Email: jko@alnylam.com

Background and aims: Acute hepatic porphyrias (AHPs) are rare, often misdiagnosed genetic diseases due to enzyme deficiencies involved in heme biosynthesis, leading to accumulation of neurotoxic heme intermediates. Clinical manifestations comprise potentially life-threatening neurovisceral attacks and chronic symptoms. At times, attack symptoms are managed through hemin, or prophylactically, with off-label hemin, GnRH, or carbohydrates. Given that differences exist among healthcare systems in Europe (EU) and United States (US), this study aimed to characterize AHP management in EU and US.

Method: EXPLORE (NCT02240784) is an international, prospective, natural history study of AHP patients. Eligible patients were those with ≥ 3 attacks/year or those on prophylaxis to prevent attacks. On separate questionnaires, investigators and patients reported attack history, including hemin use for attacks and off-label prophylaxis. Patients also reported perception of treatment effectiveness and ability to predict attack onset. Descriptive statistics were used to analyze outcomes, treatment location, and dosing frequency/duration by region.

Results: A total of 112 patients (EU: n = 63; US: n = 49) from 21 centers (EU: 14; US: 7) were enrolled (mean age 39 years; 89% female). In the year preceding the study, patients' mean (SD) attack rate was 9.2 (10.1) and 6.2 (7.8) for attacks requiring hemin or hospitalization. Attacks were managed at healthcare facilities (69%) and at home (31%). During attacks, hemin (69%), opioids (54%), and other medications (45%) were administered. Sixty-two patients (total: 55%; EU: 43%; US: 71%) reported use of any prophylaxis, and 52 patients (total: 46%; EU: 41%; US: 53%) reported prophylactic hemin use, mostly weekly (51%). Attack rate for patients on hemin prophylaxis was 10.0 (11.1), and for those who were not, 8.7 (8.9). Among EU patients who ever used hemin for attacks (78%), attack treatment spanned: 1 day (18%), 2-4 days (76%), and > 4 days (6%). Among US patients who ever used hemin for attacks (92%), treatment spanned: 1 day (13%), 2-4 days (51%), and > 4 days (36%).

Conclusion: Hemin prophylaxis was less frequent and hemin treatment duration for attacks was shorter in the EU than in US. Patient selection bias and variable access to treatments may account for this difference. Overall, attack rates and burden of illness remain high, regardless of prophylaxis treatment, underscoring the need for therapies to address AHP patients' unmet medical needs.

FRI-441

A novel heterozygous ABCB4, RUNDC3B and ABCB1 deletion associated with severe cholestatic liver disease in adults

Benedetta Terziroli[1], Richard Thompson[2], Pierre Foskett[2], Andreas Cerny[1], Elisabetta Merlo[3], Diego Vergani[2], Anne-Laure Rougemont[4], Isabelle Moix[5], Giorgina Mieli-Vergani[2], Michael Morris[5].

Email: benedetta.terziroli@hin.ch

Background and aims: We report a large family with an autosomal dominant progressive cholestatic liver disease due to a heterozygous deletion involving *ABCB4*, *ABCB1* and *RUNDC3B*.

Method: DNA sequencing by next generation and Sanger sequencing of patient I.6 did not reveal known or potentially pathogenic nucleotide variants in *ABCB4, ABCB11, ATP8B1, JAG1* and *NOTCH2*; expanded copy number variation analysis of next generation sequencing data revealed a heterozygous deletion removing the 5' region of *ABCB4* and the entire coding sequences of *ABCB1* and *RUNDC3B* on chromosome 7. The same deletion was identified in 11 family members by quantitative polymerase chain reaction of *ABCB4* exon 1 and of the adjacent *ABCB1* exon 32, and by multiplex ligation-dependent probe amplification.

Results: Family tree and clinical characteristics of affected patients are presented in Figure. Two patients (I.4A and I.6) underwent liver transplantation.

All three symptomatic patients treated with UDCA normalized liver biochemistry and did not progress to cirrhosis over a follow-up period of 34, 15 and 15 years.

Age of clinical disease onset was highly variable. Child III.8 had neonatal cholestasis, with normalization on ursodeoxycholic acid (UDCA) and no progression of liver disease. The remaining affected children had no evidence of liver disease, but were not tested at birth. Of note, in symptomatic patients the liver histology at early disease stages was normal, even in the presence of elevated liver enzymes.

Hepatobiliary malignancies were remarkably frequent, affecting 3/5 cirrhotic patients, suggesting that this large deletion is a significant cancer risk factor in addition to cirrhosis, age and sex. While *ABCB4* defects are known to be associated with hepatic cancers even in the absence of cirrhosis, the consequences of *RUNDC3B* and *ABCB1* defects on the liver are unknown.

Conclusion: Our findings indicate that heterozygous deletions involving the *ABCB4, RUNDC3B* and *ABCB1* genes should be included in the genetic analysis of high GGT cholestasis, as patients have an elevated risk of developing chronic liver disease and hepatic malignancies, warranting cancer surveillance; UDCA treatment normalizes liver biochemistry, possibly preventing disease progression.

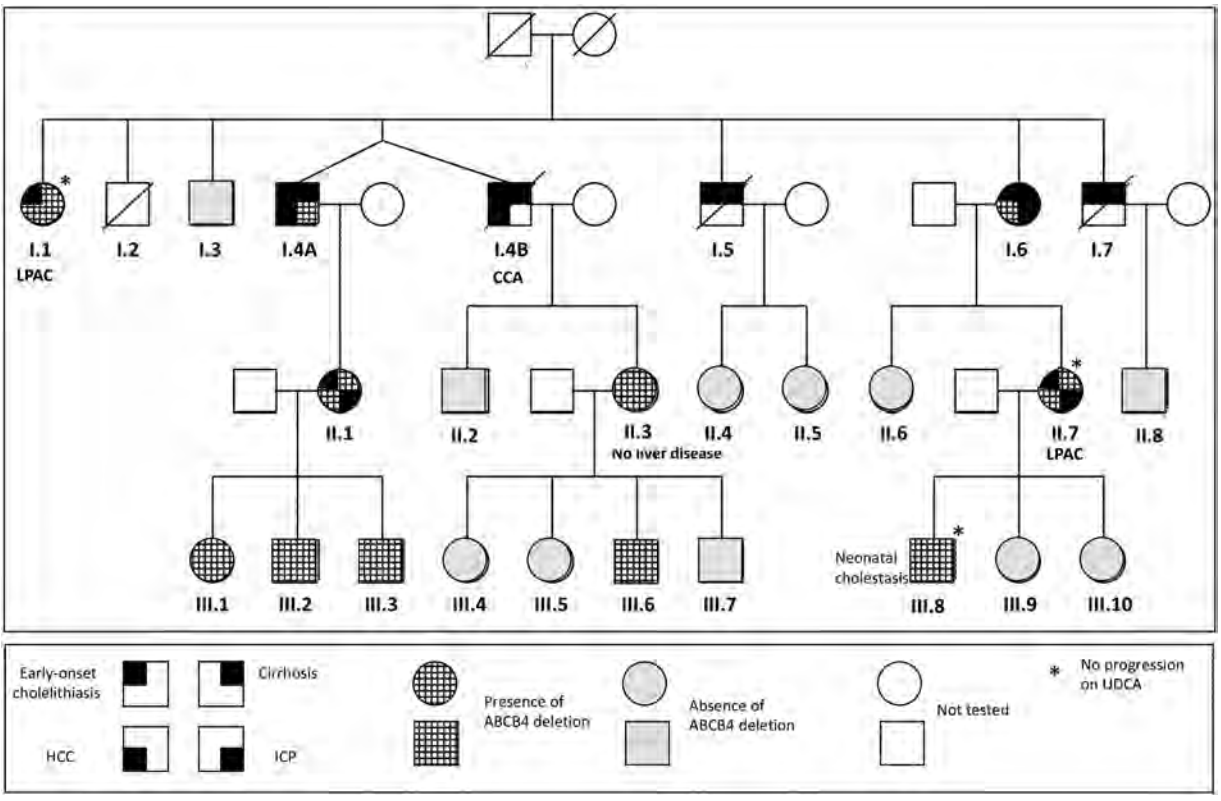

Figure: (abstract: FRI-441): Pedigree of the family. HCC, hepatocellular carcinoma; CCA, cholangiocarcinoma; LPAC, low phospholipid-associated cholelithiasis; ICP, intrahepatic cholestasis of pregnancy; UDCA, ursodeoxycholic acid. Subjects without black squares do not have liver disease. Subject I.2 died at age two days for unknown reasons.

Email: jko@alnylam.com

Background and aims: Acute hepatic porphyrias (AHPs) are rare, often misdiagnosed genetic diseases due to enzyme deficiencies involved in heme biosynthesis. AHPs include acute intermittent porphyria (AIP), variegate porphyria (VP), and hereditary coproporphyria (HCP). Clinical manifestations comprise potentially life-threatening, neurovisceral attacks and chronic symptoms. This study aimed to characterize the disease manifestations and daily life impacts of AHPs in Europe (EU) and United States (US).

Method: EXPLORE (NCT02240784) is a prospective, international, observational study of the natural history and clinical management of AHP patients with recurrent attacks (≥ 3/year) or on prophylactic treatment to prevent attacks. At baseline, patients reported number of attacks, attack symptoms, chronic symptoms between attacks, and completed quality of life and health utilization questionnaires. During the 12-month study, patients also completed a porphyria attack symptom inventory questionnaire when they experienced attacks.

