daclatasvir; LDV, ledipasvir; RBV, ribavirin
Cirrhosis treatment path:
Non cirrhotic treatment path:

Conclusion: This study has demonstrated that our decentralized algorithm based public health HCV elimination programme can ensure high efficacy (SVR 12, 96.9%), safe, and low-cost generic direct acting antiviral based treatment of pediatric HCV.

THU-287

Treatment of chronic hepatitis C with direct acting antivirals and its effect on body mass index and hepatic steatosis as measured by controlled attenuation parameter

H. Shousha[1], R. Abdelaziz[1], S. Musa[1], M. Khairy[1], S. Afifi[2], M. Mehrez[2], A. Yosry[1]. [1]*Faculty of Medicine, Cairo University, Endemic Medicine Department, Cairo, Egypt;* [2]*NHTMRI, Endemic Medicine Department, Cairo*
Email: hendshousha@yahoo.com

Background and Aims: Direct Acting Agents (DAAs) have high cure rate but still lack the knowledge of their effect on hepatic steatosis in chronic hepatitis C (CHC). Controlled Attenuation Parameter (CAP), evaluated with transient elastography, could help in assessment of steatosis grades. Aim: to evaluate the effect of DAAs on body mass index and steatosis in CHC using CAP.

Method: This cohort study included 155 CHC patients, divided into 3 groups according to the DAAs regimen. All patients were subjected to pre-treatment and 3-months post-treatment BMI, laboratory workup and liver stiffness measurement and CAP using the FibroScan® M probe. Cut off values for steatosis: S0: <238 dB/m = Grade 0, S1: 238–258 dB/m and S2: 259–291 dB/m = Grade 1 (mild-moderate steatosis) and S3: ≥292 dB/m = Grade 2 (severe steatosis). Changes in steatosis grades were defined as improvement or worsening (one grade or more change).

Results: Patients mean age was 45.78 ± 11.6 years, mean BMI 26.63 ± 2.75 and 18.1% were cirrhotic. Baseline assessment revealed no steatosis in 43.9%, 32.9% had mild-moderate steatosis and 23.2% had severe steatosis. The overall sustained virological response 12 was 93.6%. Follow up revealed stationary steatosis in 56.7% and regression in 21.3%. Mean pre-treatment CAP were significantly lower in responders 244.9 ± 62.4 dB/m vs non-responders; 300 ± 28.4 dB/m (p = 0.04). ROC curve delineated 273 dB/m as best cut-off for detection of responders with an AUC of 0.801, sensitivity 68.2%, and specificity 100%. BMI significantly increased after treatment (p = 0.004) particularly in patients with worsened steatosis (p = 0.001). On the other hand, a decrease in BMI was found in 55% of patients

Table: (abstract: THU-287)

N (%)	Total (Number (N) = 155)		Group 1 (n = 82) Sofosbuvir + daclatasvir ± ribavirin		Group 2 (n = 42) Sof + simeprevir		Group 3 (n = 31) sof + RBV + weekly Peg IFN	
Improved	33 (21.3%)		20 (24.4%)		6 (14.3%)		7 (22.6%)	
Stationary	88 (56.7%)		42 (51.2%)		27 (64.3%)		19 (61.3%)	
Worsened	34 (22%)		20 (24.4%0		9 (21.4%)		5 (16.1%)

	246.39 ± 62.34	248.03 ± 53.78	246.99 ± 55.22	249.98 ± 54.39	248.64 ± 67.51	249.52 ± 54.13	241.74 ± 73.9	240.84 ± 52.78
P value	0.726		0.533		0.846		0.651	

Steatosis							
Total (N = 155)	Improved (N = 33)		Stationary (N = 88)		Worsened (N = 34)		P value
	N	%	N	%	N	%	<0.001
BMI Decreased (N = 59)	18	55.0%	37	42%	4	12.2%	
Stationary (N = 3)	0	0%	2	2.4%	1	2.4%	
Increased (N = 93)	15	45.0%	49	55.6%	29	85.4%	

with improved steatosis grade. Steatosis significantly correlated with BMI (r = 0.3, p < 0.001).

Conclusion: DAAs cause a significant change in steatosis grade in a subset of treated patients. Pretreatment CAP was significantly lower in responders. BMI significantly increases following treatment particularly in patients with worsened steatosis.

THU-288

Factors associated with nonresponse in a cohort of 10655 chronic hepatitis C patients treated with direct acting antivirals

H. Shousha[1], M. Said[1], D. Saleh[1], Y. Saad[1], H. Dabees[2], M. El-Serafy[1], K. Elsaees[3], Y. Elshazly[3]. *[1]Faculty of Medicine, Cairo University, Endemic Medicine Department, Cairo, Egypt; [2]National Medical Institute of Damanhour, Hepatology; Egypte, [3]Ain Shams University, Internal Medicine Department, Egypte*
Email: hendshousha@yahoo.com

Background and Aims: Hepatitis C virus (HCV) is a worldwide aetiology of chronic hepatitis and cirrhosis particularly in Egypt where genotype 4 is responsible for >90% of cases, and the remaining is due to genotype-1. The introduction of interferon-free direct acting antivirals has resulted in very high sustained virological response rates. On the other hand, there are still a minority who fails to achieve SVR.

Aim: to study the factors associated with nonresponse and relapse using routine pretreatment workup.

Method: A retrospective study included 10,655 Egyptian chronic HCV patients who were candidates for anti-viral therapy according to the international and the National Committee for Control of Viral Hepatitis (NCCVH) guidelines. Pretreatment demographics, routine laboratory data, ultrasonography, FIB-4, Pretreatment, 16 and 24 weeks quantitative HCV PCR were collected.

Results: At week 16, 10,495 patients (98.5%) had negative HCV PCR and 160 (1.5%) were non responders. 50.6% of non-responders were males vs 39.7% responders, p 0.005, 61.3% were cirrhotic. They had significantly higher baseline BMI (Mean ± SD): 30.6 ± 5.6 vs 28.8 ± 5.5, p 0.005), higher liver enzymes (ALT: 63.6 ± 38.9 vs 54.6 ± 36.6, p < 0.01 and AST: 72.0 ± 42.3 vs. 57.5 ± 38.2), higher AFP: 18.4 ± 23.6 vs 10.2 ± 27.1. Significantly lower albumin level, platelet count: 141.3 ± 57.3 vs. 177.4 ± 77.7) $\times 10^3/mm^3$, p < 0.001 and FIB-4: 4.1 ± 3.2 vs 4.8 ± 25.9 p < 0.001. AST, AFP > 10, albumin, platelet count, hemoglobin, FIB-4 and having an abnormal liver echopattern on ultrasonography were the independent factors associated with nonresponse by multivariate regression model.

At week 24, HCV PCR results were available only for 7259 patients and 7049 (97.1%) were responders and 210 (2.9%) were relapsers. 54.8% were cirrhotic and 51.4% were males vs 38.8% responders, p < 0.001, significantly higher AST: 66.1 ± 40.6) vs. 58.5 ± 39.5, higher AFP: 14.3 ± 20.4 vs 9.5 ± 25.2. Significantly lower albumin level, prolonged INR, platelet count: 152 ± 62.3 vs. 175.9 ± 76.2) x103/mm3, p < 0.001 and FIB-4: 3.6 ± 2.7 vs 4.6 ± 21.7 p < 0.001. An abnormal liver echopattern on ultrasound, AST, AFP > 10, platelet count and FIB-4 were the independent factors associated with relapse.

Regression model at week 16	95% C.I.			
	P value.	Odds ratio	Lower	Upper
AST	0.014	0.981	0.967	0.996
AFP (>10 vs ≤10)	0.001	0.362	0.197	0.664
Albumin	0.044	1.854	1.017	3.380
Hb	0.045	0.861	0.744	0.997
platelets	<0.001	1.021	1.010	1.031
Fib4	0.002	1.561	0.687	2.408
Liver (abnormal echopattern)	0.021	3.016	0.934	1.021
Regression model at week 24	Sig.	OR	95% CI: Lower	95% CI: Upper
Liver abnormal echo pattern	0.005	3.622	1.467	8.942
AST	0.011	0.980	0.965	0.995
AFP (>10 vs ≤10)	0.003	0.399	0.219	0.728
platelets	0.000	1.021	1.010	1.031
Fib4	0.004	1.546	1.151	2.075

Conclusion: Routine pre-treatment workup can help in prediction of the minority of non-SVR patients.

THU-289

Incidence and outcome of portal vein thrombosis in HCV cirrhotic patients treated with direct-acting antivirals: a single-center prospective 3-year study

E. Degasperi[1], G. Tosetti[1], R. D'ambrosio[1], A. Aghemo[2], M. Borghi[1], R. Soffredini[1], M. Primignani[1], P. Lampertico[1]. *[1]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Università degli Studi di Milano, CRC A.M. and A. Migliavacca for Liver Disease, Division of Gastroenterology and Hepatology, Milan, Italy; [2]Humanitas University, Department of Biomedical Sciences, Rozzano, Italy*
Email: pietro.lampertico@unimi.it

Background and Aims: Treatment of hepatitis C virus (HCV) with direct-acting antivirals (DAAs) is associated with improved outcomes in cirrhotic patients, however the risk of portal vein thrombosis (PVT) is still undefined. We evaluated incidence and predictors of PVT in HCV cirrhotics treated with DAAs.

Method: HCV Child (CPT) A-B cirrhotic patients consecutively treated with DAAs between November 2014 and December 2016 at a single center and without PVT were enrolled. Patients underwent blood tests, 6-month abdominal imaging and regular esophageal varices (EV) screening. PVT was graded according to Yerdel classification.
Results: 557 HCV cirrhotics were enrolled: age was 64 (28–87) years, 60% males, 49% HCV genotype 1b, 83% CPT score A, platelet count (PLT) was 118 (26–753) × 10^3/mL, spleen size 13 (7–24) cm, LSM 17.0 (12.1–75.0) kPa, 32% patients had baseline EV. 465 (96%) achieved a sustained virologic response. During 22 (1–36) months of follow-up, 9 (1.6%) patients developed PVT, with a 3-year cumulative probability of 2%, 7 (78%) PVT occurring during the first 12 months from DAA start. PVT patients were CPT B (56%), all had EV at baseline (small varices CRS- in 2, primary prophylaxis in 4, secondary in 3). PVT were Yerdel grade 1 in 4 patients, grade 2 in 3, grade 3 and 4 in 1 patient. No PVT was related to tumor vascular invasion. PVT was associated with de novo or worsening of ascites in 4 (44%) patients, while it was asymptomatic and detected on routine imaging in the remaining 5 (56%). At PVT diagnosis, EV worsened compared to baseline in 3 (33%) patients but no GI bleeding occurred. Thrombophilic conditions were detected in 3/7 (43%) patients with available screening: hyperhomocysteinemia in 2 and G20210A prothrombin gene mutation in one patient. The most important baseline predictors of PVT reflected the degree of disease severity (CPT score, MELD score, bilirubin, albumin) and portal hypertension (EV and PLT count). The 3-year cumulative probability of PVT was 5.2% vs 0% in patients with or without baseline EV, respectively (p = 0.002). PVT was treated by anticoagulation in 8 (LMWH in 5 and oral anticoagulation in 3) patients, leading to partial or complete PVT recanalization in 6 (5 and 1, respectively) patients after 4 (3–7) months from anticoagulation start.
Conclusion: Among HCV cirrhotics treated with DAA, non neoplastic PVT is a rare complication that however may cause clinical decompensation.

THU-290

Diagnosis and treatment of hepatitis C virus in a Spanish jail

J.J. Urquijo, C. Albert-Antequera, M. Latorre, G.A. Castillo, P. Marqués, C. Alventosa, M. Diago. *Hospital General Universitario Valencia, Hepatology, Valencia, Spain*
Email: juanjo.urquijo@gmail.com

Background and Aims: HCV infection in prisoners is considered a special care group in the National Hepatitis C Plan in Spain with high risk of transmission.
Our aim is to assess the efficacy and safety of new DAA in VHC patients of the Picassent'S Penitentiary Center (PPC) –2,200 inmates- whose referral hospital is the University General Hospital of Valencia (CHGUV).
Method: All incoming inmates are screened for anti-HCV antibody and those with HCV viremia are remitted to CHGUV to undergo a full diagnostic study, including transient elastography (Fibroscan®), before being treated according to current guidelines.
197 patients have been treated with DAA, 182(92.4%) were males, the median age was 46 years (23–68). 77 (39%) had a history of drug addiction, 77(39%) were HIV co-infected. 32 (16.2%) had received prior treatment. According to degree of fibrosis, 51 were F0-F1 (25.9%), 60 F2 (30.5%), 42 F3 (21.3%) and 44 F4 (22.3%). The most common HCV genotypes (G) were G1a (89 patients, 45.2%), followed by G3 (43 patients, 21.8%), G4 (36 patients, 18.3%), G1b (20 patients, 10.2%), G1 (5 patients, 2.5%), G2 (1 patient, 0.5%) and 3 coinfections (1.5%): 1 + 3, 1a + 4 and 1b + 4.
The prescription and follow-up until viral response has been done by hepatologists and infectologists, and the clinical evolution by a physician of the CPP with controlled administration of the pills. Patients have been treated with different combinations of DAA according to current guidelines, taking into account comorbidities, interactions, and avoiding the use of RBV: 126 patients with SOF + LDV (63.95%, 2 to 24w, 94 to 12w, 21 to 8w); 34 with SOF + DAC (17.2%), 10 with SOF + VEL (5.1%); 9 with EBV + GZV (4.6%); 8 with SOF + SMV (4%); 10 with 3D or 2D regime (5%).
Results: 135 of 197 (68.5%) treated patients have reached 12w after treatment, showing an overall SVR of 97.8% (132 patients), and 3 relapses (2.2%), 1 to 12w SOF + DAC and 2 to 12w SOF + LDV, one of them retreated with 24w SOF + EBV + GZV + RBV.
There hasn't been any serious adverse drug event nor death, although a chronic myeloid leukemia and a laryngeal neoplasm were diagnosed, both with SVR. Follow-up was more difficult due to frequent transfers of inmates from one prison to another and prisoners released during treatment and lost in follow-up.
Conclusion: Most of our inmates were men, naïve to treatment and infected with 1a, 3 and 4 genotypes. The most used treatment has been SOF + LDV. DAA show a high efficacy (97.8%) and good security profile, similar to general population.

THU-291

Sofosbuvir + Glecaprevir/Pibrentasvir in patients with difficult to treat HCV infection. Final results of the French compassionate use

V.D. Ledinghen[1], V. Anne[2], U.-B. Jose[3], P. Lucia[4], H. Jean-Baptiste[1], S. Giovanna[2], M. Wassil[1], G.-P. Pageaux[5], F. Helene[4], L. Alric[6], C. Hezode[2]. *[1]CHU Bordeaux, Hepatology Unit, Bordeaux, France; [2]APHP Henri Mondor, Hepatology Unit; [3]CHU Montpellier, Hepatology Unit, Montpellier, France; [4]APHP Cochin, Hepatology Unit, France, [5]CHU Montpellier, Montpellier, France; [6]CHU Toulouse, Internal Medicine Unit, Toulouse*
Email: victor.deledinghen@chu-bordeaux.fr

Background and Aims: Glecaprevir/Pibrentasvir (G/P) has been poorly evaluated in difficult to treat patients including DAA failure patients. Moreover, the efficacy and tolerance, and the usefulness of adding Sofosbuvir (SOF) to G/P are unknown in these patients. The aim of this open-label study was to evaluate safety and efficacy of G/P ± SOF in HCV difficult to treat, including DAA failure, patients.
Method: A total of 60 patients (47 males; mean age 60 years) were treated with SOF + G/P (n = 26) or G/P alone (n = 34) for 12 or 16 weeks. Patients were chronically infected with HCV genotype 1 (n = 26), 2 (n = 9), 3 (n = 15), 4 (n = 9) and had advanced fibrosis or compensated cirrhosis (FibroScan > 9.5 kPa) in 39% of cases. Among the 60 patients, 5 had liver transplant recipient, 13 had end stage renal disease (ESRD), and 43 patients were DAA experienced. Previous treatment was SOF/LDV (n = 17), SOF/DCV (n = 16), 3D (n = 4), GZR/EBR (n = 2), SOF/VEL (n = 2), and SOF/DCV/SMV (n = 2). Baseline resistance testing was performed in 56 patients and NS5A, NS3, and NS5B RASs were present in 35, 5, and 3 patients, respectively.
Results: Among 21 patients with available result at SVR4, SVR4 was observed in 19/21 (90.5%). SVR12 will be available for all patients in April 2018. Two SVR4 failures were observed in two DAA experienced patients with cirrhosis treated without SOFG/P without SOF. To date, no serious adverse events (SAE) occurred. No study treatment was discontinued due to SAEs.
Conclusion: We show that G/P is a good option for difficult to treat patients, especially DAA failure patients. The role of adjunction of SOF to G/P will be evaluated in this largest cohort ever published of 26 patients.

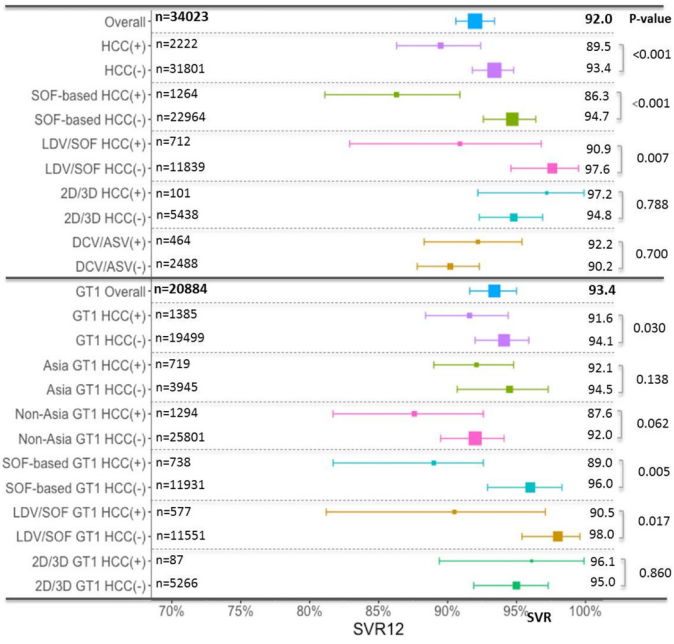
Email: mindiehn@stanford.edu

Background and Aims: Outcome data concerning DAA therapy for chronic HCV infection in HCC patients are currently limited in individual studies. Our goal was to perform a systematic review and meta-analysis to evaluate the effect of HCC on SVR 12 or 24 weeks after the end of DAA treatment.

Method: PubMed, EMBASE, Web of Science and Cochrane databases up to August 31, 2017 were searched for studies that included HCC ($n \geq 10$) and with or without non-HCC HCV mono-infected patients treated with any DAA with available SVR. All data searches and extractions were independently performed by 2 reviewers with discrepancies resolved by consensus with a third reviewer. Random-effects model was used to estimate pooled SVR. Meta-regression was performed to determine how HCC affects SVR.

Results: A total of 34 studies with 2,222 HCC and 31,801 non-HCC treated patients were included. The overall SVR12 rate in HCC patients was lower than in those without HCC (89.5 vs. 93.4%, p = 0.0004) (Fig. 1, top panel). On meta-regression analysis, HCC patients had 5.07% (95%CI 0–8.01) reduction in SVR rate compared to non-HCC patients overall. However, patients at the time of treatment with active HCC (viable tumor on imaging) (n = 217) had a 20.6% (95%CI 8.33–35.4) reduction in SVR rate compared to patients with inactive HCC (absence of residual tumor/complete necrosis) (n = 940) (71.5 vs 93.8%, p < 0.0001). HCC patients treated with sofosbuvir (SOF)-based regimens overall (I^2=76.8%, p < 0.01) or ledipasvir (LDV)/SOF (I^2=82.7%, p < 0.01) had lower SVR12 than those without HCC (I^2=95.6% and I^2 = 95.8%, both p < 0.01); however, heterogeneity was high. Heterogeneity for subanalysis of patients treated with daclatasvir/asunaprevir (DCV/ASV) (all from Japan) was lower and showed similar SVR12 between HCC (I^2 = 34.6%, p = 0.14) and non-HCC patients (I^2 = 66.4%, p < 0.01). SVR12 was similar in HCC and non-HCC patients treated with the 2D/3D ± RBV (all from non-Asia centers) though there were only 101 HCC patients in this analysis. For GT1 patients (Fig. 1, bottom panel), there was no statistically significant differences in SVR12 between HCC and non-HCC patients within Asia or within US/Europe/Australia.



SVR: Sustained virological response; HCC: Hepatocellular carcinoma; DAA, direct-acting antiviral; SOF, Sofosbuvir; LDV, Ledipasvir; 2D/3D, paritaprevir/ritonavir, ombitasvir ± dasabuvir DCV, Daclatasvir; ASV, Asunaprevir; GT1, genotype 1.

Conclusion: Overall, SVR was lower in HCC compared to non-HCC patients especially in those with active HCC. HCC treatment should be considered prior to DAA therapy. Additional large cohort studies or individual participant data meta-analysis are also needed to identify predictors for treatment failure in DAA-treated HCC patients.
The SVR12 rate of all HCC and non-HCC patients by DAA regimens (top panel) and for genotype 1 patients by study location and DAA regimens (bottom panel).

THU-293

Management of patients with chronic kidney disease in the setting of interferon-free treatment for chronic HCV hepatitis

E.L. Iliescu, S. Ioanitescu, L. Toma, M.B. Ureche, A. Mercan-Stanciu, C. Iancu, M. Dodot. *Fundeni Clinical Institute, Internal Medicine, Bucharest, Romania*
Email: laura_ate@yahoo.com

Background and Aims: Renal disease, manifest either by decreased clearance or proteinuria can appear in a variety of situations associated with chronic HCV hepatitis. Frequent situations are: chronic kidney disease, renal transplant recipients or patients under hemodialysis with HCV infection, or proteinuria due to autoimmune conditions associated with HCV. This study aims to describe the types and management of renal disease in patients undergoing treatment with ombistavir/ paritaprevir/ ritonavir (OMB/PTV/r), dasabuvir (DSV) with or without ribavirin (RBV).

Method: We included 368 patients (57% females; mean age 57 +/−21.5 years) with F2 to F4 liver fibrosis (evaluated by liver biopsy or Fibromax®) undergoing treatment with OMB/PTV/r + DSV +/− RBV during December 2015 – October 2017. Evaluations were performed at the initiation of the treatment, monthly during treatment, at the end of treatment and 12 weeks after treatment and consisted of serum urea, creatinine, uric acid, C3 and C4 fractions of the complement, rheumatoid factor, erythrocyte sedimentation rate, C reactive protein, serum cryoglobulins, proteinuria measured in 24 hours.
Results: In our study, there were 49 patients with renal lesions as previously described. According to the type of injury, 28 patients had proteinuria caused by cryoglobulinemia (23 of them with nephrotic syndrome), 6 patients had undergone renal transplantation- 2 of them had graft reject and were undergoing hemodialysis. 2 patients had stage V chronic kidney disease due to type 1 diabetes. 10 patients had stage 2 to stage 4 chronic kidney disease due to diabetes and hypertension and one patient had class 4 lupus nephritis with severe proteinuria. During antiviral treatment none of the patients experienced worsening of kidney function. However, anemia due to ribavirin was more pronounced and required discontinuation of ribavirin and administration of erythropoietin. Immunosuppressive therapies in patients with autoimmune disorders had to be discontinued because of interactions with the direct antiviral. Despite this, lower levels of proteinuria have been observed even after one month of therapy, especially in patients who had previously answered mildly to immunosuppression (p = 0.03). Serum markers of inflammation also decreased significantly (p = 0.002) In patients with renal transplant, treatment with tacrolimus had to be reduced to 5 mg/week and closely monitored. Hemodialysis was programmed before treatment hours, to minimize elimination. Notably, all patients achieved sustained virologic response.
Conclusion: All oral antiviral treatment with OMB/PTV/r + DSV +/− RBV is safe in patients with renal disease. Caution must be taken in regard to potentially severe anemia. Antivirals have proven to be more effective in decreasing proteinuria in autoimmune disorders than immunosuppressive therapy.

Email: djayawee@med.miami.edu

Background and Aims: Per AASLD-IDSA guidelines, treatment of hepatitis C should be prioritized in patients co-infected with HIV and hepatitis C virus (HCV). This recommendation is based on a higher rate of HCV disease progression in this population, along with reported treatment responses comparable to HCV mono-infected patients. However, in clinical practice many patients with HIV/HCV co-infection do not receive HCV treatment. In this study, we characterize HIV/HCV co-infected populations who were not treated for HCV.
Method: Data were extracted from the electronic medical records of 1303 HIV/HCV co-infected patients who were in care between Jan 2014 and Sep 2017 at 5 large US-based HIV treatment centers. Co-infection was confirmed by antibody-based test or RNA detection for HIV and detection of HCV RNA (HCV viremia). The primary outcome was initiation of DAA treatment. However, in a subgroup analysis we evaluated all participants who were not prescribed DAA or did not start their regimen over a minimum of 90 days follow up from the last HCV measure. Bivariate analysis was performed to assess demographic and clinical factors associated with DAA prescription and initiation. Baseline measures were relative to DAA treatment or to the last detected HCV viral measurement.
Results: Of 1,303 co-infected patients with detectable HCV, 648 (50%) were not prescribed DAA. Of the 655 (50%) patients who were prescribed DAA, 86 (13%) did not initiate treatment. Baseline characteristics of these groups are provided in the Table. Measures appropriate for DAA selection, such as Fibrosis staging and HCV genotype, were sparsely recorded in patients who were not prescribed or prescribed but did not start therapy. Variables significantly associated with not being prescribed DAA include younger age, non-Hispanic, active drug or alcohol drug use, lower baseline ALT, lower baseline CD4 counts, and baseline HIV > 200 copies/ml. Variables associated with non-starts after prescription include younger age, white, lower baseline HCV viral load, lower baseline ALT and AST, and patients with FIB-4 < 3.25.

Figure: Patient Disposition.

Conclusion: In this large US database, 56% of co-infected patients remain untreated for HCV and those with uncontrolled HIV (high HIV RNA and/or low CD4 cell count) or active alcohol or drug use were less likely to be prescribed HCV therapy. In contrast to prior TRIO studies, payer type was not associated with non-start of therapy.

Changing landscape of HCV treatment in Germany: Data from a large real-world cohort 2014–2017

J. Petersen, K. Olah, T. Lorenzen, U. Stefan, C. Harder, K. Wursthorn, A. Plettenberg, B. Andre, M. Kathrin, A. Stoehr, P. Buggisch. *IFI Institute Hamburg, Liver Center, Hamburg, Germany*
Email: petersen@ifi-medizin.de

Background and Aims: DAA therapies have yielded SVR12 rates of more than 90% in randomized clinical trials and in real-world cohorts. Understanding factors and trends in changes of patient populations and treatment failures may help in guidance of therapies towards elimination of HCV in a certain geographical region like Germany where access of drugs is not limited. We have recently reported small failure rates, equally distributed to viral and non-viral factors (Petersen et al., EASL 2017). Here we report about changes in baseline demographics over time in a large number of patients from a high volume treatment center of ID physicians and hepatologists selecting patients conjointly for HCV treatment. We assessed the characteristics of patients over time who cured HCV and who failed available DAA therapies since licensing of these all oral drugs in Germany in mid 2014.
Method: Data were collected retrospectively from patients from a single treatment center using a centralized electronic data base. All HCV patients with available data that started DAA treatment after May 2014 and finished treatment (fu12) until November 10, 2017 were included in this analysis (n = 1488).
Results: Overall, treatment initiation rate was highest in 2015 and continued to decrease until the last quarter of 2017. There was a trend towards a shift in the most common genotype, from 1b towards 1a.

Moreover, there was a significant change towards patients with low fibrosis grading starting HCV treatment, qualifying for simplified treatment or for shorter treatment duration, adding to an overall trend for less virological failures. Contrary, patients with more complicated PWID or OST history were started on DAA treatment, leading to a higher number of cases with lower adherence and more non-virological failures over time. Overall, SVR rate of this very heterogeneous patient population remained very high at 92%. Of the patients that did not achieve SVR, 4.5% lacked adherence, discontinued treatment, or were lost to follow-up. 3.5% were virologic failures, mostly relapsers, viral breakthrough only n = 3. SVR rates of retreatment of DAA virological failure patients with triple-therapy will be reported at the meeting.

Conclusion: With the reported changes in baseline demographics, patient selection and education seems to be of more importance to reduce non-virological failures compared to the development of further optimized treatment regimen. Furthermore, without more appropriate screening methods it seems unlikely to move forward towards elimination of HCV within a certain time frame, even when HCV drug access does not play a role.

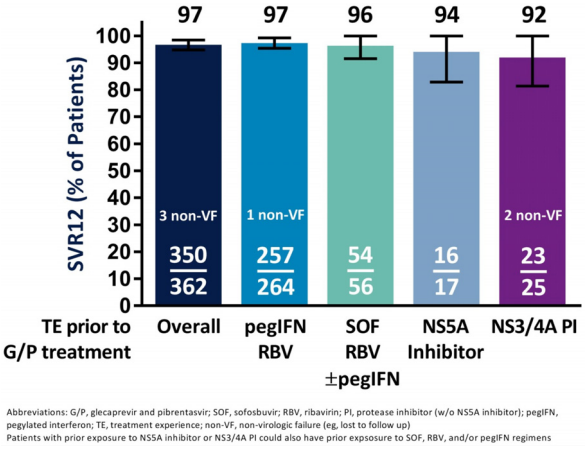
Email: poordad@txliver.com

Background and Aims: Patients with hepatitis C virus (HCV) infection who failed prior HCV therapy generally have decreased response to subsequent therapy. Glecaprevir/pibrentasvir (G/P; glecaprevir identified by AbbVie and Enanta) has demonstrated high rates of sustained virologic response at posttreatment week 12 (SVR12) across all six major HCV genotypes, including patients with prior treatment experience.

Method: This integrated analysis included efficacy and safety data from nine phase II and III clinical trials. Patients had chronic HCV genotype 1–6 infection and prior HCV treatment experience with at least one of the following treatments: interferon or pegylated interferon (pegIFN) plus ribavirin (RBV), sofosbuvir (SOF) plus RBV (with or without pegIFN), or a regimen that contained either an NS3/4A protease inhibitor (PI) or an NS5A inhibitor, but not both. Patients were included in the analysis if they received the European EMA and/or US FDA label-recommended duration of G/P treatment (8, 12, or 16 weeks) based on genotype, prior treatment history, and cirrhosis status. Safety was assessed in all patients that received at least one dose of G/P and the primary efficacy endpoint was the percentage of patients with SVR12.

Results: Overall, 362 patients with prior treatment experience were treated with G/P for an EMA/FDA approved duration. A majority of patients was male (65%), white race (81%), and was experienced with pegIFN plus RBV (73%); 31% of patients had compensated cirrhosis. HCV genotypes 1, 2, 3, and 4–6 were represented by 64%, 9%, 20%, and 6% of patients, respectively. Across all patients who received at least one prior treatment regimen, <2% and 13% of patients had key baseline substitutions in NS3 and NS5A, respectively. Overall, 97% (350/362) of patients had SVR12; 2% (9/362) of patients had virologic failure. Additional efficacy data are shown in the Figure. Presence of NS3 and NS5A baseline substitutions was not predictive of virologic failure. Adverse events occurring in ≥10% of patients were headache and fatigue. There were no serious adverse events considered related to study drug administration, there was a low rate of grade ≥3 increases in total bilirubin (<1%), and no patient had grade ≥3 increases in alanine aminotransferase.



Conclusion: HCV retreatment with G/P demonstrated a high overall rate of SVR12 (97%), including in patients with prior NS3/4A PI or NS5A inhibitor experience, and was well tolerated.

Email: Di.Maio@med.uniroma2.it

Background and Aims: Pan-genotypic direct acting antivirals (DAA) will be the most used anti-HCV regimens against all genotypes (GTs). However, their use in short, ribavirin (RBV)-free regimens may be affected by the presence of resistance-associated substitutions (RASs), whose prevalence is variable within the different GTs. This study aimed to investigate the resistance profile in HCV 2-3-4 infected, DAA-naïve and DAA-experienced, patients (pts) in Italy.
Method: Pts with GT2-3-4 (n = 109/289/121) infection, either naïve (n = 419) or DAA-experienced to a recommended regimen according to European 2017 guidelines (n = 116, including 16 with also baseline sample available) were included. Sanger sequencing of NS3 ± NS5A ± NS5B was performed by home-made protocols.
Results: Phylogenetic analysis identified the following HCV subtypes: GT2c (100%), GT3a/h (99.3%/0.7%), GT4a/d (11.6%/88.4%). Overall, 67/419 (16.0%) DAA-naïve and 97/116 (83.6%) DAA-failures had at least 1 RAS (p < 0.001). Notably, 11.2% of pts were treated with a suboptimal DAA-regimen due to a previous incorrect GT assignment and harbored RASs in 92.3% of cases.
The NS3-Q80K was mainly detected in GT3a paritaprevir-failures (25%, vs 1% in DAA-naïves, p = 0.007). The NS3-D168V was detected in 66.7% GT2c and 100% GT4d paritaprevir-failures, and in 45.4% GT4d simeprevir failures, while was rarely observed in naïve GT2c and GT4d pts (0.0% and 2.6%, respectively). The Y93H NS5A RAS was highly prevalent in NS5A-experienced GT3a (78.9%), GT4a (25%) and GT4d (14.3%) pts, while it was rarely detected in DAA-naïves (3.9% prevalence in GT3a, and <2% in GT4a/d). No pts with GT2c infection ever showed the Y93H RAS, while the F28C was detected in 71.4% GT2c NS5A-failures and in 27.8% GT2c DAA-naïves (p = 0.03). The S282T sofosbuvir RAS was found only in pts failing a sofosbuvir-containing regimen, rarely in GT4d (3.3%) and GT3a (4.4%), while was frequently detected (75%) in GT4a (p = 0.001).
Notably, of the 75 GT3 DAA-naïve pts treated with daclatasvir + sofosbuvir ± ribavirin for 12-24w, 67 (89.3%) reached a sustained virological response (SVR). 2/4 (50.0%) pts with baseline Y93H RAS reached SVR *vs* 63/68 (92.6%) without NS5A-RAS (p = 0.04).
Conclusion: HCV sequencing allows correct GT assignment and evaluation of resistance in all GTs. Failure is frequently associated with RASs, particularly Y93H-NS5A in GT3a, F28C-NS5A in GT2c and S282T-NS5B in GT4a, with potential impact on retreatment efficacy.

THU-298

Impact of direct acting antiviral treatment in hospital admission rates in patients with cirrhosis and hepatitis C virus infection

Á.H. Romero, L.C. del Campo, E.G. Domínguez, M.B. Valbuena, M.L.M. Alonso, R.M. Gómez, G.C. Tortajada, I.F. Vázquez. *Hospital Universitario Doce de Octubre, Gastroenterology and Hepatology, Madrid, Spain*
Email: lccampo06@gmail.com

Background and Aims: Wide availability of direct acting antivirals (DAA) agents has led to a substantial improvement in hepatitis C virus (HCV) infection treatment and might change the natural history of the disease. To evaluate the impact of DAA treatment in hospital admission rates and causes in cirrhotic hepatitis C patients, as subrogated markers of morbidity and mortality.
Method: Retrospective and observational study, which analyzes the frequency and causes of hospital admission in hepatitis C patients due to hepatic decompensation in the Hepatology department of a reference hospital. We compared two equal periods of time (group 1: 2013–2014 and group 2: 2016–2017) taking as reference the beginning of DAA treatment in 2015. We considered HCV infection as etiology whether it was associated to other hepatic diseases or not. We performed the statistical analysis using Epidat 4.2 program.
Results: A total of 496 patients with cirrhosis were included (170 hepatitis C; 224 alcoholic cirrhosis, 57 idiopathic or criptogenetic, 8 autoimmune hepatitis, 20 non-alcoholic fatty liver disease, 7 cardial cirrhosis and 10 hepatitis B), 315 of whom were admitted at the hospital in the first period (group 1) and 181 in the second (group 2). The hospital admission rates of hepatitis C patients decreased since DAA introduction from 39.7% (125/315) in the first period to 24.8% (45/181) in the second (p = 0.001). Regarding causes of hospitalization of hepatitis C cirrhotic patients, ascites was the main cause (55 [44%] vs 27 [60%], p = 0.06), followed by hepatic encephalopathy (29% vs 31%, p = 0.8) and hemorrhage due to variceal bleeding (16% vs 8%, p = 0.2), respectively. Other less frequent causes of admission were acute or chronic liver failure (8.8% vs 0%) and hepatocarcinoma (1.6% vs 0%). On the other hand, the rate of hospital admission of patients with alcoholic cirrhosis significantly increased in the 2nd period compared with the 1st one (129 [41%] vs 95 [52.5%] p = 0.01).
Conclusion: These results demonstrate that introduction of DAA therapy was associated with a progressive decrease on admission rates in HCV-associated cirrhotic patients. However, the causes that motivated admission did not change significantly.

THU-299

A national study of risk for non-liver cancer in people with hepatitis C treated with direct acting antivirals or an interferon-based regimen

C. Lybeck[1], D. Bruce[2], S. Montgomery[3], S. Aleman[4], A.-S. Duberg[1]. *[1]Örebro University, faculty of medicine and health., Department of Infectous diseases, Örebro, Sweden; [2]Scandinavian Development Services, Department of Statistics, Danderyd, Sweden; [3]Örebro University, Faculty of Medicine and Health., Department of Clinical Epidemiology and Biostatistics, Örebro, Sweden; [4]Karolinska Institutet, Department of Infectious Diseases, Stockholm, Sweden*
Email: lybecklotta@gmail.com

Background and Aims: Direct acting antivirals (DAA) against hepatitis C virus (HCV) have been shown to have an immune modulatory effect, with a possibly decreased tumour specific CD8 T cell response. Reports indicative of a high risk for hepatocellular carcinoma or advanced tumours early after DAA treatment, have raised concerns about whether the risk for non-liver cancer could be increased. Therefore, our aim was to study the early incidence of non-liver cancer after initiation of DAA or interferon (IFN-based) therapy in a national HCV cohort.
Method: All diagnosed HCV-infected persons in Sweden, their antiviral treatments, non-liver cancer or death/emigration were identified retrospectively, using the national HCV-surveillance

register and other national registers. Cox regression was used to compare persons treated with DAAs (n = 1,920), IFN-based therapy (n = 2,586) or no HCV therapy (n = 13,872) between 2009 and 2015. Persons with a previous cancer diagnosis (5.7%) were studied separately. Age was used as the time-scale, and the analyses were stratified by sex and adjusted for the Charlson comorbidity index.

Results: In total 492 non-liver cancers were diagnosed, with 222 among persons with no previous cancer and 270 new cancer diagnoses among those with previous cancer. Among persons with no previous cancer, 21, 24 and 177 developed non-liver cancer following DAA, IFN-based and no treatment, respectively. The corresponding numbers for those with previous cancer were 25, 20 and 225, respectively. The hazard ratios (and 95% confidence intervals) for non-liver cancer in the no previous cancer group are 1.35 (0.66–2.76; p = 0.41) for men and 1.75 (0.59–5.18; p = 0.31) for women with DAA treatment, compared with IFN treatment. For those with previous cancer, the corresponding hazard ratios are 1.03 (0.41–2.57; p = 0.95) for men and 0.86 (0.35–2.13; p = 0.75) for women with DAA treatment.

Conclusion: This study did not demonstrate any significantly increased risk for non-liver cancer early after DAA therapy initiation. The hazard ratio was slightly increased among those without previous cancer, but the cancers were few and the results were not statistically significant. Further studies with higher numbers of DAA treated patients and longer follow-up are needed to fully explore this issue.

Email: christophe.hezode@hmn.aphp.fr

Background and Aims: Data on real-life use of direct acting antivirals (DAAs) in patients with HCV genotype 2 chronic infection are limited. We report the real-life efficacy and safety data of SOF + RBV and SOF + DCV ± RBV in HCV genotype 2

Method: ANRS CO22 HEPATHER "Therapeutic options for hepatitis B and C: a French cohort" is a large multicenter observational cohort (ClinicalTrials.gov, NCT01953458). Between August 6 2012 and October 31rst 2016, Among 12,101 HCV chronically infected patients included, 278 with a HCV genotype 2 infection who initiated a combination of SOF/RBV (n = 233) for 12 or 24 weeks or SOF/DCV ± RBV (n = 45) for 12 or 24 weeks. The mean age was 62 years, cirrhosis (F4) was present in 103 (37.1%) patients. The main endpoint criteria was sustained virological response (SVR12) defined by the undetectability of HCV RNA 12 weeks after the last treatment intake.

Results: The total SVR12 was 87.8% (244/278); 87.5% (204/233) and 88.9% (40/45) for SOF/RBV and SOF/DCV ± RBV groups, respectively. AEs were more frequently observed in patients receiving RBV (p = 0.01) and SAEs were reported in only 21 (7.5%) patients.

Conclusion: In the real life setting, the combinations SOF/RBV and SOF/DCV ± RBV are suboptimal in genotype 2 patients, especially in cirrhotic and/or PR treatment experienced patients. Analysis of NS5A and NS5B RASs at baseline and at the time of failure is ongoing and will be presented in patients treated with DCV regimens for explaining these unsatisfactory and unexpected results.

SVR12	SOF + RBV 12 weeks n = 188	SOF + RBV 24 weeks n = 45	SOF/DCV ± RBV 12 weeks n = 34	SOF/DCV ± RBV 24 weeks n = 11
Total, n (%)	165/188 (88)	39/45 (87)	30/34 (88)	10/11 (91)
No cirrhosis, n/n (%)	116/130 (89)	18/20 (90)	15/16 (94)	4/4 (100)
Cirrhosis, n/n (%)	47/56 (84)	21/25 (84)	12/15 (80)	6/7 (86)
Naïve, n/n (%)	103/112 (92)	15/16 (94)	15/18 (83)	4/4 (100)
PR treatment-experienced, zn/n (%)	62/76 (82)	24/29 (83)	15/16 (94)	6/7 (86)

Efficacy and safety of Elbasvir/Grazoprevir in women infected with hepatitis C virus genotype 1 or 4 and co-administered oral contraceptives or hormone replacement therapy

C. Hezode[1], P. Kwo[2], J. Sperl[3], G. Dore[4], P. Hwang[5], J. Long[6], R. Talwani[7], M. Robertson[6], B. Haber[8]. *[1]Hopital Henri Mondor, Paris, France; [2]Stanford University, Stanford, United States; [3]Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [4]The Kirby Institute, University of New South Wales; [5]Merck & Co., Inc., UG1C-46, North Wales, PA, United States; [6]Merck & Co., Inc.; [7]Merck & Co., Inc., Kenilworth, NJ, United States; [8]Merck and Co, Merck, North Wales, United States*

Email: barbara.haber@merck.com

Background and Aims: The prevalence of HCV infection has increased among women of child-bearing potential, in part due to the opioid epidemic. Some direct-acting antiviral regimens have safety or efficacy concerns if co-administered with oral contraceptives that contain ethinyl estradiol (OCPs) or hormone replacement therapy (HRT). The aim of this study was to determine if co-administration of OCPs or HRT impacted the efficacy or safety of elbasvir 50 mg (EBR)/grazoprevir 100 mg (GZR) in women chronically infected with HCV genotype (GT) 1 or 4.

Methods: Efficacy and safety data from 12 clinical trials of EBR/GZR were pooled. A total of 1022 female participants (pts) received 12 weeks of daily EBR/GZR. 81 pts (7.9%) received and 941 pts (92.1%) did not receive concomitant OCPs or HRT. The primary efficacy endpoint was sustained virologic response 12 weeks after the end of therapy (SVR12) in the full analysis set (all patients who received at least one dose).

Subgroup	SVR12 in women not on concomitant OCP/HRT n/N (%)	SVR12 in women on concomitant OCP/HRT n/N (%)
Overall	906/941 (96.3%)	77/81 (95.1%)
18 to 35 years of age	87/89 (97.8%)	21/23 (91.3%)
>35 years of age	819/852 (96.1%)	56/58 (96.6%)
GT1a	229/245 (93.5%)	35/38 (92.1%)
GT1b/1-other	647/665 (97.3%)	39/39 (100.0%)
GT4	30/31 (96.8%)	3/4 (75.0%)
Baseline HCV RNA ≤800000 IU/mL	290/299 (97.0%)	34/35 (97.1%)
Baseline HCV RNA >800000 IU/mL	616/642 (96.0%)	43/46 (93.5%)
HCV Mono-infected	862/897 (96.1%)	75/79 (94.9%)
HCV/HIV Co-infected	44/44 (100.0%)	2/2 (100.0%)
Treatment-naive	755/785 (96.2%)	62/64 (96.9%)
Previously treated	151/156 (96.8%)	15/17 (88.2%)
Non-cirrhotic	748/778 (96.1%)	68/71 (95.8%)
Cirrhotic	146/151 (96.7%)	6/7 (85.7%)
Unknown cirrhosis status	12/12 (100.0%)	3/3 (100.0%)
IL28B CC genotype	392/409 (95.8%)	22/24 (91.7%)
IL28B non-CC genotype	507/525 (96.6%)	55/56 (98.2%)
IL28B genotype unknown	7/7 (100.0%)	0/1 (0.0%)

Results: SVR12 was similar in women on OCP/HRT (77/81 [95.1%]) compared to women not on OCP/HRT (906/941 [96.3%]). The efficacy of EBR/GZR in women on or not on OCP/HRT was similar among subgroups including HCV GT1a, GT1b/1-other, GT4, and cirrhosis/no cirrhosis (Table). Safety was similar among women on OCP/HRT or not on OCP/HRT; serious drug-related adverse event (AE) occurred in

0/81 (0%) compared to 3/941 (0.3%) in women on vs. not on OCP/HRT. One of 81 women (1.2%) on OCP/HRT discontinued due to an AE compared to 7/941 (0.7%) not on OCP/HRT. Of the discontinuations, 1 woman on OCP/HRT and 4 not on OCP/HRT discontinued due to an AE of ALT/AST increase. ALT values >5 times baseline were observed in 2/81 (2.5%) women on OCP/HRT compared to 14/940 (1.5%) not on OCP/HRT. Three-quarters of the OCP/HRT regimens taken by participants contained estradiol, estrogen, synthetic estrogen or a selective estrogen receptor modulator (69/92 [75%]), and one-quarter of the regimens contained progestin or a synthetic progesterone hormone (24/92 [26%]).

Conclusion: The efficacy and safety of 12 weeks of EBR/GZR was similar in female participants on concomitant OCP/HRT compared to those not on concomitant OCP/HRT.

THU-302

Outcomes of direct-acting antiviral therapy for chronic hepatitis C following unrestricted access in Australia: Real-world outcomes from the state of South Australia

J. Haridy[1,2], A. Wigg[3], K. Muller[3], J. Ramachandran[3], E. Tilley[3], V. Waddell[4], D. Gordon[4,5], D. Shaw[6,7], D. Huynh[8], J. Stewart[8,9], R. Nelson[7,9], M. Warner[7,9], M. Boyd[7,10], A. Chinnaratha[11], D. Harding[11], L. Ralton[10,11], A. Colman[12], G. Iyngkaran[2], E. Tse[12]. *[1]University of Melbourne, Melbourne; [2]Royal Melbourne Hospital, Department of Gastroenterology, Melbourne, Australia; [3]Flinders Medical Centre, Hepatology and Liver Transplantation Unit, Adelaide, Australia; [4]Flinders Medical Centre, Department of Infectious Diseases, Adelaide, Australia; [5]Flinders University, Bedford Park, Australia; [6]Royal Adelaide Hospital, Department of Infectious Diseases, Adelaide, Australia; [7]University of Adelaide, Faculty of Health and Medical Sciences, Adelaide, Australia; [8]The Queen Elizabeth Hospital, Department of Gastroenterology, Adelaide, Australia; [9]The Queen Elizabeth Hospital, Department of Infectious Diseases, Adelaide, Australia; [10]Lyell-McEwin Hospital, Department of Infectious Diseases, Adelaide, Australia; [11]Lyell-McEwin Hospital, Department of Gastroenterology, Adelaide, Australia; [12]Royal Adelaide Hospital, Department of Gastroenterology, Adelaide, Australia*
Email: jamesharidy@gmail.com

Background and Aims: In March 2016, the Australian Government offered unrestricted access to Hepatitis C (HCV) directly-acting antiviral (DAA) therapy, including prescription by any medical practitioner. The primary aim of this study was to determine the outcomes of DAA therapy in this setting over the first 12 months for an entire state health region, South Australia (SA).

Method: Prospective outcome data (SVR12; sustained virological response 12 weeks after treatment) was collected on all patients initiating DAA therapy for HCV at or in consultation with four tertiary hospitals in Adelaide, SA, between March 2016 and Feb 2017. Biochemistry and Fibroscan® score was collected retrospectively. Analysis was by Intention to Treat (ITT) and per-protocol (PP, including only those completing prescribed treatment and follow-up).

Results: 1921 patients were included representing an estimated 90% of patients treated in SA over the first 12-months of unrestricted DAA access.; Demographics were: mean age 52 years (range 18–92), 67% male, 2% Aboriginal or Torres Strait Islander (ATSI), 77% history of injecting drug use, 6% currently injecting, 5% incarcerated, 1% HIV co-infection, 12% diabetes, <1% hepatitis B co-infection and 19% had prior HCV treatment experience. Of the 26% of subjects with cirrhosis, 67% were Child-Pugh A. 20% of treatment initiations were through remote consultation and 25% resided in a regional or remote area.

SVR12 by ITT and PP was 80% and 96% respectively. 14% were lost to follow-up, 4% failed therapy; <1% either discontinued treatment due to adverse effects or poor adherence and <1% (13 patients) died. Factors associated with lower SVR12 on ITT analysis included ATSI (68% v 81%, p = 0.05), older age (mean 55 v 52y, p = 0.02), remote consultation (72% v 82%, p < 0.001); and incarceration (71% v 81%, p = 0.03). Factors associated with virological failure on PP analysis included cirrhosis (93% v 97%, p < 0.001) and prior HCV treatment history (92% v 96%, p = 0.03). 92% subjects achieving SVR12 experienced normalization of ALT compared to 61% who failed DAA therapy.

A marked decline in treatment initiations occurred in the latter 6 months of the study period (1251 v 668 patients) combined with a shift from hospital-based to community-based treatment via remote consultation (from 12% in first six-months to 33% in latter).