Results: A total of 112 patients (EU: 56%; US: 44%) from 21 centers (EU: 14; US: 7) were enrolled (mean age 39 years; 89% female; 93% AIP, 4% VP, 3% HCP). At baseline, the mean (SD) of all attacks reported in the last 12 months was 9.0 (10.6) for EU patients and 9.7 (9.2) for US patients. Most patients reported chronic symptoms between attacks (EU: 60.3%; US: 71.4%), often manifesting daily (EU: 63.2%; US: 80%). Pain and central nervous system involvement were the most common: abdominal (20.5%) or other origin (15.1%), anxiety (19.2%), tiredness (19.2%) and nausea (19.2%). At study entry, 47.3% of patients reported limited social interactions (EU: 37%; US: 61%) and 29% reported being unable to leave home due to their disease (EU and US: 29%). During attacks, most patients (98%) reported pain symptoms in abdomen (EU:77.5%; US:91.7%), back (EU: 65%; US: 83.3%), and arm/leg (EU:65%; US:70.8%). Pain associated with nausea was also common (EU: 65%; US: 87.5%). Patients also reported disorders of

mood or sleep during attacks, including tiredness (EU:75%; US:87.5%) and trouble sleeping (EU:80%;75%).
Conclusion: Overall, AHP patients in the EU and US showed similar symptoms during attacks and experienced comparable chronic symptoms. Some AHP patients also experienced negative impacts on daily life. Importantly, this study demonstrates that most AHP patients have chronic symptoms in addition to the significant burden associated with acute attacks.

FRI-443
Non-invasive fibrosis assessment in hyperferritinemia and hemochromatosis
André Viveiros[1], Benedikt Schaefer[1], Maria Effenberger[1], Herbert Tilg[1], Heinz Zoller[1]. [1]*Medical University of Innsbruck, Deparment of Medicine I, Innsbruck, Austria*
Email: andre.viveiros@i-med.ac.at

Background and aims: Ferritin is a surrogate of hepatic iron overload but also an indicator of inflammation and liver fibrosis, which are all common in hemochromatosis and other chronic liver diseases. Non-invasive assessment of fibrosis is important for the prognosis of chronic liver disorders and different ferritin thresholds have been proposed for hemochromatosis, NAFLD and chronic hepatitis C. The aim of the present study was to determine the prevalence of high ferritin and hepatic fibrosis as well as the association of these parameters in a large unselected cohort of patients with liver diseases of various etiologies.
Method: Between 200 and 2016 a total of 3362 patients were genotyped for the common hemochromatosis-associated gene polymorphisms (p.Cys282Tyr and p.His63Asp in *HFE*). Clinical and biochemical parameters and if available transient elastography were assessed at the time of genotyping and the non-invasive fibrosis score FIB-4 was calculated.
Results: Hyperferritinemia (> 300 µg/L for males and > 200 µg/L for females) was present in 2061 (61.3%) of patients. Fibroscan and FIB-4 showed a significant overall correlation ($r = 0.37$, $p < 0.001$). The prevalence of advanced fibrosis as indicated by elastography > 13kPa was 3% in hemochromatosis patients (p.Cys282Tyr homozygous), 4% in compound heterozygotes and 22% in patients homozygous of p.His63Asp. Single heterozygous patients and patients without *HFE* associated gene mutations had the highest prevalence of advanced fibrosis with 27.7%. These findings were confirmed when advanced fibrosis was defined as FIB-4 > 3.25. Patients homozygous for p.Cys282Tyr had a prevalence of advanced fibrosis (FIB-4 > 3.25) of 8.6%, followed by compound heterozygous patients (11.9%) and patients homozygous for p.His63Asp (15.4%). In the remaining genotypes 20.3-27% of patients presented with advanced fibrosis. Significant fibrosis (FIB-4 1.45-3.25) was present in 885 (26.4%) patients. When patients were stratified by HFE genotype again, homozygosity for the p.Cys282Tyr mutation in *HFE* was associated with the lowest fibrosis risk (FIB-4 < 1.35). Binary logistic regression analysis showed that age, ferritin, transferrin saturation and *HFE* genotype were independent predictors of significant and advanced fibrosis.
Conclusion: In conclusion, in hemochromatosis the serum-based fibrosis marker FIB-4 is a surrogate marker of significant and advanced fibrosis as determined by transient elastography. High ferritin is associated with significant and advanced fibrosis. Among patients with high ferritin, carriers of hemochromatosis-associated *HFE* mutations on both alleles are less likely to present with advanced fibrosis when compared with patients with high ferritin secondary to chronic viral hepatitis, alcoholic or non-alcoholic fatty liver disease.

FRI-444
VTX-803 AAV-mediated correction of progressive familiar intrahepatic cholestasis type 3 in a clinically relevant mouse model
Nicholas D Weber[1], Leticia Odriozola[2], Javier Martínez-García[2], Veronica Ferrer[3], Anne Douar[3], Bernard Bénichou[3], Cristian Smerdou[2,4], Gloria González-Aseguinolaza[1,2,4]. [1]*Vivet Therapeutics, Pamplona, Spain;* [2]*Center for Applied Medical Research (CIMA), Division of Gene Therapy and Regulation of Gene Expression, Pamplona, Spain;* [3]*Vivet Therapeutics, Paris, France;* [4]*Instituto de Investigación Sanitaria de Navarra (IdISNA), Pamplona, Spain*
Email: nweber@vivet-therapeutics.com

Background and aims: Progressive familial intrahepatic cholestasis type 3 (PFIC3) is a rare monogenetic disease caused by mutations in the *ABCB4* gene encoding the multidrug resistance protein 3 (MDR3), which result in a reduction in biliary phospholipid (PL) content. This reduced biliary PL is not able to counteract the detergent effects of bile salts, leading to cholangitis, cholestasis, cirrhosis and ultimately liver failure. We attempted to treat *Abcb4* (−/−) mice with an hepatotropic AAV vector carrying a codon-optimized version of human *ABCB4* in order to achieve transgene expression and reversion of PFIC3 disease markers via restoration of PL in the bile.
Method: Huh7 cells were transfected with one of six AAV plasmids encoding three different MDR3 isoforms (A, B and C), of either a codon-optimized (co) or wildtype (WT) version of each gene and analyzed by immunofluorescence microscopy. Next, *in vivo* expression was confirmed by IHC following hydrodynamic injection (HDI) of *Abcb4* (−/−) mice with plasmids expressing isoform A (co and WT). Finally, two-week-old *Abcb4* (−/−) mice were treated intravenously with hepatotropic AAV viral particles expressing the selected transgene sequence coMDR3-A. Blood samples were harvested during the subsequent 12 weeks and levels of liver transaminases, alkaline phosphatase and bile salts were measured. At sacrifice, liver tissue was analyzed for AAV transduction and transgene mRNA by qPCR and RT-qPCR, respectively. Liver sections were stained for histological analysis and MDR3 quantification via IHC. Bile was harvested from gall bladders for phosphatidylcholine (PC) concentration measurement.
Results: From *in vitro* expression tests, only MDR3 isoform A was observed to localize to the membranes of hepatic cells. In addition, HDI studies showed that only coMDR3-A was expressed efficiently *in vivo*, localizing to biliary canaliculi. When AAV-coMDR3A was administered to *Abcb4* (−/−) mice, a sustained therapeutic effect was observed as serum biomarkers of liver disease decreased significantly compared to saline-treated control animals and animals treated at a lower AAV dose. Interestingly, male mice achieved a sustained therapeutic effect up through 12 weeks. However, the effect in females lasted through 12 weeks in half of the animals, while in the other half, the effect began to wane after 8 weeks. Upon sacrifice, markers of PFIC3 disease such as liver and spleen size, PC concentration in bile and liver histology were all significantly improved. Sustained MDR3 expression was detected in AAV-treated mice via RT-qPCR and IHC, showing specific localization of the transgene product to biliary canaliculi.
Conclusion: VTX-803 AAV-directed gene therapy successfully reverted the symptoms of PFIC3 disease in a clinically relevant mouse model with a sustained therapeutic effect up through 12 weeks post-treatment.

FRI-445

Safety and efficacy of trientine treatment in Wilson disease in patients withdrawn from d-Penicillamine: Final results from a prospective study

Karl Heinz Weiss[1], Jan Pfeiffenberger[1], Isabelle Mohr[1], Christian Rupp[1], Simone Hermans[2], Carlot Kruse[2], Peter Ferenci[3].
[1]Heidelberg University, Heidelberg, Germany; [2]Univar, Rotterdam, Netherlands; [3]Medical University of Vienna, Wien, Austria
Email: Simone.Hermans@univar.com

Background and aims: Trientine dihydrochloride (Trientine; UNIVAR B.V.) is an established treatment for Wilson Disease. This study aimed to assess the efficacy, safety, and quality of life outcomes of trientine chelator-based treatment after withdrawal of d-Penicillamine and to follow the clinical course of neurological disease and hepatic disease over time. ClinicalTrials.gov Identifier: NCT02426905.
Method: This study was set up as a prospective, single-center investigation. A total of 52 patients were enrolled and assessments were performed at 6 and 12 months. Primary end point was investigator rated outcome of hepatic and neurologic symptoms. Additional efficacy assessments included parameters of copper metabolism, quality of life assessments and safety reporting (TEAE listing and discontinuation rate).
Results: The full analysis set (FAS) included data from 51 (98.1%) patients. The mean (SD) age was 42.3 (14.52) years and the patient population was predominately female (35 [67.3%]). The mean (SD) total trientine dihydrochloride dose during treatment was 1377.6 (368.78) mg per day. Fifty/51 patients (98.0%) treated with Trientine were responders, while only one patient (2.0%) showed a mild worsening of disease at Month 12.
The overall mean (SD) values for UWDRS-neurologic subscale assessment-was 11.3 (24.31) at Baseline, 9.7 (23.85) at Month 6 and 8.8 (22.86) at Month 12. The mean 24-hour basal urine copper excretion was similar at Month 6 and Month 12 (4.011 µmol/24 h versus 4.452 µmol/24 h, respectively) and the mean (SD) values for serum copper at Baseline was 4.505 (3.4036) µmol/L, 4.648 (2.9990) µmol/L at Month 6 and at 4.753 (3.6092) µmol/L at Month 12. The mean (SD) values for non ceruloplasmin bound copper at Month 6 was 1.1542 (0.92618) µmol/L and 0.9051 (0.88075) µmol/L at Month 12. Quality of life indicators (mobility, self-care, usual activities, pain/discomfort, anxiety/depression) were stable and generally similar at Month 6 and Month 12.
During the study, 42 (80.8%) patients reported treatment-emergent adverse events (TEAEs) and 8 (15.4%) patients reported serious TEAEs. None of the serious TEAEs were considered treatment-related and no patients withdrew from treatment with trientine due to serious TEAEs.
Conclusion: Treatment with trientine was effective in maintaining stable hepatic and neurologic disease condition in patients with Wilson Disease. Trientine was generally safe and well tolerated.

Reduction of hepatic Z-alpha1 antitrypsin by RNA interference prevents and reverses liver disease including hepatic mitochondrial injury in the PiZ mouse model

Christine Wooddell[1], Keith Blomenkamp[2], Ryan Peterson[1], Vladimir Subbotin[1], Qili Chu[1], Holly Hamilton[1], Dawn Christianson[1], Steven Kanner[1], Jeffrey Teckman[2]. [1]*Arrowhead Pharmaceuticals, Arrowhead Madison, Madison, United States;* [2]*St. Louis University School of Medicine, Pediatrics, St. Louis, United States*
Email: cwooddell@arrowheadpharma.com

Background and aims: Autosomal co-dominant genetic disorder alpha-1 antitrypsin (AAT) deficiency causes pulmonary and liver disease. Individuals homozygous for the mutant Z allele accumulate polymers of Z-AAT protein in hepatocytes, where AAT is primarily produced, resulting in hepatocyte injury and fibrosis that may over time lead to cirrhosis and hepatocellular carcinoma. Injury to mitochondria, dilated endoplasmic reticulum (ER), microvesicular fat and other ultrastructural changes can be visualized by electron microscopy (EM). These livers also exhibit increased autophagic activity as a response to Z polymer accumulation. In this work, adult PiZ mice were treated with RNAi-based therapeutic ARC-AAT to reverse the AATD-associated liver disease phenotype.
Method: Efficacy of ARC-AAT, consisting of RNAi trigger plus an endosome-release agent, was evaluated in the PiZ mouse model that harbors the human Z-AAT gene and recapitulates AATD liver disease. Liver inflammation and Z-AAT polymer aggregates were assessed by histological evaluation. Soluble (monomeric) and insoluble (polymeric) Z-AAT in the liver were measured by semi-quantitative Western blotting. Expression of genes previously implicated in liver injury and development of fibrosis was measured by RT-qPCR. The intracellular state of hepatocytes, including dilated ER and mitochondrial injury, was assessed by EM.
Results: Male PiZ mice 11-17 weeks old at baseline had high levels of Z-AAT polymer aggregates in their hepatocytes. Mice treated biweekly with ARC-AAT for 32 weeks had sustained reduction of serum Z-AAT (> 90%) and similarly reduced soluble Z-AAT in the liver. They had 2.2-fold less Z-AAT polymer in liver lysate than saline controls and 1.6-fold less than baseline mice, indicating partial clearing. Reduction of disease phenotype was demonstrated by a 23-fold decrease in liver area of inflammatory foci and reduced expression of disease-related genes that contribute to inflammation and fibrosis. EM showed fewer autophagic vacuoles, normalization of ultrastructural cellular features and reduced mitochondrial injury in ARC-AAT treated mice compared to the saline control group.
Conclusion: Sustained RNAi treatment not only prevented accumulation of disease-causing Z-AAT polymer but also reduced pre-existing polymer, inflammation, expression of fibrosis-associated genes and damage to hepatic mitochondria. RNAi holds great promise for the treatment of patients with AATD-associated liver disease.

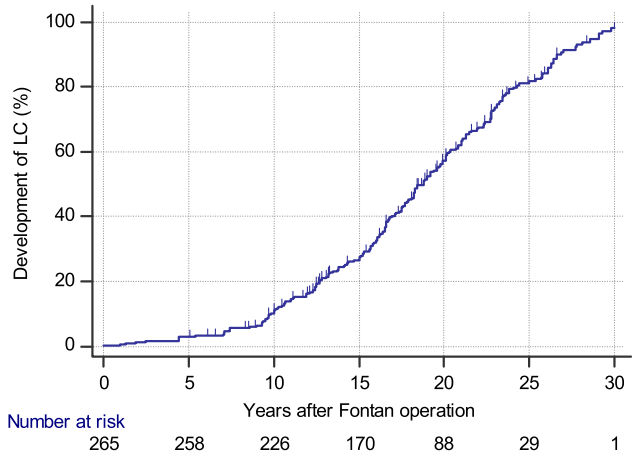
Clinical characteristics of liver cirrhosis and hepatocellular carcinoma occuring after Fontan operation

Jun Sik Yoon[1], Dong Ho Lee[2], Eun Ju Cho[1], Hyo Young Lee[1], Sun Woong Kim[1], Young Chang[1], Yun Bin Lee[1], Jeong-Hoon Lee[1], Su Jong Yu[1], Yoon Jun Kim[1], Jung-Hwan Yoon[1]. [1]*Department of Internal Medicine and Liver Research Institute, Seoul National University College of Medicine, Seoul, Korea, Rep. of South;* [2]*Department of Radiology, Seoul National University College of Medicine, Seoul, Korea, Rep. of South*
Email: creatioex@gmail.com

Background and aims: Hepatocellular carcinoma (HCC), which can be arising from cardiac cirrhosis, is one of the most serious late complications in patients after Fontan operation. In post-Fontan patients, benign arterial phase hyper-enhancing (APHE) nodules are frequently observed at multiphasic abdominal CT scan and are difficult to differentiate from HCCs. The aim of our study was to investigate the cumulative incidence of liver cirrhosis (LC), and to identify specific features which can distinguish HCC from benign APHE in patients after Fontan operation.
Method: We performed a retrospective cohort study of patients who had undergone Fontan operation and were followed at our hospital for more than 5 years, and who had undergone ultrasound or CT scan of the liver between January 2000 and December 2015. Cirrhosis was diagnosed using abdominal imaging tests such as ultrasound and CT. The clinical and radiographic features of HCC nodules were compared to those of APHE nodules who had undergone multiphasic abdominal CT scan.
Results: A total of 265 patients with a mean duration after Fontan operation of 19.3 ± 6.6 years were included in the study. The cumulative incidence of cirrhosis at 5, 10, 20, 30 years of duration after Fontan operation were 2.7% (7/265), 13.8% (28/254), 60.5% (135/223), 99.5% (203/204), respectively. The multiphasic abdominal CT

scan was performed in 82 patients and APHE nodules were observed in 42 patients. Of the 42 patients, 17 patients had APHE nodules more than 1 cm in size with washout on portal venous and/or delayed phase in cirrhotic liver. In these patients who met current non-invasive imaging diagnosis criteria for HCC, only 6 patients were diagnosed with HCC either by histology (n = 2) or clinical features (n = 4), and therefore, positive predictive value of current non-invasive imaging diagnosis criteria for HCC was only 35.3% (6/17). The presence of washout on portal venous phase ($p = 0.012$) and the serum AFP level ($p < 0.001$) were significantly associated with HCC nodules.



Conclusion: Cirrhosis is a frequently developed late complication in patients after Fontan operation, and its incidence has increased rapidly after 10 years from Fontan operation. Diagnosis of HCC in post-Fontan patients should not be made solely depending on the current imaging criteria, and presence of washout on portal venous phase and measurement of serum AFP might be helpful to differentiate HCC nodules from benign APHE nodules.

Correction of a metabolic liver disease after ex vivo gene editing of defective human primary hepatocytes

Stephen Strom[1], Mihaela Zabulica[1], Raghuraman chittoor srinivasan[1], Christina Hammarstedt[1], Tingting Wu[1], Olav Rooyackers[2], Beat Thöny[3,4], Gabriella Allegri[3], Johannes Häberle[3]. *[1]Karolinska Institute, Department of Laboratory Medicine, Stockholm, Sweden; [2]Karolinska Institute, Department of Clinical Science, Intervention and Technology, Stockholm, Sweden; [3]University Children's Hospital, Division of Metabolism and Children's Research Centre, Zurich; [4]Zurich Centre for Integrative Human Physiology and the Neuroscience Centre, Zurich, Switzerland*
Email: stephen.strom@ki.se

Background and aims: Urea cycle disorders are inborn errors of ammonia detoxification. The most common urea cycle defect is ornithine transcarbamylase deficiency (OTCD). The only definitive treatment for the urea cycle defects is orthotopic liver transplantation. Partial and temporary corrections of OTC deficiency has been reported with hepatocyte transplantation. An attractive approach for treating inborn errors of metabolism is the genetic correction of patient's own cells and autologous transplantation. However, the efficiency and safety of *ex vivo* gene editing and correction of human primary hepatocytes have not yet been established.
Method: Human hepatocytes were isolated from normal patients, that is, those proficient in urea cycle activity and from an 8 month old patient who received a liver transplant for severe OTC deficiency. Human primary hepatocytes were genetically corrected, ex vivo, though CRISPR/Cas9 technology. Special mutant mice (FRGN) where the Fumarylacetoacetate hydrolase (*Fah*), *Rag2* and *Il2rg* genes are knocked out are profoundly immunodeficient and produce tyrosine metabolites that are toxic to mouse liver cells. When the protective drug, NTBC drug is removed, the animals progress to liver failure, and transplantation of human hepatocytes at that time, leads to the high-level repopulation of the liver with human hepatocytes.
Results: Molecular analysis revealed a one-point mutation in an intronic region of OTC which creates a new acceptor splice site and includes an intronic region in the OTC mRNA between exons 5 and 6 and a premature stop codon shortly after exon 5. OTCD primary hepatocytes were corrected *ex vivo* achieving editing efficiencies > 50%, after verification of DNA and mRNA and the metabolism of ^{15}N-ammonium chloride into urea was significantly enhanced in the gene-edited hepatocytes. Mice that were highly repopulated with uncorrected, mutant OTC human hepatocytes displayed elevated levels ammonia on a regular protein diet and a significant delay in the metabolism of an ammonia challenge.
Conclusion: In summary, mice created with mutant OTC human hepatocytes display characteristic symptoms of the human disease which can be corrected by *ex vivo* gene editing of human hepatocytes preocedures. This study provides evidence of the efficiency of correcting a liver metabolic disease *ex vivo*. Additional safety and specificity analysis are currently being investigated.