Conclusion: PP results were consistent with the high responses in clinical trials but a significant gap exists between SVR12 on ITT analysis in our real-world cohort, primarily due to loss to follow-up. A shift to community-based management highlights a need to develop and support additional models of care including GP and nurse-led treatment. The declining treatment initiation rate observed emphasizes the importance of exploring additional strategies to identify and recall the large number of remaining patients in Australia in order to achieve elimination targets.

THU-303

Risk and outcome of hepatitis B virus reactivation during chronic hepatitis C treatment with direct-acting antivirals in patients with HCV-related advanced fibrosis: a single-center experience

R. D'ambrosio[1], E. Degasperi[1], A. Aghemo[2], M. Borghi[1], R. Perbellini[1], S.D. Nicola[3], G. Lunghi[4], P. Lampertico[1]. *[1]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Università degli Studi di Milano, CRC A.M. and A. Email: pietro.lampertico@unimi.it

Background and Aims: Reactivation of hepatitis B virus (HBV) following treatment of hepatitis C virus (HCV) infection with direct-acting antivirals (DAAs) has been described in patients with HBV coinfection (HBV/HCV) or resolved HBV infection, however studies in patients with advanced fibrosis are lacking. Therefore, we investigated the prevalence and outcome of HBV reactivation in a large cohort of HCV patients with advanced fibrosis treated with DAAs.

Method: All consecutive patients treated with DAAs for advanced HCV-related fibrosis were prospectively enrolled. HBV/HCV coinfection was defined by the presence of both detectable HCV-RNA and HBsAg positivity; resolved HBV infection was defined as HBsAg negativity and anti-HBc positivity (± anti-HBs). Fibrosis stage was defined clinically, histologically (METAVIR F3 or F4) or according to liver stiffness measurement (LSM: 10 kPa for F3, 11.9 kPa for F4). Treatment monitoring was performed monthly. HBV reactivation was defined as an increase of HBV-DNA > 1 Log in HBV/HCV patients, and as HBsAg seroreversion ± detectable HBV-DNA in anti-HBc positive patients.

Results: Between January 2015 and December 2016, 692 patients with F3-F4 fibrosis started DAAs. They were males (60%), with a median age of 63 (23–89). HCV genotype was 1a in 16%, 1b in 46%, 2 in 14%, 3 in 11%, 4 in 12% and 5 in 1%; median HCV-RNA was 581,270 (764–13,333,872)IU/ml. Baseline LSM was 14 (9–75)kPa, and cirrhosis was present in 526 (76%) patients. Patients with HBV/HCV coinfection were 10 (1.4%), while 301 (43%) were anti-HBc positive (54% anti-HBs positive). HBV/HCV patients were males (60%), aged 67 (45–79), mainly cirrhotics (70%). Median LSM was 21 (9–43.5)kPa. They were all HBeAg negative, with baseline HBV-DNA values undetectable in 5 (50%); anti-HBV nucleot(s)ides (NUCs) had been previously started in 4 (40%). After 2 weeks of DAAs treatment, HBV reactivated in 3 (50%) patients who were left untreated for HBV. At reactivation, ALT was 21 (18–52)U/l, HBV-DNA was 330 (248–6,915) IU/ml, HBsAg was 62 (1.1–1,329)UI/ml and HCV-RNA was 148 (18–389)IU/ml. No episodes of clinical decompensation were recorded and NUC was started in all of them. HBV-DNA became undetectable

after 8 (6–39) weeks, whilst HBsAg was lost in one patient, only. None of the 301 anti-HBc positive patients experienced any clinical or virological reactivation. Overall SVR rates to HCV treatment were 96%, without differences according to HBV status (p = 0.71).
Conclusion: HBV reactivation is frequently observed among HBV/HCV coinfected patients but not among HCV patients with resolved HBV infection.

Generic sofosbuvir-based interferon-free direct acting antiviral agents for patients with chronic hepatitis C virus infection: a real-world multicenter observational study

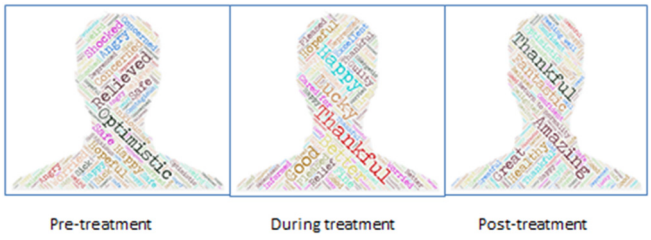
C.-H. Liu[1], S.-S. Yang[2], S.-S. Yang[3], H.-Y. Sun[4], C.-J. Liu[5], W.-C. Liu[4], T.-H. Su[6], H.-C. Yang[7], C.-M. Hong[4], T.-C. Tseng[4], P.-J. Chen[8], D.-S. Chen[9], C.-C. Hung[4], J.-H. Kao[10]. *[1]National Taiwan University Hospital, Internal Medicine, Taipei, Taiwan; [2]Taichung Wing total (Taiwan Avenue), Taiwan; [3]Cathay General Hospital , Taiwan; [4]National Taiwan University Hospital, Taiwan; [5]Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; [6]National Taiwan University Hospital, Department of Internal Medicine, Taipei, Taiwan; [7]National Taiwan University Hospital, Department of Internal Medicine, Taiwan; [8]Department of Medical Research, National Taiwan University, Taiwan; [9]National Taiwan University Hospital, National Taiwan University Hospital and National Taiwan University College of Medicine, Taipei, Taiwan; [10]National Taiwan University Hospital, Zhongzheng District, Taiwan*
Email: jacque_liu@mail2000.com.tw

Background and Aims: Data regarding to the effectiveness of generic sofosbuvir (SOF)-based interferon-free direct acting antiviral agents (DAAs) for patients with chronic hepatitis C virus (HCV) infection are limited.
Method: Five hundred seventeen chronic HCV-infected patients receiving 12 or 24 weeks of SOF-based therapies were retrospectively enrolled in 4 academic centers in Taiwan. The rate of sustained virologic response, defined as HCV RNA level < lower limit of detection (LLOD, 15 IU/ml) at week 12 off-therapy (SVR_{12}), was assessed for each regimen. The baseline characteristics and on-treatment HCV viral decline potentially related to SVR_{12} were analyzed.
Results: The SVR_{12} was achieved in 29 of 34 patients (85.3%, 95% confidence interval [CI]: 69.6%–93.6%), 130 of 139 patients (93.5%, 95% CI: 88.2%–96.6%), 119 of 124 patients (96.0%, 95% CI: 90.9% –98.3%) and 215 of 220 patients (97.7%, 95% CI: 94.8%–99.9%) who received SOF in combination with ribavirin (RBV), ledipasvir (LDV), daclatasvir (DCV) and velpatasvir (VEL), respectively. All 15 patients with virologic failures were relapsers. Two patients with decompensated cirrhosis had on-treatment deaths which were not related to DAAs. All the 7 patients who were lost to follow-up had HCV RNA level < LLOD at the last visit. The SVR_{12} rates were comparable in terms of baseline patient demographics, HCV viral load/genotype, treatment regimen, or viral decline at week 4 of treatment.
Conclusion: Generic SOF-based therapies provide high SVR_{12} rates for patients with chronic HCV infection.

THU-305
"How do you feel about your diagnosis of Hepatitis C today?": The emotional benefits of direct-acting antiviral therapy

S. Montague, C. Mazzarelli, T. Ow, K. Childs, L. Smith, G. Dusheiko, K. Agarwal, M.D. Cannon. *Institute of Liver Studies, King's College Hospital, London, United Kingdom*
Email: sarah.montague@nhs.net

Background and Aims: Direct-acting antiviral (DAA) therapy for hepatitis C (HCV) and virologic "cure" is associated with improvements in quality of life. This has been demonstrated in numerous studies which demonstrated improvement in patient-reported outcome measures. The literature is lacking with regard to qualitative data of patients' emotions about the diagnosis of HCV, and how this changes in parallel with DAA treatment for HCV. Inspired by the work of Feighan et al.,[1] we explored the feelings and emotions of patients with HCV before, during and after treatment with DAAs.
Method: Over a five-week period (September-October 2017), patients with HCV attending the viral hepatitis outpatient clinic at King's College Hospital were invited to participate in this study. All participants were either about to start DAA treatment, currently on treatment, or attending for post-treatment follow-up. A single question was posed in writing: "How do you feel about your diagnosis of Hepatitis C today?". 52 patients of a target enrolment of 250 patients consented verbally to participate. Data collection is ongoing and complete data will be presented at the meeting. We replicated the method of analysis of Feighan et al.[1] by transcribing patient responses verbatim and manually coding by theme. Results were visualised using Wordle and WordArt software.
Results: As suggested by the images, a patients' perception of the impact of HCV on their lives evolves during the course of DAA treatment. In fact, it is clear that patients feel much better about their diagnosis of HCV once they initiate DAA therapy, with further improvements following treatment completion. Pre-treatment responses were predominantly negative, although some patients expressed hope and optimism regarding the commencement of an effective treatment in the foreseeable future. Negative emotions appeared to subside once treatment had been initiated. Although reasons for expressed emotions were not always given, we can perhaps deduce that the information given to patients at their clinic appointments enabled them to feel more informed and less worried about their future. Limitations of our data included not being able to further explore unexpected responses, for example, why some patients continue to experience depression after treatment completion.



How do you feel about your diagnosis of Hepatitis C today?

Conclusion: In summary, our study demonstrates that treatment of HCV not only brings about physical health advantages. A cure has far reaching benefits such as improved mental health, and can also promote a more positive outlook on life. Responses, on the whole, although not unexpected will help to further remind us that for some patients HCV also confers an emotional burden, and a broader view should be taken with regard to DAA treatment benefits.

Rapid virological response, as a predictor of sustained virological response of Sofosbuvir and Ribavirin in Korean patients with genotype 2 chronic hepatitis C virus infection

H.Y. Woo, J. Heo, S.Y. Han, Y.J. Park, D.H. Baek, D.U. Kim, G.H. Kim, G.A. Song. *Pusan National University Hospital, Department of Internal Medicine, Busan, Republic of South Korea*
Email: jheo@pusan.ac.kr

Background and Aims: Recent advances in testing instruments have enabled the measurement of HCV RNA levels below 50 IU/ml, even 15 IU/ml and its utility for predicting sustained virological response (SVR) has not been investigated. The aim of this study is to investigate

real-world data with sofosbuvir/ribavirin (SOF/RBV) in Korean patients with genotype 2 hepatitis C virus (HCV) infection and to investigate predicting factor of SVR 12.
Method: 140 patients with genotype 2 chronic HCV infection treated with SOF/RBV were investigated prospectively. 400 mg of SOF combined with weight adjusted RBV was administered for 12 weeks in patients without cirrhosis and for 16 weeks with cirrhosis. HCV RNA level was examined in pre-treatment, 4 weeks, end of treatment, and 12 weeks after end of treatment by RT-PCR method (COBAS® TaqMan® Analyzer, low detection limit, 15 IU/ml; non-detection and below 15 IU/ml reported separately). The definition of rapid virological response (RVR) was defined as non-detection of HCV RNA at 4 weeks only.
Results: A total of 136 completed the treatment. 55 was male (40.4%) with a mean age of 61.6 ± 11.1 years. 99 (72.8%) were treatment naïve, 6 (4.4%) had a history of HCC, 23 (16.9%) had diabetes, and 33 (24.3%) had cirrhosis, of which had decompensation in 6. RVR was 77.9% (106/136), end of treatment response was 100% (136/136) and SVR12 was 96.0% (122/127). Of 5 with relapse, 4 were received 12 weeks of treatment and three of them did not reach RVR. Clinical factors associated with SVR12 were RVR status in multivariable analysis (p = 0.031). Contributing factors of RVR, cirrhosis, estimates glomerular filtration rate, and pre-treatment HCV RNA level were found to be significant. According to treatment duration, in 16 weeks treatment, SVR12 was not significantly different in RVR (−) and RVR (+) (94.7% vs. 100%, p = 0.483). However, in 12 weeks treatment, SVR12 was significantly higher in RVR (+) than RVR (−) (98.7% vs. 83.3%, p = 0.003). During treatment, 51/136 (37.5%) showed mild to moderate adverse events (urticaria, anemia, fatigue, insomnia, headache). 26 (19.1%) were reduced RBV dose due to anemia.
Conclusion: SOF/RBV treatment in genotype 2 HCV was effective, tolerable and RVR is an important predictor of SVR12. 16 weeks of treatment would be better for patients without RVR.

THU-307

Ledipasvir 90 mg/sofosbuvir 400 mg for treatment of children with CHC genotype 4: Single Centre experience

G. Sheha[1,2], R. Elsayed[1,3], M. Elbasiony[1,2], N. Mikhail[4]. *[1]Egyptian Liver Research Institute and Hospital (ELRIAH), Mansoura, Egypt; [2]Mansoura University, Internal Medicine Dept, Mansoura, Egypt; [3]Port Said University, Tropical Medicine, Mansoura, Egypt; [4]Egyptian Liver Research Institute and Hospital (ELRIAH)*
Email: g_shiha@hotmail.com

Background and Aims: A considerable number of children have chronic HCV infection and are at risk for complications. Approximately 11 out of 115 million of the infected persons in the world are younger than 15 years. Newly developed DAAs provide powerful tool in treatment of chronic HCV patients with good safety profiles. Food and Drug Administration (FDA) in April 2017 approved supplemental applications of sofosbuvir and ledipasvir in treatment of HCV in children aged 12 to 17 years.
Blood transfusion and some surgical interventions (circumcision) are the main risk factors of HCV infection in young in the developing countries.
Our aim is to evaluate the safety and efficacy of single daily dose of Ledipasvir 90 mg/sofosbuvir 400 mg in treatment of HCV infected children (12–17 years) either treatment-naïve or experienced to INF therapy, with or without history of blood disease (leukemia, lymphoma, thalassemia).
Method: Seventy three child with positive HCV antibodies examined at outpatient clinic of ELRIAH from the period of May 2017 till now, 53 (72.6%) were positive for HCV RNA, 15 (28.3%) patients were treatment experienced, 12 (22.6%) patients had history of blood diseases: acute lymphocytic leukemia (n = 3), non-Hodgkin lymphoma (n = 4), β thalassemia (n = 2) and hemophilia A (n = 3). 45 children (54.9%) are males. All children are not cirrhotic (fibroscan < 10 Kpa) and received treatment in the form of Ledipasvir 90 mg/sofosbuvir 400 mg for 12 weeks.
Results: Log10 HCV RNA level was 5.41 ± 0.85 IU (By cobas Taqman). All patients achieved early virological response (PCR < 15 IU at week 4 of treatment). Twenty patients reached PTW12, all of them achieved SVR12.BY time of the conference all patients will reach PTW12 and complete results will be presented. No serious adverse events reported till now.
Conclusion: Ledipasvir 90 mg/sofosbuvir 400 mg for 12 weeks was well tolerated and promising in treatment of children with CHC genotype 4.

Clinical trial number: ClinicalTrials.gov # NCT03343444.

Email: pietro.lampertico@unimi.it

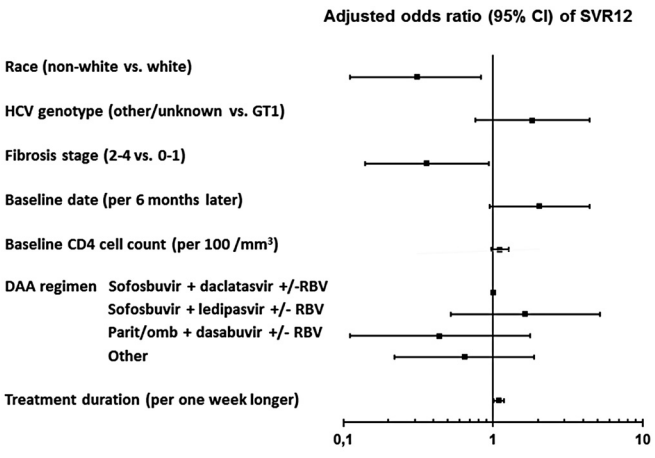
Background and Aims: Hepatitis C virus (HCV) recurrence after liver transplantation (LT) was associated with a poor clinical outcome until the new introduction of direct-acting antiviral agents (DAAs). This study was aimed to report the clinical outcome of DAA treated recipients with recurrent hepatitis C after LT.
Method: from May 2012 to January 2016, 125 HCV-RNA positive LT patients received DAA-treatment (with/without IFN) 46 (0–268) months from LT: 78% of the patients received a SOF-based regimen plus ribavirin (RBV), 6% patients SIM/DCV/RBV or 3D-regimen and 17% received PEG-IFN/RBV plus Telaprevir or Sofosbuvir. At DAA start, age was 61 years, 76% males, 71% HCV-1 infected, 69% treatment naïve, 48% transplanted for HCC, 58% on dual immunosuppression (CNI plus MMF), 75% had arterial hypertension, 52% diabetes, 23% cirrhosis/FCH, 5 patients portal vein thrombosis, 42% eGFR < 60 ml/min. The median HCV-RNA level was 1.890.231 UI/ml (14.588–51.491.894).
Results: A virological response was achieved in all patients (in 97% of them after the first course of therapy). DAA treatment was well tolerated and side effects were anaemia (erythropoietin support = 57 and blood transfusion = 15), asthenia and mild gastrointestinal disorders. After a median time of 10 months (3–18) from DAA start, 10 (8%) patients showed a liver graft dysfunction successfully treated by increasing immunosuppression. After a median follow-up of 26 months, liver stiffness declined from 11 to 7 kPa (p < 0.05), while 4% of patients developed a de-novo portal thrombosis 30 months after starting DAA; HCC recurred in 2 out of 60 HCC transplant recipients (at month 2 and 13). Extra-hepatic cancer (renal, bladder) occurred in 2 patients (month 26 and 12). eGFR values did not significantly change (65 vs 63 ml/min) but 5 patients ultimately worsened kidney function (one required haemodialysis 8 months post-DAA; 3 had a nephrotic syndrome 9 to 20 months post-DAA). Overall, the 3-year cumulative incidence of hepatic and extrahepatic complications was 24% and the 3-year survival was 99%, as only one patient died after 19 months post-DAA due to sepsis-related multi-organ failure.
Conclusion: DAA-treatment for HCV recurrence after LT is highly effective and safe. The 3-year survival was excellent but a quarter patients experienced hepatic or extrahepatic complications.

THU-309

Efficacy and safety of IFN-free DAA therapy in HIV/HCV co-infected patients: Results from a pan-European study

L. Peters[1], J.D. Lundgren[1], J. Rockstroh[2], A. Mocroft[3]. [1]*Rigshospitalet, CHIP, Department of Infectious Diseases, Copenhagen, Denmark;* [2]*University of Bonn, Medizinische Universitätsklinik I;* [3]*Institute for Global Health, UCL, Centre for Clinical Research, Epidemiology, Modelling and Evaluation (CREME)*
Email: Lars.peters@regionh.dk

Background and Aims: Real-life data on efficacy and safety of direct-acting antiviral (DAA) therapy in HIV/HCV co-infected patients from Europe, especially Eastern Europe, are scarce. We aimed to investigate the efficacy of DAAs and the prevalence and reasons for premature discontinuation of DAAs.
Method: We included all HIV/HCV coinfected from the EuroSIDA study who started IFN-free DAAs after June 1 2014 and had ≥12 weeks of follow up after completing treatment. Sustained virological response (SVR) was defined as undetectable HCV-RNA ≥ 12 weeks after treatment completion. Logistic regression was used to examine factors associated with SVR.
Results: Among 632 persons starting DAA, the median age was 51 years, 79% were males, 58% with a history of injecting drug use and 19% MSM; 98.6% had HIV-RNA < 500 cp/ml and median CD4 cell count was 600/mm^3; 32.4% had cirrhosis.164 persons had unknown SVR status, 82 (50%) of whom were HCV-RNA negative at end of treatment and 82 (50%) with unknown treatment response. Ribavirin was used in 272/632 (43%) DAA regimens. Patients with unknown SVR status were generally similar to those with known SVR status, but more likely to be from Central East and Eastern Europe, p = 0.059). In an intention to treat analysis, 433/632 (68.5%; 95% CI 64.9–72.1) achieved SVR. In a per protocol analysis, 433/468 (92.5%; 95% CI 90.1–94.9%) achieved SVR. The SVR rate was 95.8% in Western Europe and 92.0%, 89.6%, 88.9% in South, North and Central East/East Europe, respectively, p = 0.27. In adjusted analysis, only white race vs. non-white race, fibrosis stage 0–1 vs. 2–4 and treatment duration per one week longer were associated with higher odds of SVR (figure). Thirty-one (4.9%; 95% CI 3.2–6.6%) out of 632 patients stopped one or more HCV drugs earlier than scheduled. The reasons included toxicity (n = 11), viral failure (n = 1), physician choice (n = 3), drug out of stock (n = 1), substance abuse (n = 1), other (n = 7) and unknown (n = 7). In nine out of 11 treatment stops due to toxicity, ribavirin was the only drug in the regimen that was stopped due to well-known adverse effects.



Model adjusted for factors shown. Gender, age, region of Europe, HIV risk, HCV viral load, prior HCV treatment, HBsAg, nadir CD4 cell count and treatment duration ≤ 12 vs. >12 weeks all had p>0.1 in univariate analysis

Conclusion: In a diverse population of HIV/HCV co-infected patients from all regions of Europe, DAA therapy was generally well tolerated and resulted in high SVR rates in all regions. Further data is required from Central East and Eastern Europe as we found a non-significant trend towards missing SVR12 results which could reflect loss to follow-up.

Email: thithu-thuy.nguyen@aphp.fr

Background and Aims: Resistance-Associated Variants (RAVs) are one of the main reasons for failure to Direct-Acting Antiviral (DAA) therapies in HCV infected patients. Studies realised by population (Sanger) sequencing about the impact of RAVs at baseline to treatment outcome by inhibitors of NS5A, NS3, and NS5B possibly underestimated their prevalence and their clinical significance. Moreover, these studies focused largely on HCV of genotype 1 (1a and 1b). In this study, we investigated presence of RAVs prior and post-treatment, their emergence under DAA pressure, and the possible impact of baseline RAVs on treatment outcome in patients infected by HCV of various genotypes and failing DAA therapies by ultra-deep sequencing technique (UDS).
Method: Sanger and UDS were performed for plasma samples prior and post-treatment of 23 patients failing DAAs [3 genotypes (GT)1a, 3 GT1b, 2 GT1not-a not-b, 5 GT3a, 3 GT4a, 5 GT4d, 1 GT4r, 1 GT2q]. The SmartGene IDNS ASP service was used to analyze UDS data. We analyzed amino acid positions considered to be implicated in resistance to DAAs which were mentioned in *geno2pheno* rules (updated February 2017) and EASL guidelines 2016.
Results: At baseline**,** pre-existing RAVs and natural polymorphisms including minority RAVs were detected by UDS in viruses of 10 patients (1 on NS3 and 9 on NS5A) among whom 4 were treatment-naïve. At failure, 1/23 patients developed S282T on NS5B which was not detected at baseline even by UDS. Presence of RAVs or polymorphisms on NS3 and NS5A genes was detected at relapse by Sanger and UDS in viruses of 1/1 and 14/18 patients, respectively. Emergence of substitutions from minority at baseline to majority at failure was detected on NS5B for viruses of 2/23 and on NS5A for 7/18 patients especially L28M/F for 3 GT4, L31M for 1 GT1e, and Y93H for 1 GT3a virus. Furthermore, these minority substitutions were accompanied by polymorphisms detected at 100% at baseline and at failure such as L28F accompanied by T58P in 1 GT4d, L28M by L30R in 1 GT4a and 1 GT4d, and L31M by K24R and S58P in 1 GT1e virus.
Conclusion: Viruses of a large part of patients failing NS5A inhibitors carried pre-existing RAVs and natural polymorphisms at baseline and developed majority RAVs at failure. The emergence at failure of pre-existing substitutions on NS5A and NS5B genes especially in little explored GT3 and GT4 virus is undoubtedly important and needs to be further investigated.