Complex ATP7B mutation patterns in Wilson disease and a evaluation of a yeast model for functional analysis of the individual variant

Xiaojin Li[1], Wei Zhang[2], Donghu Zhou[1], Tingxia Lv[1], Anjian Xu[1], Hejing Wang[1], Xinyan Zhao[2], Bei Zhang[1], Yanmeng Li[1], Siyu Jia[1], Yu Wang[2], Xiaoming Wang[2], Zhen Wu[2], Weijia Duan[2], Qianyi Wang[2], Yuemin Nan[3], Jia Shang[4], Wei Jiang[5], Yongpeng Chen[6], sujun Zheng[7], Mei Liu[7], LiYing Sun[8], Hong You[2], Ji-Dong Jia[2], Xiaojuan Ou[2], Jian Huang[1]. *[1]Beijing Friendship Hospital, Experimental Center, Beijing, China; [2]Beijing Friendship Hospital, Liver Research Center, Beijing, China; [3]Third Hospital of Hebei Medical University, Department of Traditional and Western Medical Hepatology, Shijiazhuang, China; [4]Henan Provincial People's Hospital, Department of Infectious Diseases, Zhengzhou, China; [5]Zhongshan Hospital, Department of Gastroenterology, Shanghai, China; [6]Nanfang Hospital, Department of Infectious Diseases, Guangdong, China; [7]Beijing You-An Hospital, Artificial Liver Center, Beijing, China; [8]Beijing Friendship Hospital, Liver Transplant Center, Beijing, China*
Email: huangj1966@hotmail.com

Background and aims: Wilson disease (WD) is a rare autosomal recessive genetic disorder that is associated with various mutations in the *ATP7B* gene. Although *ATP7B* variants have been frequently identified, the exact mutation patterns remain unknown due to the absence of pedigree study, and the functional consequence of the individual *ATP7B* variant remain to be clarified.
Method: We recruited 65 clinically diagnosed WD patients from 60 unrelated families for the analysis of *ATP7B* variants and corresponding allele genotypes. The biological functions of the novel and representative *ATP7B* variants were evaluated by a yeast complementation assay.
Results: Pedigree analysis showed that besides *ATP7B* homozygous variants (8/65, 12.3%), compound heterozygous variants (43/65, 66.2%) were identified in the majority of the WD patients. More than 20% of the patients had one (13/65, 20.0%) or multiple (1/65, 1.5%) variants in only single allele, featured by a high ratio of splicing or frameshift variants. Six *ATP7B* variants were constructed into a pAG426GPD yeast expression vector to evaluate the functional consequence, and the results suggested different degrees of the disrupted function as severe, uncertain or mild, which were consistent with the corresponding phenotypes.
Conclusion: Our study revealed the complex *ATP7B* mutation patterns in WD patients and the applicability of the yeast model

system for the evaluation of functional consequence of *ATP7B* variants, which are essential for those WD cases difficult to interpret.

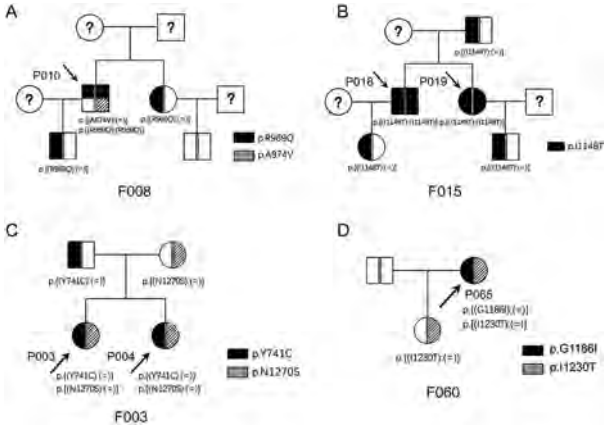

Figure 1: **Representative pedigree analysis of four families.** (A) Pedigree chart of family 8 (F008). The patient (P010) harboured homozygous mutation of p.R969Q, as well as heterozygous mutation of p.A874 V. (B) Pedigree chart of family 15 (F015). The patients (P018 and P019) harboured homozygous mutation of p.I1148 T. (C) Pedigree chart of family 3 (F003). The two patients (P003 and P004) both had compound heterozygous mutations of p.Y741C and p.N1270S in different alleles, which were inherited from their father and mother, respectively. (D) Pedigree chart of family 60 (F060). The patients (P065) had compound heterozygous mutations of p.G1186I and p.I1230 T in different alleles. The arrow indicates the propositus.

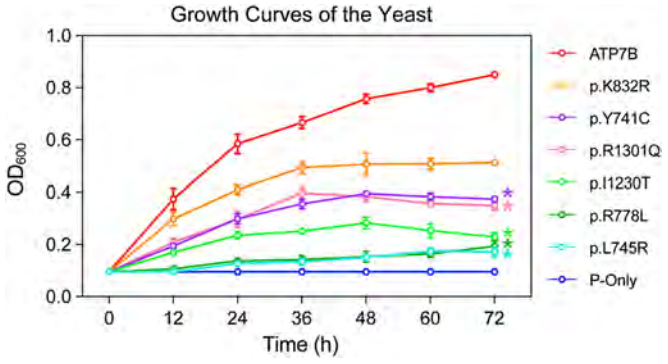

Figure 2. **Consequences of the predicted deleterious *ATP7B* variants on biological functions analysed by a yeast model**. The growth curve of the yeast. The growth of the strains transfected with $ATP7B^{Y741C}$, $ATP7B^{L745R}$, $ATP7B^{I1230T}$ and $ATP7B^{R1301Q}$ was significantly inhibited compared with that of those transfected with $ATP7B^{WT}$. *, p < 0.05, compared with the ATP7BWT and ATP7BK832R groups. Each line represents three biological replicates.

Transarterial chemoembolization versus best supportive care for patients with hepatocellular carcinoma with portal vein tumour thrombus

Xiao Xiang[1,2], Jian-Hong Zhong[2], Qian Cheng[1], Zhao Li[1], le-qun Li[2], Ji-Ye Zhu[1]. *[1]Peking University People's Hospital, Department of Hepatobilliary Surgery, Beijing Key Surgical Basic Research Laboratory of Liver Cirrhosis and Liver Cancer, Beijing, China; [2]Affiliated Tumor Hospital of Guangxi Medical University, Department of Hepatobiliary Surgery, Nanning, China*
Email: zhongjianhong66@163.com

Background and aims: Portal vein tumor thrombus (PVTT) can be divided into four types. This study aims to compare the efficacy and safety of treatment after transarterial chemoembolization (TACE) with best supportive care (BSC) in patients with hepatocellular carcinoma (HCC) with PVTT.
Method: This retrospective study was conducted on 1, 038 patients with HCC with PVTT who were treated either with TACE (n = 675) or BSC (n = 363). BSC did not include sorafenib. The two groups of patients were compared with or without propensity score matching to study the impact of possible bias in case selection. A subgroup analysis was subsequently performed by stratifying patients according to the stages of PVTT in the Cheng's PVTT classification.
Results: In PVTT types I-III, TACE was associated with significantly better overall survival (OS) than BSC ($p < 0.05$). No significant difference was observed in type IV PVTT ($p = 0.638$). Within each type of PVTT for patients who received TACE or BSC, OS was significantly worse in patients with type IV PVTT than in any of the other three types of PVTT (all $p < 0.05$). TACE was associated with better long-term OS than BSC after propensity score matching or on stratification by the PVTT types.

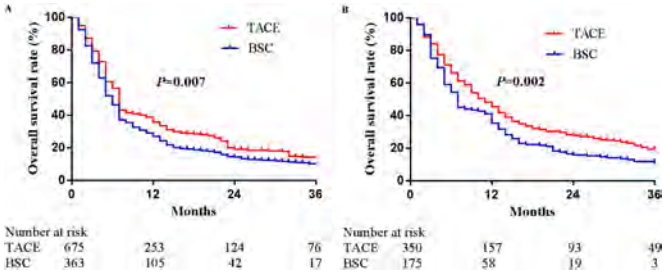

Figure 1: Overall survival rates for all the patients with HCC with any type of PVTT ('Total') or trios of propensity score-matched patients ('Matched') treated with TACE or best supportive care (matched in 2:1 ratio).

Conclusion: TACE was associated with better OS than BSC in HCC patients with PVTT types I-III but not type IV. Patients with type IV PVTT showed the worst prognosis, regardless of whether TACE or BSC was used.

FRI-452

Synergistic reduction of cancer proliferation and tumour growth in advanced murine hepatocellular carcinoma vis skewing and activation of innate and adoptive immunity

Muhammad Ashfaq-Khan[1], Misbah Aslam[1,2], Asif Qureshi[3], Yong Ook Kim[1], Tim Zimmermann[4], Detlef Schuppan[1,5]. *[1]Institute of Translational Immunology and Research Center for Immunotherapy, Mainz, Germany; [2]Shaheed Benazir Bhutto Women University, Peshawar, Pakistan; [3]Dow university of medical sciences, Karachi, Pakistan; [4]Department of medicine 1 university medical center, Mainz, Germany; [5]Division of Gastroenterology, Beth Israel Deaconess Medical Center, Boston, United States*
Email: m.ashfaq_biotech@yahoo.com

Background and Aims: Hepatocellular carcinoma (HCC) is the sixth most common cancer and the leading cause of death worldwide. HCC presents with a complex mutational landscape and thus treatment options remain limited. Drugable targets that induce a tumoricidal immune microenvironment may open novel therapeutic opportunities to control tumour progression and block metastatic spread. We assessed single and combined treatments of experimental syngeneic HCC with Zoledronic Acid (ZA, a bisphosphate) and Rapamycin (RA, an mTOR inhibitor), two drugs that display myeloid cell regulating potential.
Methods: Mdr2 (Abcb4)−/− mice and FVB wildtype were injected intraperitoneally with diethyl-nitrosamine DEN (10μg/g of bw) at the age of 5 days, followed by 0.05% phenobarbital in drinking water starting at the age of 3 weeks. Mice were treated with vehicle, (ZA

three times/week as ip injection, 100 µg/kg), RA (three times/week as oral gavage, 5 mg/body weight), or a combination of ZA and RA from age 5-6 months. After 6 months, tumour volume and number of nodules were counted. DEN injected Mdr2 (Abcb4)−/− and FVB mice served as additional controls. qPCR and IHC were performed, and FACS analysis was done using antibodies to CD11b, CD11c, Ly6C, Ly6G, CD86, CD4, CD8, CD25, CD3, CD90.2, CD206, F4/80, MHC-II, NK1.1, Foxp3 and CD19.

Results: Treatment with RA > ZA significantly reduced tumour growth in both Mdr2 (Abcb4)−/− and wildtype FVB DEN injected mice vs untreated controls. Moreover, the combination of ZA and RA synergistically reduced the volume and number of HCC foci highly significantly by 90 and 85%, respectively ($p < 0.0001$) compared to the single treatment and the untreated groups. FACS analysis revealed that the combination significantly reduced the population of tumor associated macrophages (TAM) and of myeloid derived suppresser cells, representing central tumour promoting myeloid cell populations. In contrast, myeloid derived dendritic cells that promote anti-cancer immunity were significantly upregulated. In parallel, total CD4 + T cells and especially CD4+CD25 regulatory T cells were significantly suppressed, while CD8+ cytotoxic T cells were significantly upregulated in the combination treatment vs the single treatment and especially the untreated groups. This was accompanied by reduced transcript levels of extracellular matrix remodeling (MMP2, MMP9, MPP12) and angiogenesis related genes (Cox2, HIF1α, VEGF CCL17). IHC staining revealed that Ki-67+ HCC cells were nearly undetectable, and IHC for CD68 and YM-1and CD31 confirmed a dramatic shift from tumour associated M2 to M1 tumoricidal macrophages and reduced angiogenesis in the combination treatment group.

Conclusions 1. Combination therapy of RA and ZA synergistically repolarized the immunosuppressive myeloid cells towards M1, and promoted CD8+ T cells, resulting in a robust anti-HCC response.

FRI-453

Rapamycin promotes tumoricidal immunity in murine HCC by inducing M1-type macrophages and dentritic cells polarization and enhancement of cytotoxic T-cells

Misbah Aslam[1,2], Muhammad Ashfaq-Khan[2], Asif Qureshi[3], Simap Celik[2], Jan-Timon Werle[2], Marcel Senkowski[2], Yong Ook Kim[2], Leonard KAPS[2], Detlef Schuppan[2]. *[1]Shaheed Benazir Bhutto Women University, Peshawar, Pakistan; [2]Institute of Translational Immunology and Research Center for Immunotherapy, Mainz, Germany; [3]Dow university of medical sciences, Peshawar, Germany*
Email: misbahmmg@gmail.com

Background and Aims: Primary hepatocellular carcinoma (HCC) arises mostly in the background of hepatic injury and chronic inflammation. Chronic inflammation in HCC is associated with the infiltration of bone marrow derived cells, mainly tumour associated macrophages (TAM, M2) and myeloid-cell derived suppressor cells (MDSC). These cell types markedly suppress anti-HCC immune responses and are present in all stages of HCC. Rapamycin (RAPA) deregulates mTOR signalling in cancer cells and modulates the tumor microenvironment, thereby possibly promoting anti-tumour immunity. We hypothesized that RA may repolarize tumour promoting TAM and MDSC towards M1 macrophages, and augment dendritic cell (DC) tumor antigen presentation finally enhancing the priming of tumour specific cytotoxic T lymphocytes (CTL) with anti-tumour activity.

Methods Mouse bone marrow derived in vitro M1 or M2 polarized macrophages, and mature and immature DC were exposed to increasing concentrations of RAPA. Transcript and protein levels of M1/M2 markers (VEGF, Arg1, TGFβ1, IL-10, IL-12p70) and DC activation markers (CD86, CD40, MHC-II) were determined by qPCR and ELISA. Mice bearing a syngenic HCC (DEN/Mdr2KOand DEN/FVB wild type mice) received 3 doses of 5 mg RA/kg BW or vehicle (control) orally per week for a period of one month from age month 5-6. After treatment, mice were sacrificed to measure hepatic tumor number and volume and livers were assessed by HandE histology, IHC, qPCR and FACS. Cytokine level of IL-10 and IL-12p70 were quantified through ELISA in all sera samples.

Results: RA dose-dependently decreased M2 and immature DC markers (Arg1, TGFβ1, VEGF, IL-10) and increased M1 macrophage and mature DC transcripts (CD86, IL-12p35, MHC-II, CD40). This was paralleled by a significant upregulation of IL-12p70 and down-regulation of IL-10 protein secretion into the cell supernatant. In DEN/Mdr2KO mice RAPA reduced tumor cell proliferation as evaluated via Ki-67+ staining, and tumor number and volume by 70% and 68%, respectively vs the control group. Transcript and protein level also showed remarkable switching of macrophages from M2 to M1. Staining of YM-1+ and glypican+ M2 and CD68+ total macrophages in livers of RA treated HCC showed a significant upregulation of M1 > M2-type macrophages.CD3/CD8 ratio was also high in rapamycin treated group as compared to control group as depicted by immunohistochemistry. FACS analysis revealed a significant increase of mature DC (CD45+CD11c+MHC-II+CD86+) and CTL (CD45+CD3 +CD8+) in the RAPA treated mice vs vehicle.

Conclusions: RAPA 1. enhances the maturation of DC, improving tumor antigen presentation for CTL activation; 2. exhibits potent macrophage repolarizing activity (M2 to M1-type) in vitro and in vivo, thereby increasing anti-HCC immune responses and limiting angiogenesis.

FRI-454

Reappraisal of portal vein tumor thrombosis as a prognostic factor for patients with hepatocellular carcinoma

Young Chang[1], Su Jong Yu[1], Jun Sik Yoon[1], Hyo Young Lee[1], Sun Woong Kim[1], Sungwon CHUNG[1], Minseok Albert Kim[1], Yun Bin Lee[1], Eun Ju Cho[1], Jeong-Hoon Lee[1], Yoon Jun Kim[1], Jung-Hwan Yoon[1]. *[1]Department of Internal Medicine and Liver Research Institute, Seoul National University College of Medicine, Seoul, Korea, Rep. of South*
Email: ydoctor2@hanmail.net

Background and aims: The presence of portal vein tumor thrombosis (PVTT) is a poor prognostic factor for patients with hepatocellular carcinomas (HCC). HCC patients with PVTT are considered advanced stage regardless of the tumor factor and only sorafenib is recommended for those patients by current guidelines. This study was aimed to assess whether HCC patients with PVTT could have better prognosis with proper treatment in selective conditions.

Method: This single-center retrospective study involved 1, 171 patients diagnosed HCC from January 2005 to December 2006, before sorafenib era. Overall survival (OS) was estimated by the Kaplan-Meier method and Cox proportional hazards model. To control the different distributions of the covariates, inverse probability weighting using propensity score was conducted.

Results: The prognosis was dismal regardless of PVTT in patients with diffuse infiltrative type HCC, however, in nodular HCC, there was significant difference in the OS according to the presence of PVTT ($p < 0.001$). The level of PVTT, not only the presence of PVTT, was a major independent factor of the OS. Although there was no significant difference in OS between patients with PVTT at segmental branch and left or right portal vein (LPV/RPV) (log-rank P = 0.122), segmental PVTT was associated with significantly longer OS than PVTT at main trunk (log-rank P = 0.002). The level of PVTT was consistently associated with the OS in nodular HCC patients treated by TACE. In multivariate analysis, patients without PVTT showed significantly longer OS than those with main trunk PVTT ($p = 0.002$), while there were no significant differences between no PVTT and segmental ($p = 0.074$) or LPV/RPV ($p = 0.069$) PVTT. When we compared the OS of the patients without PVTT to those with PVTT below main trunk, there was no significant difference in OS according to the presence of PVTT ($p = 0.159$).

Conclusion: Active treatment such as TACE could be considered in selected patients even with PVTT. The level of PVTT as well as the type of HCC matters.