THU-311

HCV clearance and pro-thrombotic shift in advanced liver disease

E. Biliotti[1], D. Palazzo[1], R. Cangemi[2], R. Carnevale[3], R. Esvan[1], P. Maida[1], C. Nocella[3], P. Perinelli[1], M. Santori[1], M. Spaziante[1], L. Sulekova[1], F. Tamburini[1], F. Violi[2], G. Taliani[1]. [1]*Sapienza University of Rome, Clinical Medicine, Rome, Italy;* [2]*Sapienza University of Rome, Department of Internal Medicine and Medical Specialties, Rome, Italy;* [3]*Sapienza University of Rome, Department of Medical-Surgical Sciences and Biotechnologies, Rome, Italy*
Email: elisabiliotti@yahoo.it

Background and Aims: Hepatitis C virus (HCV) infection is associated to an increased risk of cardiovascular disease (CVD) and thromboembolic events. Direct acting antiviral (DAA) agents have an excellent safety profile and induce HCV viral clearance in almost all treated patients, but their impact on CVD risk remains unclear. Platelet activation and oxidative stress play a crucial role on the onset of thrombosis and CVD. We investigated the levels of urinary thromboxane B2 (TxB2), a marker of platelet activation, and 8-iso-prostaglandin F2α (8-iso-PGF2α), a marker of oxidative stress, during and after DAA treatment in HCV patients with advanced liver disease.
Method: We enrolled 90 consecutive HCV patients with advanced fibrosis (Metavir F3-F4) who achieved SVR after DAA treatment (65.6% with ribavirin, 77.8% with sofosbuvir). Urinary levels of TxB2 and 8-iso-PGF2α were measured at baseline (T0), end-of-treatment (EOT) and after 12-weeks of follow-up (FU) by ELISA commercial kits. Statistical analysis was performed by IBM SPSS version 21.0.
Results: The characteristics of enrolled patients were: age 59.3 ± 10.8 years, 58.9% males, BMI 25.0 ± 3.6, 75.6% HCV Gt-1, HCV viral load 6.1 ± 0.8 Log 10 IU/ml, platelet 156.0 × 10^6/mm^3, liver stiffness 19.7 ± 12.7 KPa. Urinary TxB2 levels increased sharply and significantly during antiviral treatment (161.5 [150.0–188.5] vs 230.0 [185.0–265.0]ng/mg creatinine, $p < 0.001$) with a small further increase during FU (242.5 [179.7–298.5]ng/mg creatinine, $p = 0.057$). Conversely, urinary 8-iso-PGF2α levels increased steadily during therapy (150.0 [136.5–161.0] vs 165.0 [151.5–210.0]pg/mg creatinine, $p < 0.001$) and FU (210.0 [167.5–255.0] pg/mg creatinine, $p < 0.001$). A significant correlation between the increase of TxB2 and 8-iso-PGF2α levels was observed during the study period ($r = 0.421$, $p < 0.001$). Modifications of platelet levels did not correlate neither with TxB2 ($r = -0.043$, $p = 0.48$) nor with 8-iso-PGF2α increase ($r = -0.027$, $p = 0.66$) and no clinical, biochemical, virological or treatment factors were found to correlate with TxB2 and 8-iso-PGF2α level changes.
Conclusion: The fast and significant increase of TxB2 and 8-iso-PGF2α levels observed in patients with advanced fibrosis successfully treated with DAA might indicate a shift toward a pro-thrombotic profile concomitant with viral clearance. These findings support the potential need of an antithrombotic prophylaxis administration early on treatment with DAA therapy.

THU-312

Identification of novel resistance associated substitutions for sofosbuvir in HCV genotype 3a

D. Smith[1], A. Ansari[1,2], A. Magri[1], D. Bonsall[1,2], C. Ip[1,2], A. Trebes[2], A. Brown[1], P. Cicconi[2], R. Bowden[2], P. Simmonds[1], E. Barnes[1]. [1]*University of Oxford, Peter Medawar Building for Pathogen Research, Nuffield Department of Medicine, Oxford, United Kingdom;* [2]*University of Oxford, Oxford Genomics Centre, Wellcome Centre for Human Genetics, Oxford, United Kingdom*
Email: david.smith@ndm.ox.ac.uk

Background and Aims: Sofosbuvir is a key component in the treatment of genotype 3 (gt3) HCV infected patients, with a higher barrier to resistance than other direct acting anti-viral compounds. However, resistance associated substitutions (RASs), like NS5B S282T, have been documented. Here, we report novel amino acid substitutions associated with treatment failure identified from a large cohort of gt3a-infected patients treated with sofosbuvir, ribavirin, +/– PEG-interferon (Boson study).

Method: Viral RNA was extracted from 428 baseline (BL) and 68 non-SVR 12-week post treatment (12WPT) viraemic samples, then sequenced with the Illumina MiSeq. To account for host and viral population structure, we only used samples from gt3a infected patients with self-reported "White" ethnicity. BL consensus sequences were scanned for known sofosbuvir RASs in the NS5B protein (L159F, S282T, C316H/N, L320F and V321A). The BL sequences were used to perform a systematic and unbiased viral genome wide association study (GWAS) to investigate the effect of individual amino acid substitutions on SVR. Finally, we compared the BL sequences to the 12WPT sequences and investigated enrichment of previously reported and putative RASs.
Results: No previously reported sofosbuvir RASs were present at BL, however the NS5B RAS L159F was significantly enriched in the 12WPT sequences in comparison to the BL sequences ($p = 6 \times 10^{-4}$). In our viral GWAS of BL sequences for SVR, the only site significantly associated with treatment outcome (at a 10% false discovery rate (FDR)) was I129V in the NS2 protein (Figure), this site was also enriched in our 12WPT samples ($p = 0.01$). Within the NS5B protein, there were no significant associations with SVR at baseline (at 10% FDR), however from the top two strongest associations with SVR, site A150V was significantly enriched in the 12WPT samples ($p = 9 \times 10^{-4}$).

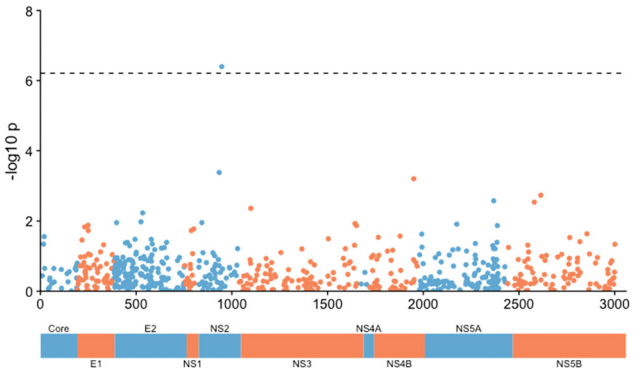

Figure: Manhattan plot of sites in HCV proteome association with SVR. Y-axis shows amino acid position in HCV proteome, X-axis shows the –log10(p) of the association test between the amino acid and SVR. Only the most significant association is shown per position. The dashed line indicates a 10% FDR.

Conclusion: In addition to known sofosbuvir RAS L159F, we identify novel amino acid substitutions in NS2 I129V and NS5B A150V associated with sofosbuvir treatment failure in HCV gt3 infection. Interestingly, A150V has been previously reported as being significantly associated with host IFNL4 genotype in this cohort (Ansari MA, et al., Nat Genet. 2017).

Email: naoky@hawaii.edu

Background and Aims: Genotype 1B (GT1B) is the most prevalent genotype in many European countries. This study examines utilization of and outcomes with elbasvir/grazoprevir (EBR/GZR)-

containing regimens in an updated cohort of GT1B Chronic Hepatitis C (HCV) patients treated as part of the TRIO network in the US.

Method: Data were collected from providers and specialty pharmacies through Trio Health's disease management program. Patients (n = 319) with GT1B HCV who initiated EBR/GZR therapy between Jan 28, 2016 (FDA approval) to Jun 2017 were included. The primary outcome was per protocol sustained virologic response at 12 weeks post treatment (SVR12).

Results: 307 (96%) patients received 12-week EBR/GZR, 6 (2%) 12-week EBR/GZR + RBV, 1 (<1%) 16-week EBR/GZR, and 5 (2%) 16-week EBR/GZR + RBV. Of the patients that received 12-week EBR/GZR, 68/269 (22%) had eGFR < 30 ml/min, 81/267 (26%) had FIB-4 > 3.25 and 55/307 (18%) were treatment experienced. Of the patients that received EBR/GZR with RBV and/or 16 weeks of therapy, 2/10 (20%) had eGFR < 30 ml/min, 3/10 (30%) had FIB-4 > 3.25 and 7/12 (58%) were treatment experienced. At time of data extraction, outcomes were available for 204/319 patients and were: 2% (4/204) died, 6% (12/204) discontinued, 3% (7/204) completed but were lost to follow up, 1% (3/204) completed therapy and had virologic failure, and 87% (178/204) achieved SVR12. The resultant per protocol (PP) SVR12 rate (limited to patients who completed therapy and had an SVR assessment) was 98% (178/181). By regimen, the PPSVR12 was 171/173 (99%) for 12-week EBR/GZR, 4/4 (100%) for 12-week EBR/GZR + RBV, 1/1 (100%) for 16-week EBR/GZR, and 2/3 (67%) for 16-week EBR/GZR + RBV.

Conclusion: The majority of patients with GT1B HCV were treated with 12-week EBR/GZR without RBV in clinical practice with 99% PPSVR. 12-week EBR/GZR is highly effective in this population. Complete SVR results will be available for the conference.

THU-314

Effectiveness and utilization of Grazoprevir and Elbasvir in HCV genotype 1 and 4 infection in the veterans affairs healthcare system in the US

A. Puenpatom[1], J. Kramer[2], Y. Cao[2], D. Smith[2], H. El-Serag[2], F. Kanwal[2].
[1]*Merck Sharp & Dohme Corp;* [2]*Michael E DeBakey VA Medical Center, United States*
Email: puenpatom.amy@merck.com

Background and Aims: Elbasvir/grazoprevir (EBR/GZR), which is indicated for the treatment of chronic Hepatitis C genotype (GT)1 and GT4 infection, has demonstrated high efficacy across clinical studies. We evaluated the real-world effectiveness and utilization among HCV GT1 and GT4 infected patients treated with EBR/GZR regimens in clinical settings within the US Department of Veterans Affairs (VA) healthcare system.

Method: This was a retrospective database analysis of HCV-infected patients treated with EBR/GZR ± RBV in VA clinics. The nationwide VA Corporate Data Warehouse includes laboratory, pharmacy, hospitalizations, and clinical diagnoses data. We included patients with positive HCV RNA who received EBR/GZR ± RBV from January-December 2016 who received treatment for at least 11 weeks. SVR rates were examined overall and by clinical characteristics and comorbidities. We calculated 95% confidence intervals (CIs) for SVR rates using the binomial distribution.

Results: After applying inclusion and exclusion criteria, we identified 4,755 HCV-infected veterans treated with EBR/GZR regimens. Mean age (± SD) was 63.5 ± 6.1 years, 97.0% were male, and 66.3% had viral load higher than 800,000 IU/ml. There were 30.5 percent with cirrhosis, 32.1% with chronic kidney disease (CKD) stage 3–5, and 52.8% diagnosed with diabetes. More than half had history of drug and alcohol abuse (54.2% and 62.9%, respectively). 92.3% of those with GT1 and GT4 were treated with EBR/GZR, 5.8% with EBR/GZR + RBV, and 1.9% with EBR/GZR + SOF ± RBV.

Overall, 96.3% (4579/4755, 95%CI: 95.7%-96.8%) achieved SVR. Of the 4,660 GT1 or GT4 patients, 96.3% (4489/4660, 95%CI: 95.8%-96.9%) achieved SVR. By genotype, 94.8% (1863/1966) of patients with GT1a reached SVR compared to 97.4% (2430/2494) with GT1b, and 97.9% (95/97) with GT4. SVR rates were high across patient subgroups, including for cirrhosis (95.4%, 1356/1421), CKD stage 3–5 (96.5%, 1456/1509), African American (96.6%, 2548/2639), and viral load > 800 k IU/ml (95.5%, 2960/3101).

Conclusion: In this large VA cohort, EBR/GZR was highly effective in GT1 and GT4. HCV-infected veterans in this real-world cohort were older and had high prevalence of health and mental comorbidities. High SVR was achieved across patient subgroups regardless of gender, race/ethnicity, presence of cirrhosis, or level of viral load.

Email: 95565@parcdesalutmar.cat

Background and Aims: The interferon-free 3D regimen (OBV/PTV/r + DSV) has shown high efficacy in patients with hepatitis C virus (HCV) genotype 1b infection. The 3D regimen can achieve sustained virological response (SVR) in 100% of genotype 1b infected patients with or without cirrhosis when administered during 12 weeks [*Andreone et al, Gastroenterology 2014; Feld et al, JHepat 2016*]. Recently, the 8 week administration of the 3D regimen (3D8) has shown 98% SVR rates in treatment-naive non-cirrhotic patients infected by genotype 1b [*Welzel et al, Hepat Int 2017*]. The aim of our study was to assess the efficacy and safety of 3D8 in a real-world cohort of genotype 1b infected treatment-naive patients with mild-moderate liver fibrosis (F0-2).

Method: Multicenter observational study from a Spanish real-life cohort. Treatment-naive patients infected by genotype 1b receiving 3D during 8 weeks (October'16–July'17) and registered in Hepa-C were included. Patients with advanced fibrosis (liver stiffness measurement, LSM > 9.6 kPa [*Ziol et al, Hepatology 2005*]) were excluded. Clinicaltrials.gov: NCT03122132.

Results: A total of 155 patients were registered from 21 Spanish centers. Six patients were excluded (LSM > 9.6 kPa). Preliminary results are presented. Baseline characteristics: 41.6% (n = 62) male, median (range) age was 56.5 (23–86), ALT 48 (22–494)IU/ml, viral load 6.1 (3.3–8.2) $\log^{10}$ IU/ml, 74.5% mild (F0-1) and 25.5% moderate (F2) liver fibrosis. Among patients with available data, viral load was undetectable (<15 IU/ml) at week 4 after treatment initiation in 107 out of 119 (89.9%) patients, at end of treatment (EOT) in 126 out of 126 (100%) and at week 12 after EOT (SVR12) in 93 out of 96 (96.9%). No virological failures occurred during antiviral treatment. After EOT, a relapse in viral load was observed in 3 patients. Regarding treatment safety, one patient showed anemia (Hb < 10 g/dl) not related to 3D regimen (basal Hb level of 9.6 g/dl), and 2 patients developed an

increasement of ALT > 5xULN. No patients had to be discontinued due to adverse events.
Conclusion: Preliminary results of eight weeks of OBV/PTV/r + DSV (3D8) in genotype 1b infected treatment-naive patients with mild-moderate fibrosis show excellent efficacy in a real-life cohort similarly to clinical trials. Moreover, treatment safety of 3D8 is excellent, without treatment discontinuations due to adverse events. Final results will be presented in International Liver Congress®.

THU-316
Multidisciplinary Support Program for patients with addictions and suspected chronic hepatitis C (MSP ADIC-C) to improve their evaluation and access to antiviral treatment
M. Puigvehí[1], F. Fonseca[2], E. González-Colominas[3], D. Giménez[1], A. Viu[1], R. Fernández[1], J. Tirado[2], L. Badenas[2], P. Samos[2], S. Jornalé[2], G. Vallecillo[2], C. Castillo[2], N. Cañete[1], T. Broquetas[1], M.G. Retortillo[1], S. Coll[1], R.S. Lamoglia[1], M. Torrens[2], J.A. Carrión[1]. *[1]Hospital del Mar, IMIM (Hospital del Mar Medical Research Institute), Liver Section, Gastroenterology Department, Barcelona, Spain; [2]Institut de Neuropsiquiatria i Addicions, Hospital del Mar, IMIM (Hospital del Mar Medical Research Institute), Barcelona, Spain; [3]Hospital del Mar, Pharmacy Department, Barcelona, Spain*
Email: 95565@parcdesalutmar.cat

Background and Aims: Patients with addictions (illicit drugs or heavy alcohol intake) have high chronic hepatitis C (CHC) prevalence (32% in our area) (Roncero et al. EJGH, 2017). Alcohol intake and HIV coinfection accelerate the progression to cirrhosis and hepatocellular carcinoma in patients with CHC. Thus, it is a priority to create Multidisciplinary Support Programs (MSP) to identify, evaluate and treat these patients with direct acting antivirals (DAAs). The aim of our study was to create a MSP including primary care physicians and specialists in Mental Health, Internal Medicine, Pharmacy and Hepatology, for the screening, diagnosis, evaluation, treatment and follow-up of patients with addictions and suspected CHC (MSP ADIC-C).
Method: Open prospective study since January 2016, including patients with addictions and suspected CHC (HCV + antibodies) from our hospital. Patients dependent in basic activities of daily living (DBADL), deceased or in jail during the study period were excluded. CHC was confirmed using a PCR test with 15 IU/ml sensitivity. Fibrosis stage was evaluated using transient elastography (TE).
Results: 110 patients with HCV+ antibodies and addictions have been evaluated. Nine patients were excluded. Among 101 included patients, 78 (77.2%) were male, with median (range) age of 45.6 (25.6–64.4), 19 (18.8%) consumed some illicit drug, 17 (16.8%) alcohol intake, 57 (56.4%) under opioid replacement therapy and 8 (7.9%) were abstinent. Forty-seven (46.5%) had a severe mental disorder. Only 6 (5.9%) had received previous antiviral treatment. HIV antibodies were determined in 100 (99%) patients, being positive in 42 (42%), HCV-RNA in 91 (90%) confirming CHC in 90 (98.9%), and HCV genotype in 60 (59.4%). Liver fibrosis was evaluated in 55 (54.5%) patients, showing advance fibrosis or cirrhosis (TE > 9 kPa) in 23 (41.8%). Treatment with DAAs was started in 22 (21.8%): 7 are in treatment, 2 lost during follow-up and 13 are in week 12 after end of treatment; 12 of them (92.3%) have achieved SVR12.
Conclusion: A Multidisciplinary Support Program for patients with addictions and suspected HCV infection (MSP ADIC-C) has allowed to identify and to diagnose practically all patients. Liver fibrosis has been evaluated in more than a half of them, identifying advanced fibrosis or cirrhosis in 41.8%. Preliminary SVR rate is high (92.3%).

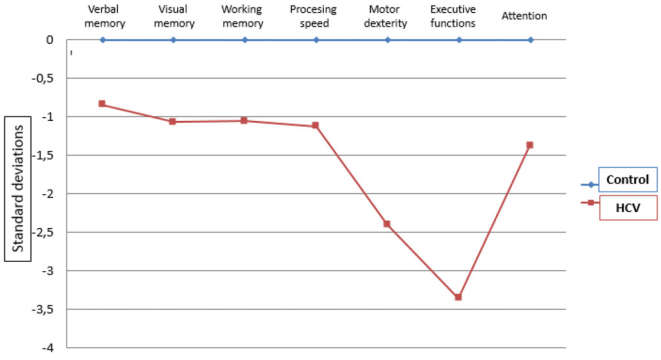
Background and Aims: Hepatitis C-related extra-hepatic manifestations include those affecting central nervous system that could drive to neurocognitive impairment. Our aim is to investigate relationship between chronic hepatitis C and neuropsychological derangements.
Method: We have included two cohorts: 1. Inmates from a penitentiary centre (n = 41), we evaluated them at baseline and post-treatment, after receiving an IFN-free DAA (direct acting antiviral) regimen; 2. Patients attended in our regular out-patient clinic (non-cirrhotic, n = 55). And a control group of 15 subjects, matched by age, gender and educational level. Inmates' post-treatment results were compared to their baseline data.
Results: Inmates (Mean 45.5 ± 6.5 years-old) showed a significant cognitive impairment in visual memory ($p < 0.05$), working memory ($p < 0.05$), processing speed ($p < 0.05$), executive function ($p < 0.05$), attention ($p < 0.05$) and motor dexterity ($p < 0.05$). Executive function and motor dexterity domains showed an intense impairment (Figure). After DAA treatment (all patients achieved sustained virological response), patients showed a significant improvement in: initial verbal learning ($p < 0.05$), speed processing ($p < 0.05$) and attention ($p < 0.05$). Patients at the out-patient clinics showed slight changes, we found a trend in motor dexterity domain ($F = 3.7$, $p = 0.056$), HCV infected patients got the lowest punctuations.



Conclusion: Our preliminary results suggest that HCV infected patients develop motor dexterity impairment; this dysfunction can be recovered after a successful DAA treatment.

THU-319
Effectiveness of 8 vs. 12 week ledipasvir-sofosbuvir (LDV/SOF) in black, treatment naïve patients with non-cirrhotic, genotype 1 HCV and baseline viral load
M. Curry[1], B. Bacon[2], S. Flamm[3], A. Landen[4], S. Milligan[4], N. Tsai[5], Z. Younossi[6], N. Afdhal[1]. *[1]Beth Israel Deaconess Medical Center, Boston, United States; [2]Saint Louis University School of Medicine, St. Louis, United States; [3]Northwestern University Feinberg School of Medicine, Chicago, United States; [4]Trio Health, La Jolla, United States; [5]Queens Medical Center – University of Hawaii, Honolulu, United States; [6]Inova Fairfax Hospital, Department of Medicine, Falls Church, United States*
Email: mcurry@bidmc.harvard.edu

Background and Aims: AASLD/IDSA guidance does not recommend shortening ledipasvir-sofosbuvir (LDV/SOF) to less than 12 weeks for treatment-naïve black patients with non-cirrhotic genotype 1 (GT1) HCV. In the ION-3 trial, black patients who were treatment naïve, F0-3

with GT1 HCV treated with LDV/SOF had SVR rates of 96% (26/27) with 8 weeks and 96% (22/23) with 12 weeks which was similar to that observed in non-black patients (97% and 96% for 8 and 12 weeks, respectively). This updated analysis of TRIO health examines the efficacy of LDV/SOF for 8 or 12 weeks in a larger sample of black, treatment naïve patients with non-cirrhotic genotype 1 HCV and baseline viral load <6 mm IU/ml.

Method: Data were collected from providers and specialty pharmacies through Trio Health's disease management program. Exclusion criteria included baseline platelets <150 K/mcl, baseline FIB-4 > 3.25, HIV or HBV coinfection, unknown genotype 1 subtype, and prior treatment experience. Patients not removed by the exclusion criteria, self-identified as black, and who initiated 8 (n = 114) or 12 (n = 98) week LDV-SOF therapy between Oct 2015 to Mar 2017 were included.

Results: The 8 and 12-week treatment groups were similar for baseline characteristics of genotype subtype, viral load, eGFR, ALT, AST, BMI, and FIB-4. Also similar were mean age, percent male gender, and rates of anxiety, depression, diabetes, and hypertension. Significant differences between the groups were limited to payer type; a greater percentage of patients treated for 8 weeks had commercial or Medicaid coverage. Patient disposition is shown in the Figure. The per protocol (PP) SVR12 rates, limited to patients who completed therapy and an SVR assessment, were 97% (93/96) for the 8-week treatment group and 99% (86/87) for the 12-week group; rates not statistically different (Z = –0.91; p = 0.36).

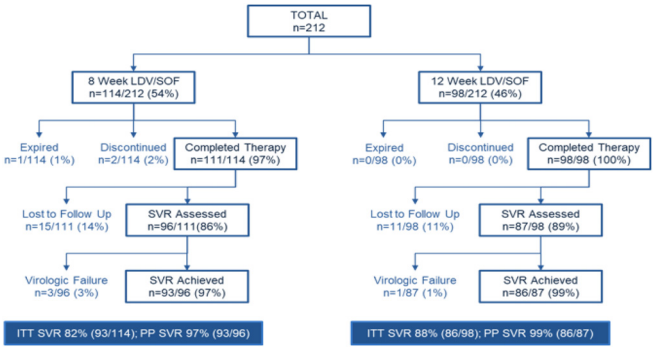


Figure: Patient Disposition.

Conclusion: Clinical efficacy as measured by PP SVR12 is high with both 8 and 12 week LDV/SOF in black, treatment naïve patients with non-cirrhotic genotype 1 HCV and baseline viral load <6 mm IU/ml, demonstrating that this population does not benefit from extended duration of treatment.

THU-320

Effectiveness of elbasvir/grazoprevir in patients with cirrhotic genotype 1 or 4 chronic hepatitis C: updated retrospective data analyses from the Trio network

M. Curry[1], S. Flamm[2], B. Bacon[3], S. Milligan[4], C. Nwankwo[5], N. Tsai[6], N. Wick[4], Z. Younossi[7], N. Afdhal[1]. [1]*Beth Israel Deaconess Medical Center, Boston, United States;* [2]*Northwestern University Feinberg School of Medicine, Chicago, United States;* [3]*Saint Louis University School of Medicine, St. Louis, United States;* [4]*Trio Health, La Jolla, United States;* [5]*Merck & Co., Inc., Kenilworth, United States;* [6]*Queens Medical Center-University of Hawaii, Honolulu, United States;* [7]*Inova Fairfax Hospital, Department of Medicine, Falls Church, United States*
Email: mcurry@bidmc.harvard.edu

Background and Aims: Historically, HCV treatment has been less effective in patients with cirrhotic disease. This study examines utilization of and outcomes with elbasvir/grazoprevir (EBR/GZR)-containing therapies in patients with cirrhosis and genotype (GT) 1 or 4 Chronic Hepatitis C (HCV).

Method: Data on patients who initiated EBR/GZR therapy between Jan 28, 2016 (FDA approval) to Jun 2017 for GT1 or 4 were collected from providers and specialty pharmacies in the US through Trio Health's disease management program. To ensure the correct identification of cirrhosis, patients were required to have both a baseline FIB-4 > 3.25 and practice-reported fibrosis score 4 for inclusion in the analysis. The primary outcome assessed was per protocol (PP) sustained virologic response at 12 weeks post treatment (SVR12).

Results: 115 patients met the study inclusion criteria. 3/115 (3%) patients had GT4 HCV. 2/3 of GT4 patients received 12 week EBR/GZR; 1 completed therapy and was lost to follow up and 1 achieved SVR. The resultant per protocol (PP) SVR12 rate (limited to patients who completed therapy and had an SVR assessment), was 1/1 (100%). 1/3 GT4 patients received 12 week EBR/GZR + RBV and achieved SVR (PPSVR12 1/1, 100%). 112/115 (97%) patients had GT1 HCV; 103/112 (92%) received 12-week EBR/GZR and 9/112 (8%) received EBR/GZR with RBV and/or for 16 weeks duration. At time of data extraction, outcomes were available for 85/112 GT1 patients and were: 5/85 (6%) died, 3/85 (4%) discontinued, 2/85 (2%) completed therapy but were lost to follow up and 75/85 (88%) had an SVR12 assessment. The PPSVR12 rate for GT1 was 72/75 (96%); by regimen, the PPSVR12 rates were 66/67 (99%) and 6/8 (75%) for 12-week EBR/GZR and EBR/GZR with RBV and/or for 16 weeks duration, respectively.

Conclusion: In this study of cirrhotic, EBR/GZR-treated patients in US clinical care, most patients were with GT1 HCV and treated with 12-week EBR/GZR without RBV. 12-week EBR/GZR was highly effective with an overall PPSVR12 rate of 67/68 (99%). Complete SVR results will be available for the conference.

Email: vanessa.witte@msd.de

Background and Aims: HCV GT1b infection independent of baseline viral load (BVL) as well as GT1a infection with BVL < 800,000 IU/ml can be successfully treated with EBR/GZR for 12 weeks. In contrast, for GT1a infection with BVL > 800,000 IU/ml European guidelines recommend baseline NS5A RAS-testing and lengthening of EBR/GZR to 16 weeks together with RBV in the presence of NS5A RAS or when RAS-testing is not available. Therefore, the present analysis investigated the real-world utilization of this recommendations and the possible impact on EBR/GZR effectiveness in a large GT1 cohort of the German Hepatitis C Registry.

Method: From September 2016 until August 2017, 535 patients (pts) with genotype 1 infection were treated with EBR/GZR +/– RBV for 12 to 16 weeks in 110 medical practices and hospital outpatient departments. The present interim analysis was restricted to 531 pts with documented GT1 subtypes.

Results: In total, 180 pts with GT1a infection (33.9%) and 351 pts with GT1b infection (66.1%) received EBR/GZR-based treatment and showed the following characteristics (GT1a vs. GT1b): mean age 48 vs. 56 years, female gender 27 vs. 44%, BVL > 800.000 IU/ml 52 vs. 58%, liver cirrhosis 18 vs. 18%, opioid substitution 27 vs. 4%, HIV co-infection 9 vs. 2%, renal dysfunction 8 vs. 12% and treatment-naïve 75 vs. 77%. RAS at baseline were tested in 39 of 92 GT1a pts (42%) with BVL > 800.000 IU/ml. 4 pts (10%) had NS5A RAS of which 3 were treated with EBR/GZR + RBV and 1 with EBR/GZR. Furthermore, 3 pts without RAS and 29 pts without RAS testing received RBV. In total, 35/92 of GT1a pts (38%) with high BVL were treated with EBR/GZR + RBV. Although not recommended by the European guidelines, NS5A RAS were tested in 35 of 86 GT1a pts (41%) with low BVL and in 23 of 351 pts (7%) with GT1b infection while 7 of 86 pts (8%) with GT1a and low BVL and 1 of 351 pts (0.3%) with GT1b infection received RBV. By now SVR12 results were available from 63/531 pts. Overall per protocol SVR12 was 98% (61/62) with comparable SVR12 rates for GT1a (100%, 18/18) and GT1b (98%, 43/44).

Conclusion: In German real-world practice, 92% of pts with GT1 receiving EBR/GZR are treated without RBV. Addition of RBV is mainly restricted to pts with high BVL > 800,000 IU/ml of which more than 40% are tested for NS5A RAS at baseline. The current treatment with EBR/GZR seems to be highly effective. Full SVR12 data by GT1 subtypes and BVL will be presented at the conference.

THU-322

High efficacy of IFN-free DAA therapy for acute HCV infection in HIV patients

D. Chromy[1], M. Mandorfer[1], T. Bucsics[1], P. Schwabl[1], B. Scheiner[1], C. Schmidbauer[1], M. Aichelburg[2], P. Ferenci[1], M. Trauner[1], M. Peck[1], T. Reiberger[1]. *[1]Medical University of Vienna, Department of Internal Medicine III, Division of Gastroenterology and Hepatology, Vienna, Austria; [2]Medical University of Vienna, Dermatology, Immunology, Allergy and Infectious Diseases, Vienna, Austria*
Email: n1142399@students.meduniwien.ac.at

Background and Aims: In a recent study treatment of acute hepatitis C (AHC) with direct-acting antivirals (DAA) for 6 weeks was highly effective in AHC mono infection. However, same treatment duration resulted in suboptimal sustained virologic response rates twelve weeks after treatment (SVR12) in AHC/HIV coinfection. Thus, we evaluated the virological response to IFN-free DAA regimens in HIV+ patients with AHC.

Method: All patients diagnosed with AHC at our HIV/Liver outpatient clinic since the availability of DAAs were retrospectively analyzed. Diagnosis of AHC was established in accordance with the criteria defined by the European AIDS treatment network (NEAT) consensus conference. Two patients with chronification prior to treatment uptake and diagnosis of plasma cell myeloma, respectively, were excluded from analysis.

Results: n = 28 HIV+ male patients with AHC with high-risk MSM practices under recreational drug influence as the main suspected route of transmission (86%, 24/28) were started on IFN-free DAA regimens. The mean age was 44.5 ± 9.85 years, HCV Genotype (GT) was predominately GT-1a in 71% (20/28) followed by GT-1b 11% (3/28), GT-3 11% (3/28) and GT-4 7% (2/28). Alanine transaminase (ALT) was significantly elevated at AHC diagnosis (280 ± 260 IU/mL) and 64% (18/28) presented with a median liver stiffness (LS) of 7.70 kPa (5.00).

Most patients (57%; 16/28) received ombitasvir/paritaprevir/ritonavir/dasabuvir, while ombitasvir/paritaprevir/ritonavir, sofosbuvir/ledipasvir, grazoprevir/elbasvir and glecaprevir/pibrentasvir were initiated in 7% (2/28), 18% (5/28), 7% (2/28) and 11% (3/28), respectively.

All patients were on antiretroviral therapy (ART), mostly on nucleosidic reverse transcriptase inhibitors (96%; 27/28) plus integrase inhibitors (79%; 15/28), prescribed concomitantly. In 25% (7/28) was an ART switch required prior to treatment initiation to avoid drug-drug interactions. Suppression of HIV-RNA under antiretroviral therapy (<50 copies/ml) was observed in 89% (25/28).

Patients received HCV treatment for at least 12 weeks following recommendations for chronic HCV. At the time of data collection, information on SVR12 was available in 64% (18/28) of patients with all (100%) achieving SVR12. Furthermore, all patients had ALT levels within the upper limit of normal at SVR12 while median LS declined (6.50 kPa (3.80) vs. baseline; p = 0.334).

Conclusion: In our cohort, treatment with IFN-free DAA regimens achieves 100% SVR12 rates in HIV+ patients with AHC. SVR12 resulted in significant decreases in transaminases and a trend towards LS reduction. Future studies should evaluate shorter treatment durations with IFN-free DAA regimens in AHC/HIV coinfection.

THU-323

High SVR rates in patients with and without cirrhosis treated in real life with Sofosbuvir/Velpatasvir (SOF/VEL) combination for 12 weeks without Ribavirin (RBV)

A. Mangia[1], V. Piazzolla[1], R. Losappio[2], M. Mazzola[2], E. Visaggi[3], D. Bacca[4], F. Sogari[5], D. Potenza[6], R. Santoro[1], I. Carraturo[7], V. Tagarielli[8], G. Lauletta[9], A. Giannelli[2], A. Gesualdo[10], N. Minerva[11]. *[1]Liver Unit IRCCS "Casa Sollievo della Sofferenza", San Giovanni Rotondo, Italy; [2]Infectious Diseases, Bisceglie, Italy; [3]Infectious Diseases, Terlizzi, Italy; [4]Gastroenterology, Casarano, Italy; [5]Internal Medicine, Tranto, Italy; [6]Infectious Diseases, Brindisi; [7]Infectious Diseases, Lecce; [8]Infectious Diseases, Acquaviva delle Fonti; [9]Internal Medicine Baccelli Policlinico, Bari; [10]Internal Medicine Murri Policlinico, BAri; [11]Internal Medicine, Canosa*
Email: a.mangia@tin.it

Background and Aims: Pangenotypic regimens are now available for treatment of patients with chronic HCV infection. However, for some of them, treatment duration needs to be adjusted depending on cirrhosis and/or genotype. To confirm in real life usefulness of "one size fits all" strategy using SOF/VEL for 12 weeks regardless of baseline features, we analysed data on treatments performed in Puglia (Italy) in patients with and without cirrhosis regardless of HCV genotype.

Method: From the Regional register, 1,099 patients were started on treatment from May 15th to November 1st 2017. Patients were treated at physician discretion and data collected within a collaborative group. Diagnosis of advanced fibrosis/cirrhosis was based on transient elastography and APRI score according to the standard thresholds. This analysis refers to 513 HCV mono-infected patients who completed SVR4 by November 1st.

Results: The majority of patients were male (55%), of mean age 63.2 (18–90). High proportion of patients (38.9%) was older than 70 yrs. 223 (43.5%) had cirrhosis/advanced fibrosis as compared to 27.8% with stage 0-1; the remaining had fibrosis stage 2. The proportion of naïve was 75.3%. Diabetes was present in 20.5%, history of IVDA in 19.5%% and active IVDA in 8.8%. GT1 was represented in 36.2% of cases; however, as a consequence of high GT2 prevalence in our region, GT2 was the most frequent (46.8%). Of the remaining, 17.2% had GT3 and 9.8% GT4. All but 4 patients received 12 weeks of therapy without RBV. 4 patients prematurely discontinued treatment; in 2 of 4 HCV RNA is currently undetectable.

Overall, SVR was 98.6% at ITT analysis and 99% at PP analysis. Rates were 97.9% in patients with advanced fibrosis/cirrhosis and 98% in those with mild fibrosis. Among fibrosis stage 2, 100% of patients achieved SVR. No differences in SVR rates were observed across HCV genotypes: SVR was 100% in GT1b, 98% in GT1a, 97.9% in GT2 and 100% in GT3 and GT4. SVR was 99.2% and 98.6% in naïve and experienced respectively. No difference in SVR rates was observed between diabetic and non-diabetics (100% vs 98.6%). Among IVDA, 100% achieved SVR.

Conclusion: Pangenotypic SOF/VEL combination is associated with 98.6% SVR4 in patients with all HCV genotypes, with or without cirrhosis treated for 12 weeks. RBV is not needed in patients with compensated cirrhosis treated with this combination. SOF/VEL is a suitable treatment for HCV infected patients regardless of baseline characteristics.

THU-324

The evolution of treatment for HCV Genotype 3 (GT3) infected patients with advanced fibrosis/cirrhosis over time

A. Mangia[1], G. Cenderrello[2], M. Copetti[3], R. Santoro[1], F. Sogari[4], V. Piazzolla[1], N. Minerva[5], M. Mazzola[6], R. Losappio[6], P. Vincenzo[7], G. Spinzi[8], D. Potenza[9], G.D. Stefano[10]. *[1]Liver Unit IRCCS "Casa Sollievo della Sofferenza", San Giovanni Rotondo; [2]Galliera Hospital, Infectious Diseases, Genova; [3]Biostatistic Unit IRCCS "Casa Sollievo della Sofferenza", San Giovanni Rotondo; [4]Internal medicine, SS Annunziata Hospital, Taranto; [5]Internal Medicine, Ospedale Caduti in Guerra, Canosa; [6]Infectious Disease, Vittorio Emanuele II Hospital, Bisceglie; [7]Internal Medicine, Padiglione Murri Policlinico, Bari; [8]Gastroenterology, Valduce Hospital, Como; [9]Infectious Disease, Perrino Hospital, Brindisi; [10]Infectious Disease, Ospedale Santa Maria delle Grazie, Matera*
Email: a.mangia@tin.it

Background and Aims: Treatment of GT3 remains challenging. To identify, in a large cohort of Italian patients with cirrhosis/advanced fibrosis, the impact of viral predictors of virological failure, across recently used Interferon-(IFN) free regimens.
Method: Patients were treated following the Italian guidelines within a protocol implemented by 9 centers from South and 2 from North of Italy working together on genetic projects.
Results: Between March 2015 and September 2017, the combinations of sofosbuvir (SOF) plus ribavirin (RBV), SOF plus daclatasvir (DCV) and SOF plus velpatasvir (VEL) were implemented. Of 355 patients with available SVR, 39.2% were Peg/IFN-experienced. SOF/RBV was used in 19.5%, SOF/DCV in 62.0%, SOF/VEL in 18.5%. Overall SVR was 87.5% ranging from 78.6% after SOF/RBV to 87.2% after SOF/DCV or 98.4% after SOF/VEL (p = 0.003). 169 patients (47.6%) had cirrhosis. SVR was 83.2% for cirrhotics and 91.4% for non cirrhotics (p = 0.024). Baseline NS5A associated RASs were present in 9.2%, PNPLA3GG genotypes in 8.2%, IL28BCC in 33.7%. No association between favorable genetics and SVR was observed. Independent predictors of relapse were prior Peg/IFN/RBV failure (OR = 3.82, 95%CI 1.70–8.58), baseline NS5ARASs (OR = 3.73 95%CI 1.32–10.51), cirrhosis (OR = 2.41, 95%CI 1.10–5.31) and treatment regimen (OR = 2.88 95% CI 1.56–5.33).

	Overall n = 355	SOF/RBV n = 70	SOF/DCV n = 219	SOF/VEL n = 66	P value
Male (n, %)	289 (81.5)	60 (85.7)	173 (79.0)	56 (89.1)	0.28
	66 (18.5)	10 (14.3)	46 (21.0)	10 (14.2)	
Age (mean, range)	50.5	50.9	50.7	49.2	0.45
	18–87	37–66	26–87	18–69	
Treatment history					
Naive	216 (60.8)	33 (47.1)	136 (62.1)	46 (69.8)	0.06
Relapser	52 (14.8)	12 (17.1)	34 (15.5)	6 (9.5)	
Prior Non responders	87 (24.4)	25 (35.7)	49 (22.4)	14 (20.6)	
Cirrhosis	169 (47.6)	37 (52.9)	100 (45.7)	32 (48.4)	0.57

Conclusion: Our real-world results validate the efficacy of past and current GT3 IFN-free regimens suggesting that, among patients with severe disease, Peg/IFN/RBV experience and NS5A associated RASs resulted till recently predictors of relapse. Their relevance can be expected to decline with the use of SOF/VEL.

THU-325

Impact of acid-reducing agents on effectiveness of Elbasvir/Grazoprevir in treating US veterans affairs population with hepatitis C virus

J. Kramer[1], A. Puenpatom[2], Y. Cao[1], D. Smith[1], H. El-Serag[1], F. Kanwal[1]. *[1]Michael E DeBakey VA Medical Center, Center for Innovations in Quality, Effectiveness and Safety (IQuESt), Houston, United States; [2]Merck Sharp & Dohme Corp, Whitehouse Station, United States*
Email: jkramer@bcm.edu

Background and Aims: Acid-reducing agents (ARAs) including proton pump inhibitor (PPI) and histamine H2-receptor antagonist (H2RA) use may decrease bioavailability of some direct acting antiviral agents (DAAs), leading to treatment failures of hepatitis C (HCV) infection treatment. Clinical trials showed that no drug-drug interaction is expected when elbasvir/grazoprevir (EBR/GRZ) is co-administered with ARAs. This study assessed the effect of ARAs use on SVR among HCV-infected patients treated with EBR/GRZ in a large real-world clinical setting.
Method: We conducted a nationwide retrospective observational cohort study of HCV patients seen at the US Department of Veterans Affairs (VA) using the VA Corporate Data Warehouse (includes laboratory, pharmacy, hospitalizations, and clinical diagnoses). The study population included patients with positive HCV RNA who had filled prescriptions for at least 11 weeks of EBR/GRZ with or without ribavirin (RBV) during January–December 2016. Concomitant PPI or H2RA use was defined as ≥1 filled prescription <30 days prior to EBR/GRZ initiation date through the end of treatment. We examined SVR rates overall and stratified by PPI and H2RA use.
Results: We evaluated 4,755 HCV-infected patients treated with EBR/GRZ regimens. Most were male (97.0%), African American (56.3%), with mean age of 63.5 (SD = 6.1), and 96% infected with genotype (GT)1. Overall, 32.8% of patients had concomitant PPI use, of these 41.5% had twice daily and 58.5% had once daily. Other comorbidities included diabetes (52.8%), depression (57.5%), cirrhosis (30.5%), and HIV (2.8%). Among those treated with EBR/GZR regimens with GT1 and GT4, 96.3% (n = 4,489/4,660; 95%CI: 95.8%-96.9%) achieved SVR. In patients with concomitant PPI use, 96.5% (N = 1481/1535) achieved SVR compared with 96.3% (n = 3,008/3,125) in patients without PPI use (p = 0.70). There was no significant difference in SVR in patients with twice daily or once daily PPI (96.4%, n = 616/639 vs. 96.5%, n= 865/896; p = 0.92). There was no significant difference of SVR rates were found in patients with H2RA use (95.9% vs. 96.4% without H2RA; p = 0.72).
Conclusion: EBR/GRZ achieved high effectiveness in treating HCV in the VA population. These results demonstrate that PPI and H2RA concomitant use with EBR/GZR had no clinically significant effect on SVR rates in genotype 1 or 4-infected patients.

THU-326

HCV treatment responses among people who use drugs: an evaluation of patients on and off opiate agonist therapy in a real-life setting

J. Holeksa, A. Bassi, A. Alimohammadi, A. Thiam, B. Conway. *Vancouver Infectious Diseases Centre*
Email: julie.holeksa@vidc.ca

Background and Aims: Current guidelines identify people who use drug (PWUD) as a "priority population" to receive HCV treatment within a multidisciplinary system of care. Clinical trials have shown such an approach to be successful within the context of individuals integrated in opiate agonist therapy (OAT) care (C-EDGE CO-STAR). Other trials (D3FEAT, SIMPLIFY) have evaluated HCV-infected PWUD receiving health care many of whom were not on OAT. SVR12 rates > 90% were obtained in both studies, and participation in OAT did not

appear to affect the likelihood of achieving this outcome. There is a need to confirm these data in real life with a view to evaluating whether enrollment in an OAT program is necessary prior to initiating HCV therapy.

Method: Patients receiving all oral HCV therapy at the Vancouver Infectious Diseases Centre (VIDC) between 06/15 and 09/17 were enrolled in this observational study. All participants were active PWUD (positive urine drug screen for recreational drugs within the previous month) and enrolled in our multidisciplinary program (delivery of medical, social, psychiatric, and addiction-related services) for at least one month. HCV therapy was initiated according to the contemporary standard of care. At baseline, participants were considered according to enrollment on OAT (methadone or suboxone) or not, as clinically indicated. The outcome of interest was achievement of SVR12, as a function of receipt of OAT therapy, while accounting for other variables potentially correlated with successful HCV therapy.

Results: A total of 101 subjects were enrolled (64/37 on and off OAT respectively). Key baseline characteristics were: median age 52 years; 75% male; 71/6/15/8% GT 1a, 1b, 3, other; 20% F4; 77/42/41% using opiates/cocaine/amphetamines. In comparing the OAT and non-OAT patients there were no marked differences in any of these baseline parameters. Of 37 subjects not on OAT, 34 achieved SVR, 1 discontinued, and 2 were lost to follow up (ITT SVR12 92%, mITT 97%). Of 64 subjects on OAT, 55 achieved SVR, 5 were lost to follow up, and 4 experienced virologic relapse (ITT SVR 12 86%, mITT 93%). Due to sample size, significance analysis could not be performed to compare SVR rates between the two groups. The 4 virologic relapses were all male, GT 1a, 3/4 reported active drug use during treatment in addition to receiving OAT, and 2/4 are co-infected with HIV.

Conclusion: These real-life data confirm the results of clinical trials of HCV treatment among PWUD. They further suggest that prior enrollment in OAT is not a pre-condition of considering HCV therapy in this group. The variable of interest to consider HCV therapy may be enrollment in a multidisciplinary program such as ours. This information is essential to the development of programs among PWUD to achieve the World Health Organization goals for the control of HCV infection by 2030.

VIEKIRA PAK (ritonavir-boosted paritavir/ombitasvir and dasabuvir) associated drug-induced interstitial lung disease: Case series with systematic review

Y.J. Wong[1], S.Y. Chew[2], P.H. Thurairajah[3], R. Kumar[1], J.H. Chen[1], R.S. Gokhle[2], I.M. Noor[2], J. Tan[1]. *[1]Changi General Hospital, Gastroenteorlogy and Hepatology, Singapore, Singapore; [2]Changi General Hospital, Respiratory Medicine and Critical Care, Singapore, Singapore; [3]Changi General Hospital, 2 Simei Street 3, Singapore, Singapore*
Email: eugene.wong@mohh.com.sg

Chronic hepatitis C virus (HCV) infection is a serious cause of liver-related morbidity and mortality worldwide, affecting more than 170 million patients globally. Oral direct-acting antivirals (DAA) have since replaced conventional interferon and ribavirin as first line HCV therapy due to a better tolerability profile and high efficacy in achieving sustained virological response. VIEKIRA PAK (ritonavir-boosted paritavir/ombitasvir and dasabuvir), a combination of potent DAA, is an effective initial treatment for HCV genotype 1 infection in patients with or without cirrhosis and in patients who may or may not have received interferon-ribavirin therapy before. We describe two patients who developed severe DILD requiring mechanical ventilation for respiratory failure on day 8 and day 40 of VIEKIRA PAK therapy who recovered after supportive management with systemic corticosteroids and systemically reviewed the literature on VIEKIRA PAK associated DILD. Although the incidence of pulmonary toxicity is low in Phase 3 clinical studies, there have been emerging case reports of VIEKIRA PAK associated drug-induced interstitial lung disease (DILD). Although recovery is reported with supportive care in all cases, VIEKIRA PAK associated DILD is often life-threatening and VIEKIRA PAK may have to be discontinued permanently. In summary, VIEKIRA PAK associated DILD is a rare yet potentially near-fatal complication that should be recognized early by physicians.

THU-328

HCV genetic diversity by geographic region within genotype 1–6 subtypes among patients treated with Glecaprevir and Pibrentasvir

G. Schnell, R. Tripathi, P. Krishnan, J. Beyer, T. Reisch, M. Irvin, T. Dekhtyar, L. Lu, I.C. Ng, W. Xie, T. Pilot-Matias, C. Collins. *AbbVie Inc., Research & Development, North Chicago, United States*
Email: gretja.schnell@abbvie.com

Background and Aims: The regimen containing glecaprevir (GLE, NS3/4A protease inhibitor, identified by AbbVie and Enanta) and pibrentasvir (PIB, NS5A inhibitor) is highly efficacious for the treatment of HCV genotype (GT) 1–6 infection. We analyzed a large dataset of NS3/4A and NS5A sequences generated from HCV GT1–6-infected patient samples to assess genetic diversity within HCV subtypes by geographic region, and determined the activity of GLE or PIB against NS3 or NS5A GT1–6 clinical isolates.

Methods: The full-length HCV NS3/4A and NS5A genes from 2416 available baseline samples in studies SURVEYOR-1, -2, ENDURANCE-1, -2, -3, -4, -5/6, and EXPEDITION-1, -4 were sequenced by next-generation sequencing using Illumina MiSeq. NS3/4A and NS5A sequences were grouped by genotype and subtype, and included in phylogenetic analyses to assess genetic relationships within GT1–6 subtypes and prevalence of baseline polymorphisms by country. The activity of GLE or PIB was assessed against HCV transient replicons containing NS3 or NS5A from a panel of GT1–6 clinical samples.

Results: Among 2416 baseline samples, 47 subtypes were identified, including 3 GT1 (n = 861), 9 GT2 (n = 537), 3 GT3 (n = 635), 15 GT4 (n = 170), 1 GT5 (n = 49), and 16 GT6 (n = 77) subtypes. Phylogenetic analyses of GT1 sequences confirmed the presence of 2 clades in subtype 1a, and in subtype 1b clustering by country was most notable for sequences from Poland and Taiwan. In GT2a, sequences from Europe (especially Lithuania) and North America sorted away from Asian countries of Korea and Taiwan, while sequences from New Zealand clustered in both subtypes 2a and 2b. Minimal clustering was seen by country in GT3. In GT5a, clustering was most notable for sequences from Belgium. Two distinct phylogenetic groups were detected in both GT4a and GT6e, representing 2 putative clades in these subtypes. Among GT1–6 clinical isolates, GLE or PIB retained activity against NS3 or NS5A with or without polymorphisms at positions important for the inhibitor class.

Conclusions: Phylogenetic clustering by country was detected in HCV subtypes 1b, 2a, 2b, and 5a, suggesting that genetically similar virus lineages are circulating in some countries. Two putative clades were detected in GT4a and GT6e, which did not segregate by country of enrollment. Regardless of the phylogenetic diversity within each subtype, high virologic response rates were observed among GT1–6-infected patients treated with the regimen of GLE/PIB.