FRI-455

Effect of huaier granule on recurrence after curative resection of HCC: A multicenter, randomized clinical trial

Qian Chen[1], Chang Shu[2], Arian Laurence[3], Xiao-Ping Chen[2]. *[1]Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology (HUST), Division of Gastroenterology, Wuhan, China; [2]Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology (HUST), Hepatic Surgery Centre, Wuhan, China; [3]The Newcastle upon Tyne Hospitals NHS Foundation Trust at Freeman Hospital, Newcastle, United Kingdom*
Email: chenxpchenxp@163.com

Background and aims: There is little evidence that adjuvant therapy after radical surgical resection of hepatocellular carcinoma (HCC) improves recurrence-free survival (RFS) or overall survival (OS). We conducted a multicenter, randomized, controlled, phase IV trial evaluating the benefit of an aqueous extract of trametes robinophila murr (Huaier granule) to address this unmet need.
Method: A total of 1, 044 patients were randomized in 2:1 ratio to receive either Huaier or no further treatment (controls) for a maximum of 96 weeks. The primary end point was RFS. Secondary end points included OS and tumor extrahepatic recurrence rate (ERR).

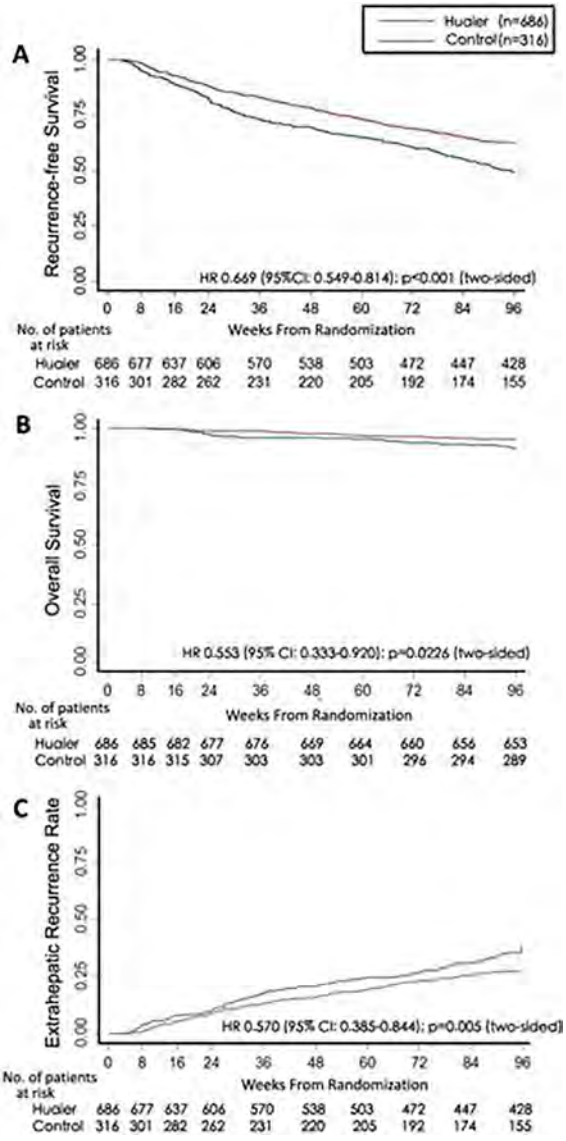

Figure: Kaplan-Meier analysis showing A, RFS, B, OS and C, ERR between Huaier and control groups

Results: The Huaier (n = 686) and control groups (n = 316) had a mean RFS of 75.5 weeks and 68.5 weeks, respectively (HR, 0.67; 95%CI, 0.55-0.81). The difference in the RFS rate between Huaier and control groups was 62.39% and 49.05% (95%CI, 6.74-19.94; p = 0.0001), this led to an OS in the Huaier and control groups of 95.19% and 91.46% respectively (95%CI, 0.26-7.21; p = 0.0207). The tumor extrahepatic recurrence rate between Huaier and control groups was 8.60% and 13.61% (95%CI, −12.59–2.50; p = 0.0018), respectively.
Conclusion: This is the first nationwide multicenter study, involving 39 centers and 1, 044 patients, to prove the effectiveness of Huaier granule as adjuvant therapy for HCC after curative liver resection. It demonstrated a significant prolongation of recurrence free survival and reduced extrahepatic recurrence in Huaier group.

FRI-456

MELD score is the only predictor for 30-day mortality in patients with ruptured hepatocellular carcinoma treated by emergent transarterial embolization

Ya-Ting Cheng[1], Wei Teng[1], Rachel Wen-Juei Jeng[1], Yi-Chung Hsieh[1], Kar-Wai Lui[2], Chien-Hao Huang[1], Wei-Ting Chen[1], Chien-Fu Hung[2], Chen-Chun Lin[1], Chun-yen Lin[1], Shi-Ming Lin[1], I-Shyan Sheen[1]. *[1]Chang Gung Medical Foundation, Linkou Chang Gung Memorial Hospital, Gastroenterology and Hepatology, Taoyuan, Taiwan; [2]Chang Gung Medical Foundation, Linkou Chang Gung Memorial Hospital, Radiology, Taoyuan, Taiwan*
Email: happy95kevin@gmail.com

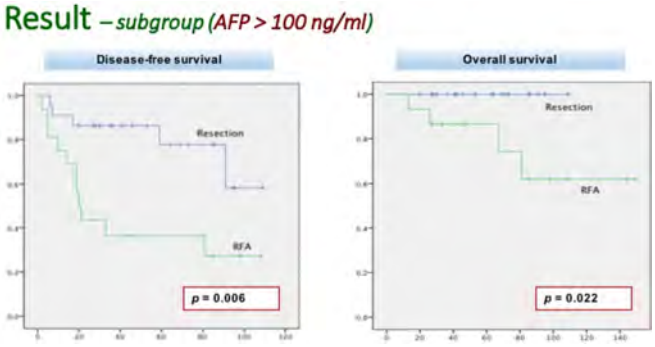
Background and aims: Spontaneous hepatocellular carcinoma (HCC) rupture with intraperitoneal hemorrhage is a life-threatening complication. Trans-arterial embolization (TAE) or trans-arterial chemo-embolization (TACE) is effective for achieving initial hemostasis in acute stage. This study aims to investigate the predictors for 30-days mortality in patients with HCC rupture and treated with TAE/TACE.
Method: Patients with ruptured HCC with emergent TAE/TACE treatment during February 2005 and December 2015 in Chang Gung Memorial Hospital, Linkou branch were recruited. The pre-TAE/TACE features including age, gender, etiology, liver biochemistry, prothrombin time, Child-Pugh score, Model for End-Stage Liver Disease (MELD) score, the presence of systemic inflammatory response syndrome (SIRS) and Barcelona-Clinic Liver Cancer (BCLC) tumor staging and liver function after TAE/TACE were collected. Mann-Whitney U test and independent student t test were applied for non-normal and normal distribution variables respectively while Chi-square test for categorical variables comparison.
Results: A total of 95 patients with 102 events were enrolled. Most of the patients (90.2%) were treated with TAE. 42.2% of these patients were Child-Pugh class A, 45.1% were class B and 12.7% were class C. The median MELD scores was 12.5 (range, 6-26) and median Na-MELD scores was 14 (range, 6-30). The successful rate of dynamic stabilization was 92.16%. The overall median survival time was 253.5 days. The 30-days mortality is 18.6%. Child-Turcotte-Pugh (CTP) score, Model for End-Stage Liver Disease Score (MELD score), advanced Barcelona-Clinic Liver Cancer (BCLC) Stage, vessel thrombosis, metastasis, treatment naïve, systemic inflammatory response syndrome (SIRS), higher total bilirubin level after TAE were poor prognostic factors associated with 30-days mortality. By multivariate logistic regression analysis, MELD score (OR: 1.44 (1.12-1.84, P = 0.004) is the only independent predictor for 30-days mortality. The cut-off point of MELD score 13 is a good predictor of 30-day mortality (AUROC: 0.882; sensitivity: 100%; specificity: 62%; positive predictive value: 39%; negative predictive value: 100%).
Conclusion: Transaretrial embolization is effective in hemostasis in patients with HCC rupture. The cut-off value of 13 in MELD score might predict the 30 days mortality in patients with ruptured hepatocellular carcinoma treated by transarterial embolization.

FRI-457

Comparative long-term outcomes of laparoscopic liver resection and radio frequency ablation for hepatocellular carcinoma: Location of tumor matters

Jai Young Cho[1], Ho-Seong Han[1], Sook-Hyang Jeong[2], Jin-Wook Kim[2], Eun Sun Jang[2], YoungRok Choi[1], Boram Lee[1]. [1]*Seoul National University Bundang Hospital, Surgery, Seongnam, Korea, Rep. of South;* [2]*Seoul National University Bundang Hospital, Internal Medicine, Seongnam, Korea, Rep. of South*
Email: jychogs@gmail.com

Background and aims: Laparoscopic liver resection (LLR) has been considered as standard surgery for small hepatocellular carcinoma (HCC) located in the anterolateral segments of the liver. However, there have been few reports comparing LLR and radiofrequency ablation (RFA) for HCC.
Method: We retrospectively compared short- and long-term outcomes of 105 patients with LLR and 272 patients with RFA for newly diagnosed single, < 4 cm size of HCC located on the anterolateral segments of the liver. We performed 1:1 propensity score matching (PSM) between two groups and matched 61 patients for both groups.
Results: After PSM, all variables including demographic, tumor factors and liver function were similar between two groups. There was no mortality in the two groups. The hospital stay was shorter in RFA group than LLR group (5.1 vs. 8.9 days; $P = 0.001$), however, there was no significant difference in complication rate between two groups (4.9 vs. 13.1%; $P = 0.114$). The 5-year overall survival rates were similar between two groups (83.6 vs. 84.5%; $P = 0.913$), but the 5-year disease-free survival rate was higher in LLR group (56.4%) than RFA group (41.8%; $P = 0.009$). In patients with alpha-fetoprotein > 100 ng/ml, LLR group showed better 5-year overall (100 vs. 80.0%; $P = 0.022$) and disease-free survival rates (76.6 vs. 45.5%; $P = 0.006$) than those in RFA group.



Conclusion: For single small HCC located in the anterolateral segments of the liver, LLR group showed similar complications and overall survival rate, but better disease-free survival rate compared to RFA group. LLR is recommended in patients with higher alpha-fetoprotein level.

FRI-458

Response evaluation using modified RECIST criteria predict outcomes better than RECIST 1.1 criteria in patients with HCC treated with Yttrium-90 radioembolization

HongJun Choi[1], Tae Seop Lim[1], Mi Young Jeon[1], In Rae Cho[1], Beom Kyung Kim[1], Jun Yong Park[1], Do Young Kim[1], Sang Hoon Ahn[1], Kwang-Hyub Han[1], Seung Up Kim[1], Jae Seung Lee[1]. [1]*Yonsei University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South*
Email: ksukorea@yuhs.ac

Background and aims: The response evaluation criteria in solid tumours (RECIST 1.1) have been commonly used for response evaluation of solid tumours including hepatocellular carcinoma (HCC). Because of the importance of the remaining 'viable cancer tissue' of HCC, the modified RECIST (mRECIST) have been adopted for HCC response evaluation. However, few studies have investigated which response evaluation method is better for predicting the treatment outcomes of HCC. Thus, we compared the performance of the RECIST 1.1 and mRECIST for predicting survival rates in patients with HCC treated with transarterial radioemoblisation (TARE) using Yttrium-90.
Method: Between 2012 and 2017, 102 patients with unresectable intrahepatic HCC treated with TARE were reviewed retrospectively. The RECIST 1.1 and mRECIST were used to evaluate the treatment responsiveness of HCC to TARE at 1, 3 and 6 months after TARE. A responder was defined as the sum of either a complete or partial response by each method and non-responder was defined as the sum of either a stable or progress response.
Results: The median age of the study patients (92 males and 19 females) was 64.1 years. The median alpha-fetoprotein and des-gamma-carboxyprothrombin levels were 42.0 ng/ml and 1693.5 mAU/ml, respectively. The median maximal tumor size was 8.3 cm, and multiple tumours were observed in 41 (36.3%) patients. During the follow-up period (median 20.7 months), 21 patients (20.6%) died, with a median survival of 32.5 months. Using the mRECIST, the treatment responders at 1, 3 and 6 months following TARE showed significantly better survival rates compared with the non-responders (hazard ratio [HR] = 5.736, log-rank P = 0.008 at 1 month; HR = 3.145, P = 0.022 at 3 months, and HR = 2.887, P = 0.061 at 6 months). In contrast, using the RECIST, the treatment responders at 1, 3 and 6 months In contrast, using the RECIST, the treatment responders at 1, 3, and 6 months showed no difference in survival from the non-responders. (all P > 0.05, log-rank test). According to multivariate analysis, non-responsiveness using mRECIST (HR = 0.217, P = 0.043 at 1 month; HR = 2.874, P = 0.05 at 3 months), as well as the serum albumin level, main portal vein thrombosis, and hepatic vein invasion, were independent predictors of mortality (all P < 0.05).
Conclusion: Risk stratification should be assessed by response evaluation using mRECIST in patients with HCC treated with TARE. Further validation in a large cohort is required.

FRI-459

Prognostic performance of ten non-invasive liver function tests in patients with hepatocellular carcinoma submitted to transarterial chemoembolization

Pedro Costa-Moreira[1], Joel Silva[1], Emanuel Dias[1], Rui Morais[1], Marco Silva[1], Patrícia Andrade[1], Hélder Cardoso[1], Pedro Pereira[1], Margarida Marques[1], Rosa Coelho[1], Rodrigo Liberal[1], Rui Gaspar[1], Susana Lopes[1], Guilherme Macedo[1]. [1]*Centro Hospitalar São João, Porto, Portugal*
Email: pedromoreira.med@gmail.com

Background and aims: Various non-invasive liver function tests have been proposed to assess hepatic reserve (Child-Turcotte-Pugh (CTP); albumin-bilirubin [ALBI] grade, platelet-albumin-bilirubin [PALBI] grade, model for end-stage liver disease (MELD), fibrosis index based on 4 factors (FIB-4), aspartate aminotransferase-to-platelet ratio [APRI], Lok index, cirrhosis discriminant index (CDS), King's score, and Göteborg University Cihhosis Index [GUCI]) in chronic liver disease. However, their performance to predict the prognosis of patients with hepatocellular carcinoma (HCC) is unknown. We aimed to elucidate the prognostic role of ten currently used hepatic function models in patients with intermediate stage HCC undergoing transarterial chemoembolization (TACE).
Method: Between 2007 and 2018, TACE procedures in a tertiary center were prospectively identified and retrospectively analyzed.

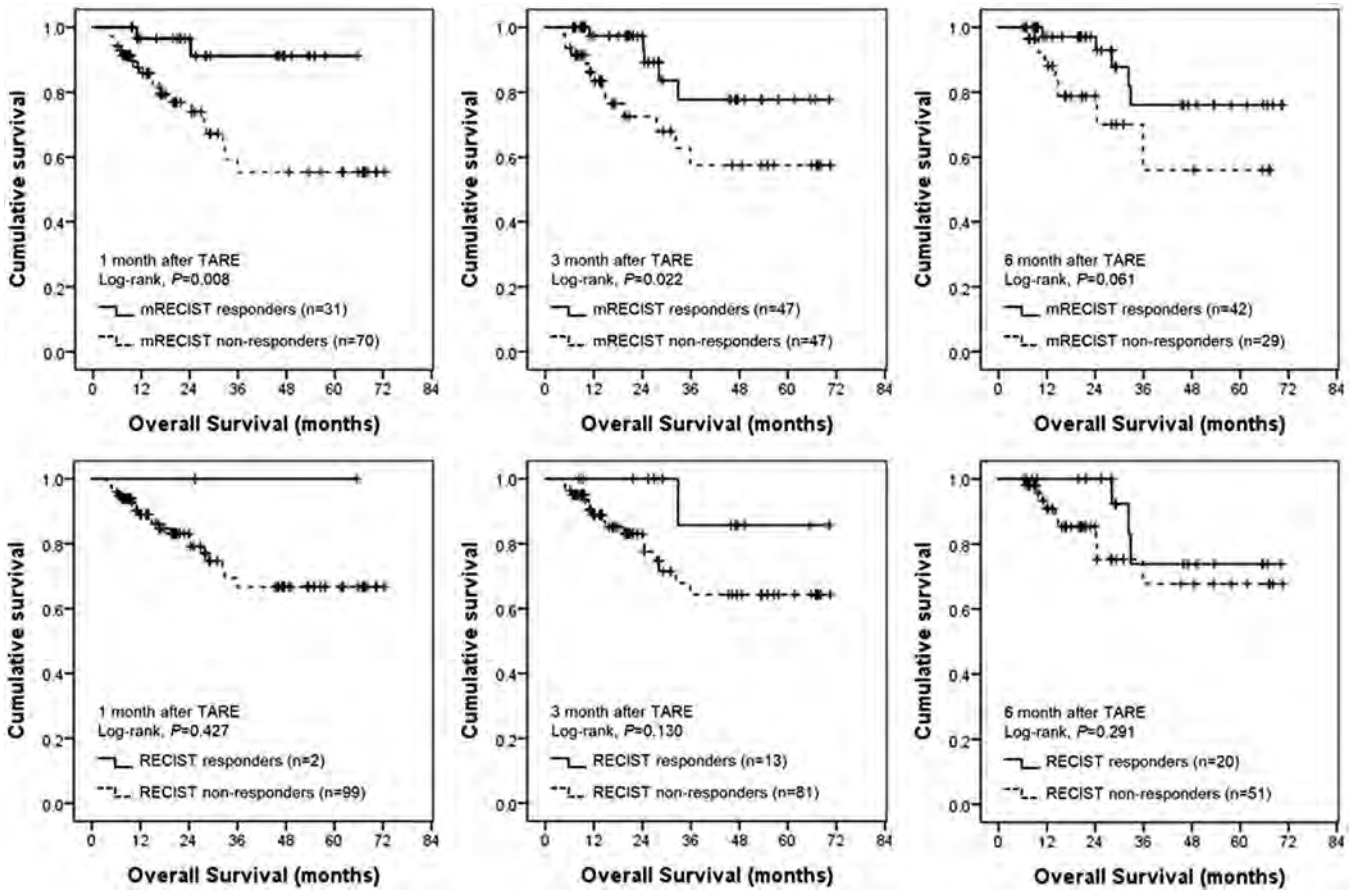


Figure: (abstract: FRI-458): Kaplan-Meier analyses for overall survival of the patients with HCC treated with TARE

For each TACE, baseline patient characteristics, tumor status and non-invasive hepatic function models at the time of procedure were collected. Each model was categorized into three classes (stage 1/2/3). Cox proportional hazards model was used to identify independent survival predictors.

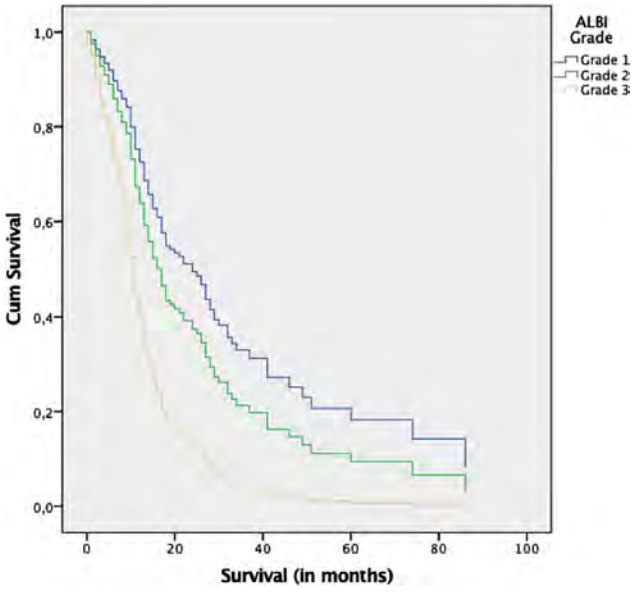
Results: A total of 206 TACE were performed in patients with a mean age of 68.9 ± 10.8 years, 77.2% were male. The main causes of liver disease were alcohol (39.8%) and HCV infection (32.5%). There was a single nodule in 59.2% of the cases, with a mean diameter of 41.6 ± 26.0 mm. TACE was performed with drug-eluting beads (DEB) in 87.9% of cases, with a mean doxorubicin dose of 41.4 ± 33.2 mg.