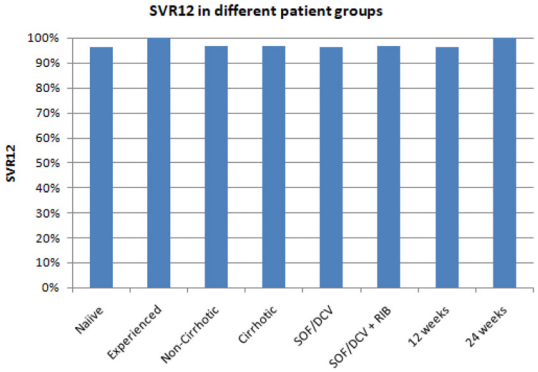
Is treatment of hepatitis C with controlled generic direct acting antiviral drugs effective? An Egyptian experience

G. Soliman[1], M.S. Negm[1], M. Elzalabany[2], A.A. Malik[1], A. Khattab[3], M. Elshair[1], M.G. Abdel-Hamid[4], M.Y. Soliman[5], D. Miller[6], T. Hassanein[7]. *[1]Faculty of Medicine, Al-Azhar University, Tropical Medicine, Gastroenterology and Hepatology Department, Cairo, Egypt; [2]Ahmed Maher Teaching Hospital, Internal Medicine Department, Cairo, Egypt; [3]Agoza Police Hospital, Tropical Medicine, Gastroenterology and Hepatology Department, Cairo, Egypt; [4]Aswan University Hospitals, Tropical Medicine Department, Aswan, Egypt; [5]Tanta Fever Hospital, Hepatology and Endoscopy Department, Tanta, Egypt; [6]John A. Burns School of Medicine, University of Hawaii, Department of Tropical Medicine, Medical Microbiology and Pharmacology, Honolulu, Hawaii, United States; [7]Southern California Liver Centers, Coronado, CA, United States*
Email: dr_msf@hotmail.com

Background and Aims: Oral DAAs have revolutionized the treatment of HCV with shorter treatment duration and higher rates of SVR, albeit being very expensive. Egypt has very high HCV prevalence and the cost of treatment is prohibitive. Here, we report real life treatment outcomes using affordable generic sofosbuvir (SOF) and daclatasvir (DCV) at Tahya Misr HCV Treatment Center in Luxor, Egypt.
Method: Patients aged 18–75 years and positive for HCV RNA were enrolled into the treatment program, while patients with advanced cirrhosis (CTP B&C), hepatocellular carcinoma, extrahepatic malignancy, uncontrolled diabetes and pregnancy were excluded. Eligible patients were classified into two groups; Easy to treat (ET) (treatment naive, albumin ≥3.5 gm/dl, bilirubin ≤1.2 mg/dl, platelet count ≥150,000 cell/mm^3, INR ≤ 1.2) and difficult to treat (DT) (interferon experienced, albumin <3.5 gm/dl, bilirubin >1.2 mg/dl, platelet count <150,000 cell/mm^3, or INR > 1.2). ET patients were treated with SOF 400 mg plus DCV 60 mg once daily for 12 weeks. Ribavirin (RBV) 600 mg daily was added for DT patients. Patients who previously failed SOF-based regimens were treated with SOF/DCV/RBV for 24 weeks. We analyzed the data of 522 patients treated at the center from June to September 2016. 12 patients (2.3%) did not complete treatment due to lack of adherence and 86 patients (16.5%) were lost to follow-up after finishing therapy.
Results: Of the 424 patients included, 251 were males (59.2%). The mean age was 55.5 ± 9.8 years. 389 patients (91.8%) were treatment naive, 15 patients (3.5%) were experienced to interferon and 20 patients (4.7%) to SOF-based regimens. 21.2% of the patients were cirrhotic. Six patients were positive for HBsAg with low HBV viral load. 262 patients (61.8%) were treated with SOF/DCV and 162 patients (38.2%) with SOF/DCV/RBV. 405 patients (95.5%) were treated for 12 weeks and 19 patients for 24 weeks. SVR12 was achieved in 410 patients (96.7%), while 14 patients (3.3%) failed therapy. SVR was not affected by the different variables (Figure). SVR was similar in both ET & DT groups. Side effects were reported in less than 10% and were mainly headaches, fatigue and nausea.



Conclusion: (1) The combination of SOF/DCV is highly effective in curing HCV GT4; (2) Applying standard protocols, SVR rate in real life is similar to clinical trials; (3) Generic SOF/DCV is safe and as effective in treating HCV GT4 as brand DAAs. In summary, guaranteeing the quality of generic DAAs will impact HCV therapy in low income countries.

THU-330

Real-life experience of ritonavir-boosted paritaprevir, ombitasvir plus ribavirin for treatment of HCV-GT4 in Egyptian patients with severe renal impairment

H. Omar[1], M. Said[1], Z. Abdellatif[1], Y. Saad[1], H. Dabes[2], S. Hamed[2], M. El-Serafy[1], K. Elsaeed[3], Y. Elshazly[3]. *[1]Faculty of Medicine, Cairo University, Endemic Medicine and Hepatology Department, Egypte; [2]National Medical Institute of Damanhour; Egypte; [3]Faculty of Medicine. Ain Shams University, General Medicine, Hepatology and Gastroenterology Department, Egypte*
Email: hebaomar1202@hotmail.com

Background and Aims: Management of HCV in adults with significant kidney disease (estimated glomerular filtration rate (eGFR) < 30 ml/min per 1.73 m^2) has been markedly revolutionized with the availability of new direct-acting antiviral agents. However, little is known about the efficacy and safety of these agents in the treatment of this historically difficult-to-treat population. The current study aimed at evaluation of the efficacy and safety of 12 weeks therapy with ritonavir-boosted paritaprevir, ombitasvir plus ribavirin for chronic HCV patients with severe renal impairment.
Method: 171 patients with HCV genotype 4 infection and severe chronic kidney disease (eGFR < 30 ml/min/1.73 m^2 +/– requiring hemodialysis) were prospectively included and treated with ritonavir-boosted paritaprevir, ombitasvir and ribavirin for 12 weeks at Damanhur specialized HCV treatment center affiliated to the Egyptian NCCVH from 4/2016 to 10/2017. The most common etiology of CKD was diabetes and/or hypertension (n = 67). The primary end point was sustained virologic response (serum HCV RNA <15 IU/ml) 12 weeks after treatment ended (SVR12). Data on on-treatment adverse events (AEs), serious AEs, laboratory abnormalities, treatment discontinuation were collected.
Results: 171 patients were included (females 35%, mean age 53 years). 29 patients had liver cirrhosis. All included patient reached the end of treatment (EOT) with no treatment discontinuations. The overall EOT response was 100%. 122/122 (100%) patients who reached 4 weeks post-treatment have achieved SVR4, and 80/80 (100%) have achieved SVR12. To date, no reported SAEs. Ribavirin therapy was interrupted in 25% (43/171) of patients due to anaemia; 16 patients required blood transfusions. The median eGFR increased from 33.5 (15) ml/min/1.73 m^2 at baseline to 35 (36)ml/min/1.73 m^2 at SVR8 (p = 0.0003).
Conclusion: In real-life, the use of ombitasvir, paritaprevir, and ritonavir in the treatment of HCV infected patients with advanced renal disease was safe and effective, Moreover, it was associated with significant improved eGFR.

THU-331

The efficacy of paritaprevir/ritonavir/ombitasvir + dasabuvir and ledipasvir/sofosbuvir is similar in patients who failed interferon-based treatment with first generation protease inhibitors

Email: e.janczewska@poczta.fm

Background and Aims: According to the EASL guidelines, recommended treatment for patients (pts) who failed to achieve an SVR on prior interferon-based triple therapy with protease inhibitors (PI) are combinations of sofosbuvir and NS5A inhibitors. Our national recommendations, supported by results of the early-access studies (AMBER) also allow the use of paritaprevir/ritonavir/ombitasvir + dasasbuvir +/–RBV (PrODR) in this group of patients. The aim of the study was to evaluate the efficacy and safety of PrODR vs. ledipasvir/sofosbuvir +/– RBV (LSR) in PI-experienced patients in real-life setting.

Method: Our analysis included patients treated with IFN-free regimens in the year 2016, voluntarily registered by treating physicians in the nationwide, multicenter EpiTer-2 database.

Results: Among 2879 pts registered in total, 313 subject with genotype 1 (95% 1b) were previously treated with IFN-based regimens with PIs: 108 with boceprevir (BOC), 180 with telaprevir (TVR) and 25 with simeprevir (SVR). Sex, age and BMI distribution were similar in all groups. Pts with advanced fibrosis (F3/F4) were significantly predominant (BOC 26%/60%, TVR 18%/65%, SMV 27%/42%, respectively). Majority of patients (303) met criteria of Child-Pugh class A, 9 pts class B and 1 subject class C.
Assignment of subjects to IFN-free retreatment was as follows:

BOC group: 55 pts (51%) PrODR and 51 (48%) LSR
TVR group: 90 pts (50%) PrODR and 85 (47%) LSR
SMV group:19 pts (73%) PrODR and 7 (27%) LSR

Pts classified as Child-Pugh B or C were treated with LSR.
SVR12/24 rates in all pts were 97% in ITT and 99% in mITT analyses.
SVR12/24 rates in particular groups were as follows:

BOC: PrODR- ITT/mITT 100%; LSR – ITT 98%, mITT 100%
TVR: PrODR- ITT 97%, mITT 99%; LSR – ITT 96%, mITT 98%
SMV: PrODR- ITT 90%, mITT 94%; LSR – ITT/ mITT 100%.

Both treatment regimens had favorable safety profile. The reported adverse events (AEs) were generally mild or moderate in severity. Two deaths were reported (not treatment-related). The treatment was stopped due to AEs in 5 pts (3 treated with PrODR and 2 with LSR).

Conclusion: Efficacy of the treatment with PrODR and LSR was similar in BOC or TVR-experienced pts. The results of treatment with PrOD in SMV group were less satisfactory than with LSR, but low number of subjects and disproportion between the patients assigned to both regimens didn't allow us to draw reliable statistical conclusions. Our findings will be verified after collecting more data in EpiTer-2 registry.

THU-332

Characteristics and retreatment of HCV DAA failure patients: Real-life experience

I. Ruiz, S. Fourati, A. Varaut, S. Giovanna, M. François, M. Wlassow, L. Poiteau, F. Donati, A. Soulier, C. Stephane, A. Mallat, J.-M. Pawlotsky, C. Hezode. *CHU Henri Mondor, APHP*
Email: isaac.ruiz@me.com

Background and Aims: In the era of DAA treatment 5 to 10% of patients fail to achieve a SVR. Baseline characteristics and retreatment data are poorly documented in these patients. The aim of this study was to report the baseline characteristics of HCV patients who failed with DAA strategy recommended by EASL guidelines and results of retreatment of these patients.

Method: 75 patients with chronic HCV infection who previously failed a DAA treatment according to EASL guidelines were studied. Clinical and virological baseline characteristics, including genotype and subtype, and RASs by population sequencing (15%) before starting the first and second course of DAA, were collected. Regarding, retreatment, the rescue-therapy was chosen during a multidisciplinary meeting, according to EASL guidelines. Patients received sofosbuvir-based regimen plus 1 or 2 DAA, with or without ribavirin, for 12, 16, or 24 weeks or were included in clinical trials or early access program. Efficacy was defined by SVR12.

Results: 75 patients, (males 63.0%, median age 59.3 years) were enrolled. Ethnicity distribution was: Caucasian (51%), black (40%), and other (9%). Concerning genotype distribution of 30 blacks: GT1, 9/30 (30%); and GT4, 15/30 (50%); of them 9/30 (30%) were GT4r. Median FibroScan score was 19.4 kPa (range 4.0–67.8), 30 (40%) of patients had a cirrhosis (FibroScan > 12.5 kPa), 5/30 (16.7%) were Child-Pugh B; 2/30 (6.7%) had MELD score >15. Genotype distribution is shown in Table 1. Median HCV RNA level before retreatment was 5.87 Log^{10} IU/ml (range 4.39–7.04). Resistance test before the retreatment has

shown NS3/4 RASs, NS5A RASs, and NS5B RASs in 20(32.9%), 54 (82.2%), and 10(27.4%) patients, respectively. Of the 9 GT4r patients, 6 were previously treated with SOF/LDV ± RBV 12/24weeks, 1 with SOF/SMV, and 1 with 2D/RBV. Résistance analysis showed that 8/9 had L28V NS5A RASs, and 3/8 had S282C/T NS5B RASs. Among the 41 patients who reached week 12 follow-up, 39 patients (95.1%) achieved a SVR12.

Table 1: Genotype distribution

HCV genotype	All patient		Blacks	
	n = 75	%	n = 30	%
Overall				
Common	37	49.3	7	23.3
Uncommon	38	50.7	23	76.7
By Genotypes				
1 a/b	19	25.3	4	13.3
1 d/e/l	6	8.0	5	16.7
2 a	1	1.3	0	0
2 (other than 2a)	6	8.0	4	13.3
3 a	16	21.3	2	6.7
3 (other than 3a)	3	4.0	0	0
4 b	1	1.3	1	3.3
4 g/h/r	20	26.7	14	46.7
5/6 c	3	4.0	0	0

Conclusion: Uncommon genotypes and black patients were over represented in patients who failed after DAA regimens according to EASL guidelines. These genotypes and patients should benefit from second generation pangenotypic regimens. In addition, retreatment according to 2016 EASL guidelines seems to be an effective strategy in these patients.

THU-333

Concomitant drug use in patients with chronic hepatitis C and change over time: A nationwide population-based register study from 2005 to 2013

J. Söderholm[1,2], O. Weiland[3], A. Brolund[1], J. Kövamees[1], M. Baartz[4], A. Nystedt[5], K. Buesch[2,6]. *[1]AbbVie, Medical Affairs, Solna, Sweden; [2]Karolinska Institutet, Department of Laboratory Medicine, Stockholm, Sweden; [3]Karolinska Institutet, Department of Medicine, Stockholm, Sweden; [4]AbbVie, Market Access, Sydney; [5]Sunderby Hospital, Center for Communicable Disease Control, Luleå, Sweden; [6]AbbVie, HEOR, Solna, Sweden*
Email: jonas.soderholm@abbvie.com

Background and Aims: Chronic hepatitis C (CHC) infection carries an increased risk of comorbidities with an overall higher use of medical drugs. The aim of the present study was to evaluate the use of co-medications and to evaluate the potential risk for Drug-Drug Interactions (DDIs) for each Direct-Acting Antivirals (DAAs) currently used for treating hepatitis C.
Method: The analysis of potential DDIs during one calendar year included all expedited drugs during 2013 for all diagnosed CHC patients in Sweden alive as of December 31st 2013 (n = 34,633). The CHC patients were identified using B18.2 according to the International Classification of Diseases (ICD)-10 diagnosis code in the inpatient care, day surgery (1997–2013) and the non-primary outpatient care (2001–2013) registries in the nationwide Swedish Patient Register. Information on expedited drugs was obtained using ATC codes in the prescribed drug register (June 2005–2013), which covers all dispensed prescriptions in Sweden. For the longitudinal analysis of drug use, only the CHC patients diagnosed as of June 2005 through 2013 were included (n = 21,954) in the analysis. Follow-up started at the diagnosis of CHC until death, emigration or 2013-Dec-31 whichever came first. The DDI profiles for the DAAs were evaluated using the HEP Drug iChart (University of Liverpool, UK, [accessed 2017-Aug-29]).
Results: A median of 4 drugs were used during the year after CHC diagnosis. During the second year, 45% of the patients used a decreased number of drugs (median 3 fewer drugs) and 37% used an increased number of drugs (median 2 extra drugs) ($P < 0.0001$ paired T-test). During 2013, a total of 974 different drugs were expedited. In a theoretical analysis, the number of drugs considered as "Do not co-administer" were 19 (2.0%) for EBR/GZR, 11 (1.1%) for LDV/SOF, 20 (2.1%) for GLE/PIB, 48 (4.9%) for OBV/PTV/r + DSV, 15 (1.5%) for SOF/VEL, and 28 (2.9%) for SOF/VEL/VOX. Carbamazepine (n = 705) was the most common "Do not co-administer" drug for EBR/GZR, LDV/SOF, and SOF/VEL, comprising of 39%, 71%, and 71% respectively of the "Do not co-administer" drugs per DAAs. Simvastatin (n = 1,695) was the most common "Do no co-administer" for GLE/PIB, OBV/PTV/r + DSV, and SOF/VEL/VOX, comprising of 45%, 15%, and 45% respectively of the "Do not co-administer" drugs per DAAs.
Conclusion: The use of co-medications significantly decreased the year after CHC was diagnosed, possibly due to a more adequate care of the patients' co-morbidities. In addition, few co-medications (1–5%) expedited to CHC patients during 2013 were considered to be in the category "Do not co-administer" (HEP Drug iChart).

Email: mdclimsg@nus.edu.sg

Background and Aims: There is a paucity of information on direct antiviral agents (DAA) HCV therapy in Asia, hence we evaluated such patients from prospectively collected databases in Asian countries with approved DAA regimens.
Method: Asia-Pacific physicians were invited to participate and the following data were collated from their database of patients enrolled for therapy of HCV. Treatment with DAA included: sofosbuvir + ribavirin (SR), sofosbuvir, pegylated interferon + ribavirin (SPR),

sofosbuvir, ledispasvir ± ribavirin (SL ± R), sofosbuvir, daclatasvir ± ribavirin (SD ± R), ombatisvir, parateprevir, dasubuvir ± ribavirin (3D ± R). Baseline clinical, virological and biochemical characteristics, sustained virological response at week 12 (SVR12), and virologic failure were collected. SVR12 outcome was based on intention-to-treat. Multivariate analysis was used to assess independent risk factors for SVR12 using SPSS version 20.

Results: A total of 2,171 patients were evaluated from India (n = 977), Myanmar (n = 552), Pakistan (n = 406), Thailand (n = 139), Singapore (n = 72) and Malaysia (n = 25). Baseline features were a mean age of 49 years, 50% were male and 41.8% had cirrhosis. Overall SVR12 was 89.5% and based on genotype (GT) was 91% for GT1, 100% GT2, 91% GT3, 64% GT4, 87% GT6, and 79% in those not tested. Virologic failure based on GT was 4% GT1, 0% GT2, 3% GT3, 4% GT4, 13% GT6 and 8% in GT not tested. Patients with cirrhosis had lower SVR12 than non-cirrhotics (85% vs 93%, $p < 0.001$). Patients with GT1 and 3 treated with sofosbuvir/ribavirin (SR) had 88% and 89% SVR12 respectively but those GT6 treated with sofosbuvir/ledipasvir (SL) had only 77.6% SVR12. Multivariate analysis showed that absence of cirrhosis was associated with higher SVR12.

Conclusion: Patients with GT1 and 3 with and without cirrhosis had surprisingly high efficacy using SR which is not recommended suggesting that Asians may respond better to some DAAs. However, poor GT6 response to SL suggests this regimen may be suboptimal for this genotype.

THU-335

A comparison of elbasvir/grazoprevir, ledispasvir/sofosbuvir and velpatisvir/sofosbuvir therapy among people who use drugs (PWUD): real world experience

A. Alimohammadi, J. Holeksa, Y. Bhutani, A. Thiam, A. Bassi, B. Conway
. *Vancouver Infectious Diases Centre, Vancouver, Canada*
Email: arshia.alimohammadi@vidc.ca

Background and Aim: Up to 70 million people are infected with Hepatitis C virus (HCV) worldwide, including more than 240,000 Canadians, over 50% of whom are PWUD. To meet the World Health Organization (WHO) goals for the elimination of HCV as a public health concern by 2030, specific outreach programs will be needed to engage vulnerable populations with a high prevalence of HCV infection, such as PWUD. The most prescribed regimens in Canada include elbasvir/grazoprevir (E/G), ledipasvir/sofosbuvir (L/S) and velpatasvir/sofosbuvir (V/S). While clinical trials have highlighted the efficacy of these regimens, real world data is required to confirm these results, especially among PWUD.

Methods: A retrospective analysis was performed on all HCV-infected PWUD (positive urine drug screen in previous month) initiating HCV treatment (rx) at our centre between 06/15–10/17. All subjects were enrolled in a multidisciplinary model of care, addressing medical, psychologic, social and addiction-related needs. The primary outcome was achievement of SVR12 (undetectable HCV RNA 12 or more weeks after the completion of HCV therapy). A secondary outcome was maintenance of SVR in long-term follow-up in subjects with ongoing risk behaviors for recurrent viremia.

Results: A total of 148 eligible individuals (all active PWUD, 66% heroin/58% cocaine) have initiated therapy with one of E/G, L/S, or V/S. The E/G cohort (n = 39) includes 6 HIV+, 18 on opiate substitution therapy (OST), 31 Rx naïve, 21 GT1a, 7 GT3a, 4 cirrhotic. To date, 29/31 achieved SVR12, with no virologic failures (2 LTFU). One LTFU individual took E/G for 2 weeks, reintegrated care and achieved SVR12. The L/S cohort (n = 64) includes 7 HIV+, 6 on OST, 36 Rx naïve, 43 GT1a, 19 cirrhotic. To date, 49/55 achieved SVR12, with 2 virologic relapses, 4 LTFU, one unrelated opioid overdose death. The V/S cohort (n = 45) includes 6 HIV+, 13 on OST, 30 Rx naïve, 9 GT1a, 23 GT3a, 10 cirrhotic. To date, 12/12 achieved SVR12. Of the 50 individuals not having reached the SVR12 time point, all remain in follow-up at our centre.

Conclusion: Currently prescribed all-oral HCV treatment regimens appear to be highly and equally effective in a real world PWUD cohort. This provides support for expanded access to HCV treatment, even in the setting of active drug use. Pending complete and ongoing follow-up in this important cohort, health care providers have three excellent options to provide HCV treatment to PWUD engaged in care, in support of the WHO's global elimination targets.

Email: karin.kozbial@meduniwien.ac.at

Background and Aims: Only few chronic hepatitis C patients treated with interferon-free DAA combinations fail to clear the virus. In this study we summarize our "real world" experience of retreating these patients in Austria.

Method: One hundred and one HCV monoinfected patients (80 male; GT1a:28, GT1b:36; GT1:5, GT2:3, GT3:26, GT4:3; IL28 non-C/C:34/41; therapy experienced:31/58; cirrhosis:57) failed IFN-free DAA therapy (98 relapsers, 3 nonresponders). These account for about 3% of DAA-treated patients in the participating centers. Drugs for the first treatment were prescribed according to availability and funding: ombitasvir/paritaprevir/dasabuvir (3D) ± ribavirin(RBV):24; ombitasvir/paritaprevir (2D):1; sofosbuvir(SOF)/daclatasvir(DCV) ± RBV:14; SOF/Ledipasvir(LDV) ± RBV:29; SOF/Velpatasvir(VEL):2; SOF/Simeprevir(SMV):10; SOF/RBV:18; Elbasvir/Grazoprevir(EG):3. Treatment duration and addition of RBV were at the discretion of the treating physician. For retreatment patients who had failed a SOF-free regimen received a SOF-containing regimen, those without a NS5A-inhibitor a NS5A containing regimen, and those after SOF/NS5A received SOF/protease inhibitor ± other NS5A-inhibitor ± RBV.

Results: Currently 73 patients have finished a DAA-retherapy and 59 (81%) achieved SVR (3D ± RBV:15, 3D/SOF/RBV:2; 2D + RBV:1; SOF/DCV ± RBV:6; SOF/LDV ± RBV:14; SOF/SMV ± RBV:2; SOF/VEL ± RBV:13, EG ± RBV:6); 14 patients relapsed (GT1a:5,GT1b:3,GT3a:5; GT4:1; 10 cirrhotics; positive NS5A-, NS5B-, or NS3 RAS in 8/11; 3D ± RBV:4; SOF/DCV ± RBV:3; SOF/LDV ± RBV:3; SOF/VEL:2; SOF/SMV:2). Further 14 are on retreatment. In two nonresponders to the first DAA-therapy retesting of the genotype revealed a different genotype: GT3a instead of GT1a and a yet unclassified subtype close to 1c instead of GT1b, respectively. Resistance-associated substitutions (RAS) analyses were available in 51 patients. Overall 42/50 had RAS; 16 in NS3, 36 in NS5A, and 15 in NS5B.

Seven of the 14 relapsers have finished a 3rd treatment yet, 3 of them relapsed again (SOF/VEL/RBV:GT3a; SOF/LDV/RBV:GT1a; EG/SOF/RBV:GT1b; 2 cirrhotics; all had NS5A RAS). One of the relapsers to the 3rd therapy achieved SVR after 24 weeks of 3D/SOF/RBV (GT1a).
Conclusion: Most DAA failures retreated with a different regimen achieved SVR, however, few patients failed multiple treatment attempts. Their treatment will require combination of existing DAAs with new antivirals. Presence of cirrhosis and IL28-T allele appear to be associated with primary DAA-failure.

THU-337

Safety and effectiveness comparing generic and original sofosbuvir-based treatment regimens in patients with hepatitis C: A prospective multicenter study from Argentina

E. Ridruejo[1,2], M. Mendizabal[3], F. Piñero[3], C. Alonso[3], A. Palazzo[4], M. Sixto[5], S. Ceballos[6], C. Gadea[4], D. Perez[4], M.V. Reggiardo[7], V. Moreno[6], S.E. Mengarelli[6], A. Bruno[8], C. Mendoza[9], J. Vila[10], F. Barreyro[11], M.G.V. Zuain[12], N. Ratusnu[13], M. Silva[3]. *[1]Hospital Universitario Austral, Hepatology and Liver Transplant Unit; [2]Centro de Educación Médica e Investigaciones Clínicas Norberto Quirno "CEMIC"., Hepatology Section, Department of Medicine; [3]Hospital Universitario Austral, Hepatology and Liver Transplant Unit, Pilar; [4]Hospital Padilla, Tucuman, Argentina; [5]Hospital Santa Fe, Santa Fe, Argentina; [6]Hospital San Roque, Argentina; [7]Hospital Centenario, Rosario, Argentina; [8]Hospital Dr Cosme Argerich, Buenos Aires; [9]Hospital Rio Cuarto, Rio Cuarto, Argentina; [10]Hospital Corrientes, Corrientes, Argentina; [11]Hospital Posadas, Posadas, Argentina; [12]OSECAC, Buenos Aires, Argentina; [13]Hospital Tierra del Fuego, Usuahia, Argentina*
Email: fpinerof@cas.austral.edu.ar

Background and Aims: A major limitation to the wide use of HCV direct acting antivirals (DAAs) in developing countries is its high cost. Generic versions of sofosbuvir are available in Argentina since 2016. Our aim was to evaluate effectiveness, safety, and post-treatment decompensation episodes in patients treated in real-life setting with generic sofosbuvir (G-SOF) or original SOF (O-SOF).
Method: A prospective multicenter cohort from the Latin American Liver Research Educational and Awareness Network (LALREAN) was analyzed. We included patients from Argentina who received either O-SOF or G-SOF in combination with daclatasvir for 12 or 24 weeks with or without ribavirin (RBV) according to international guidelines. SOF type was assigned by payers and not by physicians.
Results: From a total of 378 patients treated with DAAs, 191 patients received SOF-DCV regimen. Baseline characteristics and outcomes are in Table 1. Only 3 (1.6%) patients presented treatment failure, all of them received G-SOF. Median follow-up since the end of treatment was 10.6 weeks and 13.1 weeks in the G-SOF and in the O-SOF, respectively (p = 0.01). During post-SVR12 follow-up 1 patient developed ascites, 2 patients encephalopathy and 1 patient variceal bleeding in the G-SOF group, while in the O-SOF group only 1 patient presented ascites (p = NS). One out of 11 and 2 out of 5 patients were delisted in the G-SOF and the O-SOF groups, respectively (p = NS). One patient in the G-SOF group and 2 patients in the O-SOF group developed de-novo HCC. No major adverse events occurred requiring treatment discontinuation.

Table 1:

	Original-SOF (n = 101)	Generic-SOF (90)	P
Male sex (%)	59	48	0.13
Age (mean, yrs)	53	58	0.02
Cirrhosis (%)	70	61	0.34
GT1, 2, 3 (%)	57/8/14	62/19/9	0.4
SVR12, (%)	100	96	0.240
With RBV (%)	42	37	0.14
Any adverse event (%)	16	23	0.22

Conclusion: Although generic and original SOF presented similar safety and effectiveness, SVR12 was slightly superior in the O-SOF group. Post-treatment decompensation events were more frequent among those treated with G-SOF despite the fact they were followed for a shorter period of time. To confirm our results, larger cohorts and longer pharmacovigilance studies are need.

THU-338

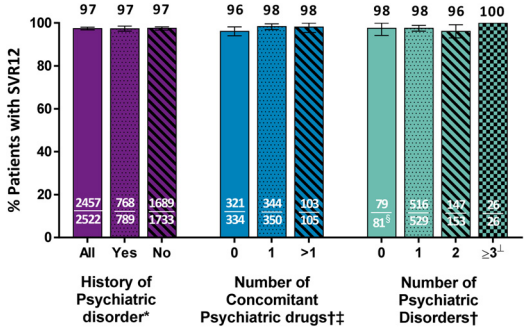
Integrated efficacy and safety of glecaprevir/pibrentasvir in patients with psychiatric disorders

D. Back[1], P. Belperio[2], M. Bondin[3], F. Negro[4], A. Talal[5], C. Park[3], Y. Lei[3], E. Crown[3], F. Mensa[3], F. Marra[1]. *[1]University of Liverpool, Liverpool, United Kingdom; [2]U.S. Department of Veterans Affairs, VA Palo Alto Healthcare System, Palo Alto, United States; [3]AbbVie, Inc., North Chicago, United States; [4]University of Geneva, Geneva, Switzerland; [5]University of Buffalo, Jacobs School of Medicine and Biomedical Sciences, Buffalo, United States*
Email: d.j.back@liverpool.ac.uk

Background and Aims: The once daily combination of glecaprevir (NS3/4A protease inhibitor; developed by AbbVie and Enanta) and pibrentasvir (NS5A inhibitor; coformulated as G/P) demonstrated sustained virologic response rate at post-treatment week 12 (SVR12) of ≥97% across HCV genotypes 1 through 6 and a favourable safety profile in clinical studies. The prevalence rates of psychiatric illness in patients with HCV infection are higher than those rates in the general US population. Herein we report the integrated efficacy and safety of G/P from ten Phase 2 and 3 studies in patients with psychiatric disorders.
Method: Data were pooled from SURVEYOR-I and -II, MAGELLAN-I, ENDURANCE-1, -2, -3, and -4, and EXPEDITION-1, -2 and -4 studies. Treatment-naive and -experienced patients were classified as having a psychiatric disorder if they were taking a psychiatric medication at the time of G/P initiation or had a medical history of a psychiatric disorder. Efficacy was assessed as the percent of patients achieving SVR12 (HCV RNA <lower limit of quantification) using an intent-to-treat analysis. Safety was assessed in all patients.
Results: Of the 2,522 HCV-infected patients included, 789 (31%) had a psychiatric disorder. Baseline characteristics are outlined in Table 1. SVR12 by history of psychiatric disorder and number of concomitant CNS medications/psychiatric disorders are reported in Figure 1. Overall, G/P was well-tolerated in patients with psychiatric disorders with no DAA-related serious adverse events (0/789) and <1% (5/789) adverse events leading to discontinuation of G/P.

Table 1: Baseline Characteristics

Characteristic, n (%)	Psychiatric disorder N = 789	No Psychiatric disorder N = 1,733
Male	403 (51)	1,043 (60)
White	685 (87)	1,344 (77)
Age < 65	703 (89)	1,489 (86)
Treatment naïve	568 (72)	1,197 (69)
Baseline HCV RNA ≥ 1 million	489 (62)	1010 (58)
Compensated Cirrhosis	124 (16)	200 (12)
Diagnosed Psychiatric Disorders ≥5% of patients, n (%)		
Depression	506 (64)	N/A
Anxiety	216 (27)	N/A
Bipolar Disorder	57 (7)	N/A
Concomitant CNS drug use in ≥10% of patients by class, n (%)		
Antidepressants	396 (50)	N/A
Opioids	272 (34)	221 (13)
Anxiolytics	244 (31)	74 (4)
Antiepileptic	217 (28)	69 (4)
Hypnotics and sedatives	159 (20)	98 (6)
Antipsychotics	117 (15)	N/A
Drugs used in addictive disorders	116 (15)	98 (6)



*Patients treated for or diagnosed with a CNS psychiatric disorder

†Only includes patients with History of Psychiatric Disorders

‡Concomitant psychiatric drug were allowed in studies except for carbamazepine, phenytoin, pentobarbital, phenobarbital, and primidone

§Patients did not have a clinical diagnosis of a psychiatric disorder, but were taking at least one concomitant psychiatric drug

⊥Includes n = 25 patients with 3 diagnoses and n = 1 patient with 4

Conclusion: Use of G/P in chronic HCV genotype 1–6 infected patients who were either receiving concomitant CNS drugs or had a history of a psychiatric disorder was well-tolerated and achieved high SVR12 rates.

THU-339

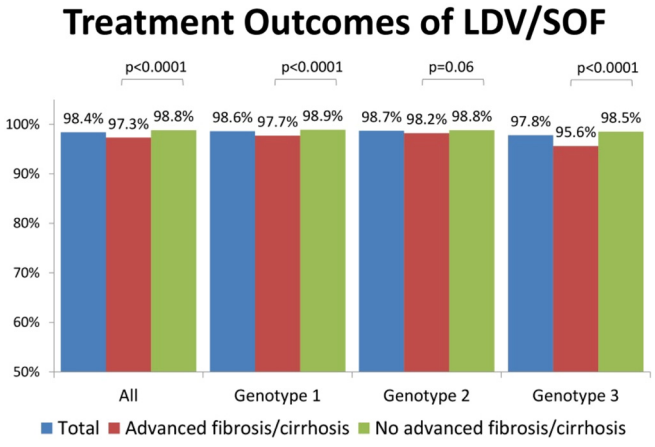
Real world effectiveness of Ledipasvir/Sofosbuvir based regimens in hepatitis C virus genotype 1,2 and 3 infection within national hepatitis C elimination program in the country of Georgia

Gamkrelidze[11], V. Kvaratskhelia[12], N. Afdhal[13], S. Zeuzem[14], S. Arora[15], K. Thornton[15], F. Averhoff[10]. *[1]Infectious Diseases, AIDS and Clinical Immunology Research Center, Tbilisi, Georgia; [2]Ivane Javakhishvili Tbilisi State University, Tbilisi, Georgia; [3]Ivane Javakhishvili Tbilisi State University, Tbilisi; [4]Hepatology clinic HEPA, Tbilisi, Georgia; [5]Health Research Union, Tbilisi, Georgia; [6]Medical Center Mrcheveli, Tbilisi, Georgia; [7]South Caucasus Office of the U.S. Centers for Disease Control (CDC), Tbilisi, Georgia; [8]CDC Foundation, Tbilisi, Georgia; [9]CDC Foundation, Atlanta, Georgia; [10]Centers for Disease Control and Prevention, Atlanta, United States; [11]National Center for Disease Control and Public Health, Tbilisi, Georgia; [12]Ministry of labour, health and social affairs of Georgia, Tbilisi, Georgia; [13]Beth Israel Deaconess Medical Center Liver Center, Boston, United States; [14]University of Frankfurt, Department of Medicine, Frankfurt, Germany; [15]University of New Mexico, Albuquerque, United States*
Email: tengizt@gol.ge

Background and Aims: Ledipasvir/sofosbuvir (LDV/SOF) is currently approved for the treatment of HCV genotypes 1 and 4. However data on its effectiveness in genotype 2 and 3 infection are limited. In April 2015, the country of Georgia, with the support of U.S. CDC and Gilead Sciences, launched a national hepatitis C elimination program. LDV/SOF was recommended for HCV genotypes 2 and 3 as well within the program. We report on real-world effectiveness of LDV/SOF-based regimens for various genotypes in Georgia.

Method: Data for analysis were extracted from the hepatitis C elimination program treatment database. The study included 20,066 treatment-naïve and treatment-experienced patients with HCV genotypes 1, 2 and 3, who completed treatment and were assessed for sustained virologic response (SVR) by April 30, 2017. Genotype 1 patients received LDV/SOF alone or in combination with ribavirin (RBV) based on condition of a patient, while all genotype 2 and 3 patients received LDV/SOF in combination with RBV. Advanced fibrosis/cirrhosis was defined as F ≥ 3 by Metavir score based on elastography and/or Fib-4 score >3.25.

Results: Among 20,066 patients included in the analysis, 9,468 (47.2%) patients had genotype 1, 4,580 (22.8%) had genotype 2, and 6,018 (30.0%) had genotype 3. Of 20,066 patients 5,073 (25.3%) persons had advanced fibrosis/cirrhosis. Overall SVR rate was 98.4% (19742/20066), including 98.6% (9,335/9,468) in genotype 1, 98.7% (4,519/4,580) in genotype 2 and 97.8% (5,888/6,018) in genotype 3. Overall, 97.3% (4,935/5,073) of patients with advanced fibrosis/cirrhosis achieved SVR vs. 98.8% (14,635/14,816) of patients without advanced fibrosis/cirrhosis ($p < 0.0001$). Difference in SVR by advanced fibrosis/cirrhosis status was statistically significant in genotype 1 ($p < 0.0001$) and genotype 3 ($p < 0.0001$). In genotype 2 patients 98.2% of patients with advanced fibrosis/cirrhosis achieved SVR compared to 98.8% among patients with no advanced fibrosis/cirrhosis ($p = 0.06$). SVR rate among patients who failed prior SOF-based regimens was 93.7% (443/473).



Conclusion: LDV/SOF-based treatment was highly effective in this real-world cohort, including among patients with advanced disease and in whom previous SOF-based therapy failed. High cure rates were observed in all genotypes. Combination of LDV/SOF/RBV appears to be an effective treatment option for genotype 2 and 3 infections at least in Georgian settings.

THU-340

Effectiveness of sofosbuvir and ledipasvir/sofosbuvir based regimens in hepatitis C virus genotype 3 infection: real-world data from Georgian hepatitis C elimination program

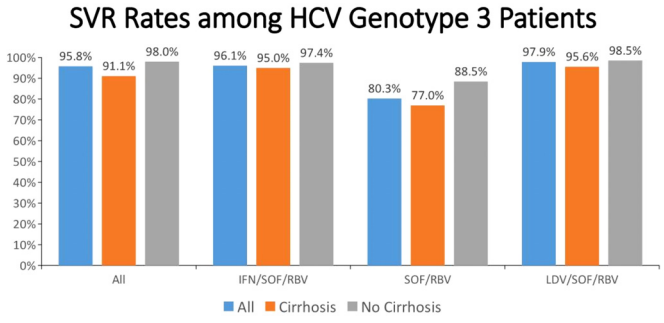
T. Tsertsvadze[1,2], N. Chkhartishvili[1], A. Abutidze[1], L. Sharvadze[2,3], V. Kerashvili[1], G. Kamkamidze[4], M. Zakalashvili[5], B. Skaggs[6], L. Gvinjilia[7], S. Shadaker[7], M. Nasrullah[8], A. Gamkrelidze[9], V. Kvaratskhelia[10], S. Zeuzem[11], N. Afdhal[12], S. Arora[13], K. Thornton[13], F. Averhoff[14]. *[1]Infectious Diseases, AIDS and Clinical Immunology Research Center, Tbilisi, Georgia; [2]Ivane Javakhishvili Tbilisi State University, Tbilisi, Georgia; [3]Hepatology clinic HEPA, Tbilisi, Georgia; [4]Health Research Union, Tbilisi, Georgia; [5]Medical Center Mrcheveli, Tbilisi, Georgia; [6]South Caucasus Office of the U.S. Centers for Disease Control (CDC), Tbilisi, Georgia; [7]CDC Foundation, Tbilisi, Georgia; [8]Centers for Disease Control and Prevention, Atlanta, United States; [9]National Center for Disease Control and Public Health, Tbilisi, Georgia; [10]Ministry of labour, health and social affairs of Georgia, Tbilisi, Georgia; [11]Goethe University Hospital, Frankfurt am Main, Germany; [12]Beth Israel Deaconess Medical Center Liver Center, Boston, United States; [13]University of New Mexico, Albuquerque, United States; [14]Centers for Disease Control and Prevention, Atlanta, United States*
Email: tengizt@gol.ge

Background and Aims: HCV genotype 3, which is considered as the most difficult to treat, accounts for 34% of all HCV infections in the country of Georgia. In April 2015 in collaboration with US CDC and commitment from Gilead Sciences to donate direct acting antivirals (DAAs) Georgia launched the world first national hepatitis C elimination program. The aim of this study was to evaluate the effectiveness of sofosbuvir (SOF)-based and ledipasvir/sofosbuvir

(LDV/SOF)-based regimens among HCV genotype 3 patients treated within the Georgian elimination program.

Method: Data were obtained from the Georgia's hepatitis C elimination program treatment database. SOF was prescribed either in combination with pegylated interferon (IFN) and ribavirin (RBV), or only with RBV. LDV/SOF plus RBV became recommended regimen for HCV Genotype 3 in Georgia. Analysis included 7,857 HCV genotype 3 patients who completed treatment and were assessed for sustained virologic response (SVR) by April 30, 2017. Advanced fibrosis/cirrhosis was defined as F ≥ 3 by METAVIR score based on elastography and/or FIB-4 score >3.25.

Results: Of 7,857 patients included 2,428 (30.9%) had advanced fibrosis/cirrhosis, 1143 (14.5%) received IFN/SOF/RBV for 12 weeks, 807 (10.3%) received SOF/RBV for 24 weeks and 5907 (75.2%) received LDV/SOF/RBV for either 12 or 24 weeks. The IFN/SOF/RBV arm had an overall SVR rate of 96.1% (1099/1143) and this regimen was more effective in patients with no advanced fibrosis/cirrhosis versus patients with advanced fibrosis/cirrhosis (97.4% vs. 95.0%, p = 0.04). SOF/RBV achieved SVR in 80.3% (648/807) of patients, with higher rates also observed in patients without advanced fibrosis/cirrhosis (88.5% vs.77.0%, p < 0.0001). Patients receiving LDV/SOF/RBV achieved SVR rate of 97.9% (5783/5907) with higher cure rate among patients without advanced fibrosis/cirrhosis vs. patients with advanced fibrosis/cirrhosis (98.5% vs. 95.6%, p < 0.0001). IFN and LDV/SOF based regimens were more effective than SOF/RBV in both patients with or without advanced fibrosis/cirrhosis (p < 0.001). LDV/SOF/RBV arm achieved higher cure rate compared to patients receiving IFN/SOF/RBV (p = 0.0004).



Conclusion: Overall SVR in genotype 3 patients was up to 98% in LDV/SOF/RBV regimens, which was more effective than SOF/RBV (80% SVR) and IFN/SOF/RBV (96% SVR) in Georgia. LDV/SOF and RBV may be considered as effective treatment option for HCV genotype 3 infection even in patients with advanced disease.

THU-341

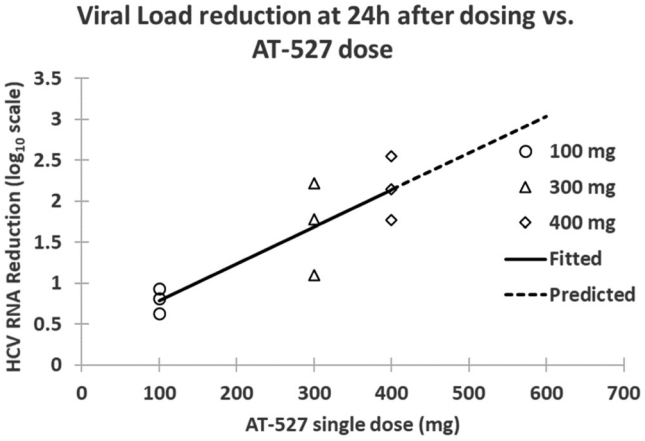
AT-527, a pan-genotypic purine nucleotideprodrug, exhibits potent antiviral activity in subjects with chronic hepatitis C

X.-J. Zhou[1], E. Berliba[2], F. Vanhoutte[3], M. Bogus[2], P.-J. Berghmans[3], K. Pietropaolo[1], S. Good[1], A. Moussa[1], R. Murphy[4], J.-P. Sommadossi[1]. [1]*Atea Pharmaceuticals, Inc., Boston, United States;* [2]*ARENSIA Exploratory Medicine, Chisinau, Moldova;* [3]*SGS Life Sciences, Antwerpen, Belgium;* [4]*North Western University, Department of Infectious Diseases, Chicago, United States*

Email: zhou.xj@ateapharma.com

Background and Aims: AT-527 is a novel purine nucleotide NS5B polymerase inhibitor currently in clinical development for treatment of chronic hepatitis C virus (HCV) infection. AT-527 possesses a favourable and highly differentiated antiviral profile compared to sofosbuvir (SOF). AT-511, the free base of AT-527, showed potent pan-genotypic antiviral activity *in vitro* against wild-type clinical isolates with EC_{95} <80 nM, which is 4- to 14-fold more potent than SOF. Moreover, AT-511 maintained antiviral activity against SOF-resistant S282T single and S282T/L159F double variants with approximately 50-fold greater potency than SOF.

Method: This is an ongoing multiple part study evaluating AT-527 in single ascending doses up to 400 mg in healthy subjects with embedded food effect at 200 mg (Part A), escalating single doses up to 600 mg in HCV-infected subjects (Part B), and escalating multiple doses up to 150, 300 and 600 mg/day (QD) for 7 days in HCV-infected subjects (Part C). Safety is assessed via adverse events (AEs), vital signs, electrocardiograms (ECGs) and standard safety laboratory tests. Plasma levels of AT-511 and its nucleoside metabolite AT-273 are measured using LC-MS/MS. HCV RNA is quantified using COBAS® AmpliPrep/COBAS® TaqMan® HCV Test, v2.0 with a LLQ of 15 IU/ml.



Results: At abstract submission, Part A was complete, Part B was complete through 400 mg, and dosing of 150 mg QD × 7 days in Part C was initiated. AT-527 exhibited comparable pharmacokinetics between healthy and HCV-infected subjects. Food had no major impact on plasma exposure of AT-273, the nucleoside metabolite representative of intracellular active triphosphate. After a single dose in GT 1b HCV-infected subjects, potent and dose-related antiviral activity was obtained: mean maximum plasma viral load reduction was 0.8, 1.7 and 2.2 $\log_{10}$ IU/ml for 100, 300 and 400 mg, respectively. Dose-response analysis suggests that viral load reduction ≥ 2.5 $\log_{10}$ IU/mL is achievable with a single dose up to 600 mg (Fig. 1). No SAEs or discontinuations were reported. The most common AE has been mild or moderate headache. No dose-related trends for laboratory parameters, vital signs or ECGs were observed.

Conclusion: AT-527 has been well-tolerated after single doses in healthy and HCV-infected subjects. Single doses resulted in potent dose-related antiviral activity, implying even greater viral suppression in the ongoing 7-day dosing cohorts.

THU-342

Impact of treatment with Elbasvir and Grazoprevir on chronic hepatitis C virus disease specific health related quality of life outcomes in HCV/HIV coinfected patients

D. Serrano[1], C. Nwankwo[2], H.L. Platt[2], S. Klopfer[2], M. Shaughnessy[2], J.M. Arduino[2]. [1]*Pharmerit International;* [2]*Merck & Co., Inc., United States*

Email: chizoba.nwankwo@merck.com

Background and Aims: Hepatitis C progresses more quickly in patients with HIV infection than in patients without HIV. In addition, HRQoL is diminished in HCV/HIV coinfected patients compared to HIV mono-infected patients. The aim of this study was to investigate the relationship between treatment of coinfected HCV/HIV patients with Elbasvir and Grazoprevir (EBR/GZR) and time-dependent mean change in Health Related Quality of Life (HRQoL).

Methods: The analysis was conducted using data from the C-EDGE Coinfection study, a Phase III, single-arm, multi-center, open-label clinical trial which evaluated the efficacy and safety of EBR/GZR

therapy, among treatment-naïve chronic HCV GT1, GT4, or GT6 patients coinfected with HIV. All subjects received the fixed-dose combination of EBR/GZR for 12 weeks. Chronic HCV disease specific HRQoL was measured by the Chronic Liver Disease Questionnaire-Hepatitis C Virus (CLDQ-HCV) which was completed at baseline, during the treatment period at Treatment Week (TW)4, and TW12, and in post-treatment follow-up at Follow-up Week (FW)12, and FW24. The full analysis set (FAS) population was the primary population within which efficacy, safety, and HRQoL outcomes were assessed.

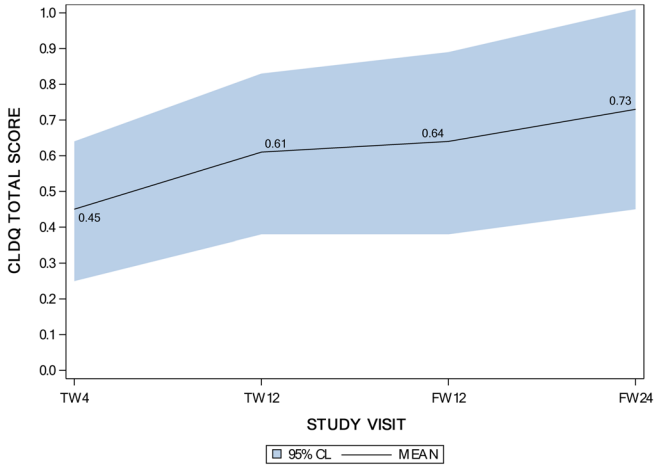


Figure 1: Mean change from baseline in CLDQ total score over time.

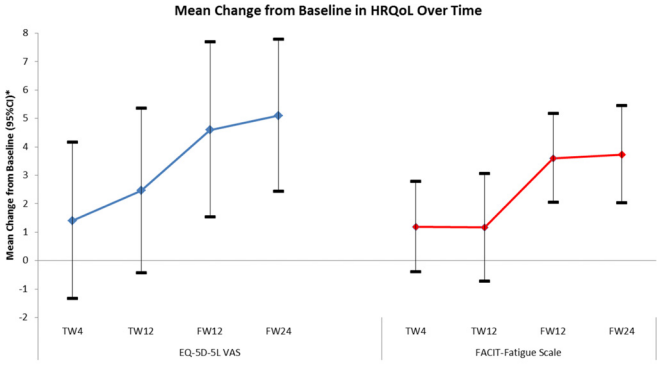
Results: 218 subjects were enrolled into the FAS, and 216 subjects completed the study. Among the FAS population, treatment efficacy for the SVR12 endpoint was 95% (207/218). Change from baseline for the CLDQ-HCV total score demonstrated significant 15% improvement ($p < 0.05$) for all follow-up periods (Figure 1). This was also true for all CLDQ-HCV sub scores. Improvement from baseline to 24-week follow-up was 14% for the Activity/Energy domain, 13% of the Emotion domain, 18.5% for the Worry domain, and 13% for the Systemic domain.
Conclusion: EBR/GZR combination therapy significantly improves HRQoL among treatment naïve coinfected HCV/HIV patients.

THU-343

C-EDGE treatment experienced: Effect of 12 week oral regimens of Elbasvir and Grazoprevir on health related quality of life in prior treatment experienced patients with chronic hepatitis C infection

C. Nwankwo[1], D. Serrano[2], B. Haber[1], P. Hwang[1], W. Li[1], L. Lin[1], J.M. Arduino[1]. [1]*Merck & Co., Inc., United States;* [2]*Pharmerit International, United States*
Email: chizoba.nwankwo@merck.com

Background and Aims: Chronic HCV infection is a major health burden and decreases quality of life HRQoL among those affected with the disease. The aim of this study was to describe the changes in HRQoL amongst prior TE patients with Chronic HCV.
Method: The analysis was conducted using patient reported outcomes (PRO) data collected from participants treated with Elbasvir and Grazoprevir (EBR/GZR) for 12 weeks with/without ribavirin (RBV) as part of the C-EDGE treatment experienced (TE) study which was a Phase III, randomized, parallel-group, multi-site, open-label trial of EBR (50 mg)/GZR (100 mg) with/without RBV in participants with chronic HCV genotypes 1, 4, or 6, who had previously failed treatment with Pegylated interferon and RBV. Participants were randomized 1:1:1:1 to 12 or 16 weeks of EBR/GZR with or without RBV. Changes in fatigue and overall general health were measured by the FACIT-Fatigue Scale and EQ-5D-5L VAS with PRO data collected at baseline, Treatment Week (TW) 4, TW12, Follow-up Week (FW) 12 and FW24.
Results: 209 participants were treated for 12 weeks: 105 with EBR/GZR only and 104 with EBR/GZR + RBV. SVR12 was achieved in greater than 90% of participants, in each cohort. At FW24 there was a 9% and 3% improvement from baseline FACIT-Fatigue scores amongst participants receiving EBR/GZR and EBR/GZR + RBV respectively. On average a 6% and 4% improvement in general health as measured by the EQ-5D-5L VAS was also observed amongst participants receiving EBR/GZR and EBR/GZR + RBV respectively between baseline and FW24. These improvements in HRQoL were also observed during treatment in participants treated with EBR/GZR (Figure) but not in participants treated with EBR/GZR + RBV, although in this cohort HRQoL improved to above baseline by FW12 and FW24.



*<0: worst health status, ≥0: same or better health status.

Conclusion: Overall, EBR/GZR regimens had a favourable impact on the HRQoL of participants after 12 weeks of treatment as demonstrated by higher PRO scores at FW24 relative to baseline.

THU-344

Impact of CD4+ T-cell count on sustained virologic response to direct-acting antivirals in HIV-negative cancer patients with chronic hepatitis C

H. Pritchard[1,2], G. Angelidakis[2], Y. Jiang[2], H. Torres[2,3]. [1]*Baylor College of Medicine, Department of Medicine, Division of Infectious Diseases, Houston, United States;* [2]*University of Texas MD Anderson Cancer Center, Department of Infectious Disease, Infection Control, and Employee Health;* [3]*University of Texas MD Anderson Cancer Center, Department of Gastroenterology, Hepatology, and Nutrition*
Email: htorres@mdanderson.org

Background and Aims: Factors associated with failure of direct-acting antivirals (DAAs) for treatment of hepatitis C (HCV) include cirrhosis, hepatocellular carcinoma (HCC), and HCV genotype 3 (HCV3) infection. Clinical trials using DAAs in HCV-HIV co-infected patients typically exclude patients with CD4+ T-cell count <100 cells/µl. We have previously shown that DAAs have equivalent safety and efficacy in cancer patients with chronic HCV compared to non-cancer patients; however to identify new risk factors for DAA failure, we evaluated the impact of CD4+ T-cell count on treatment outcomes in HCV-monoinfected cancer patients.
Method: HCV-infected cancer patients treated with DAAs between January 2014 and August 2017 were enrolled in an ongoing prospective observational study. CD4+ T-cell count was measured by flow cytometry at baseline, end of treatment (EOT), and at 12 weeks after EOT (sustained virologic response or SVR12). We evaluated demographics, HCV genotype, type of malignancy, presence of cirrhosis, and type of treatment (ribavirin-containing vs. non ribavirin-containing treatment regimens). Univariate and multivariate analyses were performed to determine impact of CD4+ T-cell count on SVR.

Results: 138 patients were included in the analysis. All were treated with DAAs either with (35/138, 25.4%) or without ribavirin (103/138, 74.6%). Most (121/138, 88%) of patients achieved SVR12. Univariate analysis showed that cirrhosis ($p < 0.001$), HCC ($p < 0.0001$), HCV3 ($p = 0.027$), and history of prior HCV treatment with an interferon-based regimen or a DAA-based regimen ($p = 0.004$) were risk factors for treatment failure with a trend toward significance by African-American race ($p = 0.073$). A multivariate logistic regression model found that the odds ratio for failure was 15.4 for HCC ($p < 0.0001$), 5.4 for HCV3 ($p = 0.027$), and 6.5 for treatment-experienced patients ($p = 0.004$). There was no statistically significant difference in median CD4+ T-cell count at baseline, EOT, or SVR12 between the responder and treatment failure groups (Figure). There was a numeric difference in median CD4+ T-cell count at EOT, but it did not achieve significance ($p = 0.11$). Only 3 patients (2.2%) had a CD4 + T-cell count less than 100 cells/μl at baseline.

	Median CD4+ T-cell count (range)		
	Baseline[a]	EOT[b]	SVR12[c]
SVR12	525 (84-1557)	621 (55-1870)	539 (83-1925)
Failure	449 (78-1293)	335 (230-1147)	512 (83-774)

[a]p= 0.89, [b]p= 0.62, [c]p=0.52

Conclusion: CD4 T-cell count appears not to impact rates of SVR12 in HCV-monoinfected cancer patients receiving DAAs. Further studies with larger sample sizes are needed to characterize novel risk factors for DAA treatment failure in the immunocompromised population.

THU-345

The real-world safety and efficacy of sofosbuvir plus ribavirin for eldery patients over 75 years of age

H. Tamai[1], N. Shingaki[1], Y. Ida[2], R. Shimizu[2], S. Maeshima[2], J. Okamura[3], A. Kawashima[3], T. Nakao[3], T. Hara[4]. *[1]Wakayama Rosai Hospital, Department of Hepatology, Wakayama, Japan; [2]Wakayama Medical University, Second Department of Internal Medicine, Wakayama; [3]Naga Municipal Hospital, Department of Internal Medicine, Kinokawa, Japan; [4]Wakayama Rosai Hospital, Department of Gastroenterology, Wakayama, Japan*
Email: hdy-tamai@wakayamah.johas.go.jp

Background and Aims: In May 2015, the clinical use of combination therapy using sofosbuvir and ribavirin was first approved in Japan for patients infected with genotype 2 hepatitis C virus. This therapy was well tolerated and achieved a high SVR rate (96%) in a Japanese Phase III trial. However, patients aged older than 75 years old were excluded in the phase III trial. The present study aimed to evaluate the safety and efficacy of sofosbuvir plus ribavirin for elderly patients over 75 years old of age and to clarify whether extremely high sustained virological response (SVR) rate can be achieved even in a real-world setting.
Method: This was a multicenter prospective cohort study. Exclusion criteria were any of followings: (1) being infected with other genotypes other than genotype 2, (2) hemoglobin level <10 g/dl, (3) estimated glomerular filtration rate (eGFR) ml/min/1.73 m^2 < 30, (4) decompensated cirrhosis, (5) any form of cancer. Between June 2015 and May 2017, 225 patients were treated by standard doses of sofosbuvir (400 mg/day) plus ribavirin (1,000 mg/day for patients weighing more than 80 kg, 800 mg/day for patients weighing between 80 and 60 kg, and 600 mg/day for patients weighing less than 60 kg) for 12 weeks. The negativity of HCV-RNA at week 12 after the end of therapy was defined as SVR.
Results: Median age was 68 (17–86) years old. There were 128 male and 97 female patients. The SVR rates of overall, patients <65 years, patients ≥65 and <75 years, and patients ≥75 years were 97% (219/225), 99% (78/79), 96% (75/78), and 97% (66/68), respectively. The SVR rates of male, female, ineligible patients to interferon, cirrhotic patients, patients with anemia (hemoglobin level <12 g/dL), patients with moderate chronic kidney disease (eGFR < 60), patients with treatment failure of ribavirin and interferon, and patients with history of HCC treatment were 97% (124/128), 98% (95/97), 97% (174/180), 95% (81/85), 93% (28/30), 96% (44/46), 97% (32/33), and 89% (25/28), respectively. The SVR rate of patients with history of HCC treatment was significantly lower than that of other patients ($p < 0.05$). One patient (0.4%) discontinued treatment due to drug-induced pneumonia. Dose reduction or interruption of ribavirin was required in 29 (13%) patients because of anemia, and that appeared in 4% (3/79) of patients <65 years, in 13% (10/78) of patients ≥65 and < 75 years, and in 24% (16/68) of patients ≥75 years.
Conclusion: In a real-world setting, although ribavirin dose reduction or interruption was required along with advanced age, extremely high SVR rate was achieved even in elderly patients older than 75 years of age. When patients without severe anemia or renal failure are selected, sofosbuvir plus ribavirin would be safe and highly effective treatment irrespective of age. However, patients with history of HCC treatment may not be good candidates for this treatment.

THU-346

Sustained virologic response rates (SVR-12) for chronic hepatitis C genotype 6 patients treated with Ledipasvir/Sofosbuvir or Sofosbuvir/Velpatasvir

E. Nguyen[1], S. Trinh[2], H. Trinh[1], H. Nguyen[1], K. Nguyen[1], B. Levitt[1], M. Nguyen[1], T. Purohit[1], E. Shieh[1], M. Nguyen[2]. *[1]San Jose Gastroenterology, San Jose, United States; [2]Stanford University Medical Center, Division of Gastroenterology and Hepatology, Palo Alto, United States*
Email: mindiehn@stanford.edu

Background and Aims: Genotype 6 (GT 6) is a rare sub-type of hepatitis c (HCV). As such, GT 6 has been underrepresented in clinical trials using the new interferon and ribavirin free all oral acting agents (DAA's) to treat and cure HCV, limiting the generalization of the results. A newer DAA combination of sofosbuvir (SOF) and velpatasvir (VEL) was recently approved for treatment of HCV GT 6. The study aim was to compare sustained virologic response (SVR-12) rates between the first approved DAA ledipasvir (LDV)/SOF and SOF/VEL for treatment naive, cirrhotic, and non-cirrhotic GT6 patients.
Method: This was a retrospective study of consecutive adult patients with HCV GT 6 (n = 114) who were treated with LDV/SOF (n = 81) or SOF/VEL (n = 33) for 8–24 weeks from 2014–2017 in the United States. These patients were not in any previous clinical trials. One patient treated with LDV/SOF/RBV was included in the LDV/SOF group. After exclusion for patients with hepatocellular carcinoma (HCC) (n = 5) and/or prior treatment (n = 9), the LDV/SOF group had 58 patients and the SOF/VEL group had 28 patients. Among the HCC patients, all had cirrhosis with 4 patients in the LDV/SOF group.
Results: Overall, the mean age was 63.5 ± 9.9 years, with 47% male, 96% Vietnamese and 96.5% GT 6 and 3.5% GT 6c (all in the LDV/SOF group). The adverse events reported were headache (3.5%), fatigue (2.6%), insomnia (4.9%), or other (2.6%) (all in LDV/SOF group besides 1 patient who experienced fatigue in the SOF/VEL group). There was a higher percentage of cirrhotic patients (49.4%) in the LDV/SOF cohort

than the SOF/VEL cohort (15.2%, p < .001). Overall, 94.8% of LDV/SOF cohort obtained SVR-12 compared to 100% of the SOF/VEL cohort. Among the non-cirrhotic patients, 96.9% of LDV/SOF cohort achieved SVR-12 compared to 100% of the SOF/VEL cohort. Among patients with cirrhosis, 92.3% of the LDV/SOF achieved SVR-12 compared to 100% of the SOF/VEL cohort (Table).

	LDV/SOF	SOF/VEL
SVR12 for genotype 6 patients		
Treatment naïve overall	55/58 (94.8%)	28/28 (100.0%)
Treatment naïve & non cirrhotic	31/32 (96.9%)	25/25 (100.0%)
Treatment naïve & cirrhotic	24/26 (92.3%)	3/3 (100.0%)
Treatment experienced overall	4/5 (80.0%)	—

Conclusion: SOF/VEL achieved a SVR 12 rate of 100% for GT 6 patients though those treated with LDV/SOF also experienced >90% SVR-12 rate. Further research is needed to determine if the difference in SVR-12 outcomes was due to the higher number of cirrhotic patients in the LDV/SOF group, the presence of GT6c or other variables. Regardless, HCV GT 6 patients have excellent treatment options.

THU-347

Clinical and virological characteristics of DAA-experienced patients with chronic HCV infection treated with sofosbuvir/velpatasvir/voxilaprevir: results from the Frankfurt Resistance Database

J. Vermehren[1], J. Dietz[1], K.-H. Peiffer[1], S. Susser[1], S. Zeuzem[2], C. Sarrazin[1]. [1]*Universitätsklinikum Frankfurt, Frankfurt am Main, Germany;* [2]*University of Frankfurt, Department of Medicine, Frankfurt, Germany*
Email: johannes.vermehren@kgu.de

Background and Aims: Patients with chronic hepatitis C virus (HCV) infection who do not achieve a sustained virologic response following treatments with direct-acting antiviral agents (DAAs) have limited retreatment options. Combination therapy with sofosbuvir, velpatasvir, and voxilaprevir (SOF/VEL/VOX) is now approved for retreatment of patients in whom prior DAA therapy has failed. Our aim was to investigate the clinical and virological characteristics of patients retreated with SOF/VEL/VOX in a real-world setting.
Method: The Frankfurt Resistance Database was retrospectively searched for all patients with prior DAA treatment failure who were retreated with SOF/VEL/VOX as rescue therapy. Resistance testing was performed in all patients prior to starting rescue therapy. Resistance associated substitutions (RASs) were determined by means of population sequencing of the NS3, NS5A, and NS5B coding regions.
Results: A total of 27 patients (81% males; mean age, 57 years; 48% cirrhosis) with previous failure to direct-acting antiviral agents (DAAs) were started on SOF/VEL/VOX rescue therapy. Patients were infected with genotypes (GTs) 1a (n = 8), 1b (n = 5), 3 (n = 11), and 4 (n = 3). The majority of patients had previously received NS5A-based (n = 18) and NS5A plus NS3-based regimens (n = 8). Five patients had failed at least two different DAA regimens. Prior to starting VOX/VEL/SOF rescue therapy, 40% of GT1 patients had resistance-associated substitutions (RASs) in NS5A and 60% had RASs in at least two DAA targets. Ninety-one percent of GT3 patients had NS5A RASs (Y93H in all but one). End-of-treatment response was achieved in 9/9 GT1 patients (n = 4 with SVR4). SVR12 data will be presented at the meeting.
Conclusion: Our preliminary real-world data confirm that SOF/VEL/VOX is an effective rescue therapy in patients with prior DAA treatment failure despite the presence of high-level RASs and/or multiple previous DAA therapies.

THU-348

Are patients treated with direct antiviral agents for HCV infection at greater risk for extrahepatic malignancies?

T. Saadi, R. Kramskay, H. Sholy, A. Yaccob, V. Ben-Hakoun, E. Veitsman, J. Khoury. *Rambam Health Care Campus, Liver Unit, Haifa, Israel*
Email: t_saadi@rambam.health.gov.il

Background and Aims: Direct antiviral agents (DAAs) have become the treatment of choice for chronic hepatitis C virus (HCV). A safety concern was raised about a possible relationship between DDAs and hepatocellular carcinoma (HCC) development. It appears that development of de-novo HCC is unrelated; however, the recurrence of HCC is controversial. We report on seven patients who developed extra hepatic malignancies after treatment with DAAs.
Method: 292 patients were treated with DAAs in our unit between January 2015 and October 2017. 246 patients finished treatment. The most common regimen used was the combination of paritaprevir/ritonavir/ombitasvir with/without dasabuvir (PrOD). The most common genotype was G1b. Two patients had viral relapse, one had a breakthrough vermia, and one patient stopped treatment because of side effects. All were treated with a second treatment regimen. All patients achieved sustained viral response (SVR). Adverse events were recorded during treatment and after finishing treatment. Efficacy was determined by assessment of serum HCV RNA.
Results: We observed unexpected development of extrahepatic malignancies in seven patients (2.4%): Three patients developed lymphoma, two developed laryngeal carcinoma, one developed pancreatic adenocarcinoma and one developed recurrent aggressive transitional cell carcinoma of the urinary bladder. Four patients were treated with PrOD, and the rest with simeprevir and sofosbuvir, daclatasvir and sofosbuvir or daclatasvir with peginterferon. The occurrence of the malignancies was three months to four years after the end of the treatment. The incidence of these malignancies in the cohort was 1.2%, 0.8%, 0.4% and 0.4% respectively, while the incidence in the general population is 7, 20, 8.8 and 142 to 100,000, respectively. Besides, 7 patients (2.4%) developed de novo or recurrent HCC.
Conclusion: This report raises a question about a possible relationship between treatment with DAAs and development of extrahepatic malignancies in addition to the reports regarding hepatic malignancied. Thus, data collection from larger cohorts is critical to determine the relationship possibility.

THU-349

Real world adherence to Direct-Acting Antivirals in a cohort of drug users in Rome, Italy

E. Teti[1], L. Foroghi[1], V. Malagnino[1], V. Cento[2], C. Stingone[1], M. Compagno[1], G. Malerba[1], A. Gentile[1], R.A. Cavasio[1], L. Coppola[1], E. Rossi[3], D. Masci[3], P. Sammarco[3], B. Coladarce[3], G. Rodoquino[3], M. Patti[3], C. Sarrecchia[4], C.F. Perno[2], F.C. Silberstein[2], M. Barra[3], L. Sarmati[1], M. Andreoni[1]. [1]*Tor Vergata University, Clinical Infectious Diseases, Rome, Italy;* [2]*Tor Vergata University, Virology Unit, Rome, Italy;* [3]*Villa Maraini Foundation, Rome, Italy;* [4]*Tor Vergata University, Clinical Infectious Diseases, Italy*
Email: elisabetta.teti@gmail.com

Background and Aims: For a long time, drug-addiction strongly limited anti-HCV treatment. Since newer direct-acting antivirals (DAAs) significantly improved tolerability and manageability, we evaluated adherence and efficacy of DAA-regimens in a drug-users cohort.
Method: Drug users with chronic hepatitis C were enrolled from June 2015 to October 2017. Adherence was calculated as percentage of control-visits attended among those scheduled (monthly during treatment and at 4, 12 and 24 weeks of follow-up). Regularity of medication uptake was investigated by questionnaires.
Results: Patients' cohort was so represented: active drug users (group A, n = 22/93, 23.7%), opioid substitution treatment patients (group B, n = 15/93, 16.1%) and rehab patients (group C, n = 19/93, 20.4%); 37/93 patients (39.8%) fell into the A/B group. Drug users (n = 93, male 82%)

with complex viral, clinical and social features received at least one DAA-dose. Genotype-1a and genotype-3 infections were the most common (54.3% and 31.5%); 47.2% of patients had cirrhosis () and 28.2% and resistance-associated variants. Overall, median [IQR] liver stiffness was 12.2 (10.4–23.4) kPa); 9.8% of patients was HIV-coinfected; 60.2% was unemployed, and 38.7% had psychiatric comorbidities. Overall treatment adherence was 91%, in particular: adherence to visit-schedule was higher among those with more stability and support (groups B [96.2%] and C [96.4%]), and lower in active drug users (group A [90.7%]; group A/B [87.4%]) (p = 0.04). The A/B group of patients was that with significant lesser adherence (60% of fully-adherent patients; p = 0.015). Full adherence was associated with shorter regimens (83% vs. 63% in 24-weeks regimens; p = 0.059), while no differences were observed according to HIV-coinfection, psychiatric comorbidities, imprisonment and unemployment. Detention resulted as a factor significantly associated with non-adherence in the whole treatment period and follow up (p = 0.01). *Per protocol* SVR_{12} rate in 64/93 patients who completed treatment at the time of the analysis was 98.4% (one relapse); four patients discontinued prematurely (three of these because of advanced liver clinical conditions).

Conclusion: Although drug users still face several clinical and social issues, our data indicate that even active drug-users can be highly adherent to DAA treatment, achieving optimal HCV cure-rates, especially with shorter DAA-regimens.

Email: furusyo@gim.med.kyushu-u.ac.jp

Background and Aims: Little real-world data has been reported for Asians who have received interferon-free regimen with direct-acting antivirals for chronic hepatitis C. Our large, multicenter, real-world cohort study of Japanese chronic hepatitis C patients was done to assess the effectiveness of Japan-approved direct-acting antiviral (DAA) treatment for patients who were both treatment-naïve and -experienced with or without compensated cirrhosis.

Method: This multicenter cohort consisted of 1,961 (GT1: 1,312, GT2: 649) consecutive Japanese patients who initiated a 12-week course of the following DAA treatment. Patients with under aged 20 years, decompensated cirrhosis, or co-infection with HBV/HIV were excluded: GT1: Sofosbuvir (SOF)/Ledipasvir (LDV) (n = 1,101), Ombitasvir (OBV)/Paritaprevir (PTV)/Ritonavir (r) (n = 106), Elbasvir (EBR)+Grazoprevir (GZR) (n = 105), GT2: Sofosbuvir (SOF)+Ribavirin (RBV) (n = 649), For GT1 patients, NS5A gene amino acid positions 31 (L31I/F/M/V) and 93 (Y93C/F/H/N/S) were measured by direct-sequencing. These resistance associated variants (RAVs) were examined at baseline and at the time of relapse.

Results: The sustained virological response (SVR) rates of the GT1 patients who underwent SOF/LDV was 98.7%, only 14 relapsers (1.3%) were found, by intention-to-treat analysis. SVR rate of those with cirrhosis plus RAVs was 87.5%; ratio among all was just 6% (n = 53). The 14 relapsers included 5 with failure of DCV + ASV. The SVR rates of the GT1 patients who underwent OBT/PTV/r and EBZ + GZR were 98.1% and 100%, respectively, by intention-to-treat analysis. The SVR rate of the GT2 patients who underwent SOF + RBV was 96.1%, 25 non-SVR (3.9%) were found, by intention-to-treat analysis. SVR rate of those with cirrhosis plus treatment-experience was 85.4%; ratio among all was just 7.4% (n = 48).

Conclusion: Japan-approved DAA treatment for both HCV GT 1 and GT2 was exceptionally effective. However, NS5A RAVs undermined the virological effect for cirrhosis GT1 patients, and RBV-experience did the effect for cirrhosis GT2 patients.

Email: padovanidiana@gmail.com

Background and Aims: Direct-acting Antiviral Agents (DAAs) have shown a high rate of Sustained Virologic Response (SVR) in the treatment of hepatitis C, with few and mild adverse reactions. The aim of this study was to evaluate: (1) The efficacy of DAAs; (2) The incidence of adverse reactions; (3) The interactions with other drugs in our centre.

Method: We performed an observational study of all HCV patients treated with DAAs in our centre from 01/01/2015 to 01/08/2017. We recorded: patient demographic information, grade of fibrosis by point-Shear Wave Elastography on Philips IU22 before and 12 months after treatment, HCV genotype, DAAs adverse reactions and therapeutic scheme, and concomitant drugs.

Results: We treated 142 HCV consecutive patients with second generation DAAs. We obtained a Sustained Virologic Response at 12 weeks (SVR12) in 93.5% of patients, 9 failures and 3 treatment interruptions due to adverse effects. Only 3 patients did not show any adverse reaction. In almost half of the cases fatigue and a reduction of at least 2 g/dL of haemoglobin levels were observed. Another frequent adverse effect was hyperglycemia (31.7%), observed in around 70% of the patients with type 2 diabetes treated with insulin or oral hypoglicemic agents and only in 25% of the non-diabetic patients. Hyperglycemia was more frequent in patients taking Daclatasvir + Sofosbuvir (45.7% vs 31.7% – p < 0.001) without a correlation with a specific antidiabetic drugs. Moreover, higher degrees of fibrosis were associated with a higher number of adverse reactions (p < 0.001). Patients who take Ribavirin display a high rate of anaemia also present with only DAA, even if less severe (67% vs 28% – p < 0.001).

Conclusion: In this real life study, DAAs confirmed the excellent therapeutic success already known in literature. However, we found a higher rate of adverse effects especially in more advanced liver disease. In particular we have noticed a relevant rate of hyperglycemia, an adverse effect that has not been reported in literature and that appears to be related to the drug's class or the hepatic effect of HCV clearance rather than drug-drug interactions.

Background and Aims: There is limited data with regard to the effect of direct acting antivirals (DAA) on renal function. The purpose of this study was to examine differences in renal function before and after treatment in HCV patients who achieved SVR with all-oral DAAs.
Method: This is a single-center, retrospective analysis of patients with chronic HCV who were treated with DAAs between December 2014 and December 2015. Patients were excluded if they did not achieve SVR or if they did not have glomerular filtration rate (GFR) and serum creatinine data before and 3–6 months after achieving SVR. Measures of central tendency and frequency distributions were used for univariate analysis. The paired-samples t-test was used to compare before and after treatment serum creatinine levels.