Median survival after TACE was 13 (IQR 7-24) months. One year after TACE, mortality was 35.9%. The value of albumin (OR 0.90, CI95% 0.87-0.93, p < 0.01) and sodium (OR 0.86, CI95% 0.77-0.95, p < 0.01) was related to 1-year mortality.

In the survival analysis of the ten calculated scores, we found significant differences for ALBI grade (median survival, stage 1/2/3-13/13/6 months; p = 0.01) and for CTP (median survival, stage A/B-13/8, p < 0.01).

In covariate adjusted multivariate Cox regression model, we found that ALBI grade 3 (HR 2.88; CI95% 1.32-6.25, p = 0.01, compared to ALBI 1-Figure) and the diameter of HCC treated nodule (HR 1.01, CI95% 1.01-1.02; p < 0.01) were significantly associated with survival.

Conclusion: Among ten non-invasive tests of hepatocellular function, only ALBI score independently predicted survival for HCC patients submitted to TACE.



FRI-460

What are the predictive factors for long-term survivors with advanced hepatocellular carcinoma treated with sorafenib?

Daniela Reis[1], Filipe de Sousa Damião[1], Carolina Simões[1], Sofia Carvalhana[1], Afonso Gonçalves[2], Rui Tato Marinho[1], Helena Cortez-Pinto[1]. *[1]Hospital de Santa Maria, Centro Hospitalar Universitário Lisboa Norte, Gastroenterology and Hepatology, Lisbon, Portugal; [2]Hospital de Santa Maria, Centro Hospitalar Universitário Lisboa Norte, Radiology, Lisbon, Portugal*
Email: daniela.ant.reis@gmail.com

Background and aims: Sorafenib is the standard therapy for advanced-stage hepatocellular carcinoma (HCC) and progressive disease after locoregional therapy. Most of these patients have an overall survival (OS) of about 10 months. However, some patients seem to have a better response to sorafenib and consequently a significantly prolonged survival time. Few data are available about this specific group. Our aim was to assess characteristics and predictive factors of long-term survivors (OS > 24 months).
Method: We retrospectively reviewed 77 consecutive patients who started treatment with sorafenib for advanced-stage HCC (Barcelona Clinic Liver Cancer-C) or progressive HCC after locoregional therapy between Oct/2007 and Oct/2016.
Results: At time of initial sorafenib prescription, median age was 63.9 ± 10.4 years, mainly males (90.9%). All patients had cirrhosis and the most prevalent etiology was HCV infection in 41.6%, followed by alcohol-related disease (40.3%) and HBV infection (16.9%). The majority was Child-Pugh A (66.2%), had multinodular disease (74%) and had alpha-fetoprotein (AFP) level < 400 ng/ml (63.6%). Portal vein thrombosis (PVT) was present in 50.6%. BCLC distribution: 96.1% in stage-C and 3.9% in D. Time between HCC diagnosis and start of sorafenib was 7.9 ± 9.8 months. In most cases, sorafenib was the first-line treatment (62.3%). For those with previous treatment, transarterial chemoembolization was the most performed technique (58.6%).
Mean OS was 32.6 months (95% CI: 23.4-41.8) with 2-year survival rate of 38.9%. Fifty-four patients died (70.1%). Twenty-five patients had a survival time superior to 24 months (32.5%) after initiating sorafenib. In this subgroup, mean age was 60 ± 7.7 years. Most patients were male (80%) and had a HCV infection-related disease (52%). Ninety-two percent were Child-Pugh A (mean value: 5.6 ± 0.8 points), AFP level was < 400 ng/ml in 84% and mean MELD-Na^+ score was 10.1 ± 2.7 points. The majority presented with multinodular disease (64%) with absence of PVT (80%).
In multivariate analysis, predictive factors significantly related to long-term survival were: absence of portal vein thrombosis (p = 0.004, OR 0.123, 95% CI: 0.031-0.491) and MELD-Na^+ score (p = 0.037, OR 0.870, 95% CI: 0.764-0.992).
Conclusion: Although mean OS in this group of patients is low, it is of note that a sub-group can really benefit from this treatment and it is worth identifying those long-term survivors, in our study those without PVT and a lower MELD-Na^+.

FRI-461

Thermal ablation is a safe and effective treatment for intrahepatic cholangiocarcinoma in patients with cirrhosis

Alvaro Diaz-Gonzalez[1], Ramon Vilana[2], Luis Bianchi[2], Ángeles García-Criado[2], Ernest Belmonte[2], Jordi Rimola[2], Anna Darnell[2], Carlos Rodriguez de Lope[1], Joana Ferrer[3], Carnen Ayuso[2], Leonardo Gomes da Fonseca[1], Maria Reig[4], Jordi Bruix[4], Alejandro Forner[4]. *[1]BCLC group. Email: diazgonz@clinic.ub.es

Background and aims: Incidence of intrahepatic colangiocarcinoma (ICC) is increasing worldwide and liver cirrhosis is a well-established risk factor for its development. Surgery is the mainstay treatment, but its applicability is limited in cirrhotic patients. Thermal ablation, including radiofrequency ablation and microwave, is suggested as an alternative treatment, but there are scarce data regarding its efficacy and safety in this population. We aimed to assess the effectiveness, safety and overall survival of thermal ablation as first-line treatment of ICC in patients with cirrhosis.
Method: This is a retrospective analysis of all biopsy-confirmed ICC in cirrhotic patients treated in our unit from 2001 to 2017. Baseline characteristics, ablation procedures and complications were recorded. Time to recurrence (TTR) and overall survival (OS) were calculated using Kaplan Meier method.
Results: Twenty-seven patients were treated in this time period in our unit. 51.7% of patients were men with a median age of 63.7 years. The most frequent cause for cirrhosis was hepatitis C Virus (63%), 70.4% were Child-Pugh A and the majority had clinically significant portal hypertension. None of them had cancer-related symptoms (ECOG-PS 0) and tumor markers (CEA, AFP and CA 19.9) were not elevated. Median tumor size was 21 mm [IQR 20-28 mm], 21 cases were uninodular (stage Ia AJCC 8th edition) and 6 were at stage II. Finally, among those patients with single ICC, 10 of them had a single ≤ 2 cm ICC.
Complete response was achieved in 25 cases (92.6%). Median OS of the whole cohort was 30.6 months (CI 95%; 22.6-46.5), and recurrence was detected in 21 cases (77.8%) with a TTR of 10.1 months (CI 95%; 7.7-20.9 months). In those patients with single ≤ 2 cm ICC, the OS was 94.5 months (CI 95%; 11.7-not reached) and this OS is statistically superior to those patients with single ICC larger than 2 cm (24.3 months (CI 95%; 10.4-44.25 months), p = 0.04) and to those with multinodular disease (26.5 months (CI 95%; 20.23-41.4); p = 0.02). Regarding safety in the whole cohort, only two patients presented a treatment related complication.
Conclusion: Thermal ablation is a safe and effective alternative to surgery for ICC in patients with cirrhosis. The global OS is similar to the reported in surgical series, but the initial treatment success is hampered by a high rate tumor recurrence. Long-term survival after thermal ablation is achieved in patients with single ≤ 2 cm ICC and is statistically superior compared to single ICC > 2 cm or intrahepatic multinodular ICC.

FRI-462

A multicenter international study of sorafenib treatment in patients with hepatocellular carcinoma and chronic kidney disease undergoing hemodialysis

Email: mreig1@clinic.ub.es

Background and aims: As patients with hepatocellular carcinoma (HCC) under dialysis are excluded from clinical trials, there are no data about safety and efficacy of sorafenib in this specific population, which has no formal contraindication for this treatment. The aim of this study is to evaluate the rate, prevalence, tolerability and effectiveness of HCC patients undergoing dialysis and being simultaneously treated with sorafenib (dialysis-sor) in clinical practice.
Method: Retrospective, international, multicenter study, including centers from Latin-America and Europe to evaluate the aim of the study. For dialysis-sor patients, baseline characteristics as well as dose modifications, adverse events, treatment duration, and overall survival were recorded.
Results: Of 6156 HCC patients treated with sorafenib between June/2006 and March/2018 in 44 centers, 22 were dialysis-sor patients. Median age of the 22 dyalisis-sor was 65.5 years, 83.4% were male, 40.9% had hepatitis C, 75% had Child-Pugh A, 85% were BCLC C, and 54.6% had ECOG-PS 1. 17/22 patients presented history of arterial hypertension (AHT), 14/22 had diabetes mellitus (DM) and 3/22 had heart disease. 12/22 patients presented with both AHT and DM, which also were the leading causes for chronic kidney disease. 15/22 patients started sorafenib at full dose, while 7/22 at half dose. 17/22 of patients required at least one dose modification. Median time to first dose modification was 2.4 months (IQR 0.8-3.8). 5 patients never required any dose modification. Maximum and medium number of dose modifications were 4 and 2, respectively. The most frequent causes of first dose modification were asthenia 3/22, worsening of ECOG-PS 3/22 and diarrhea 3/22.
Median treatment duration was 10.8 months (IQR 4.5-16.9) and median overall survival was 17.5 months (CI 95%; 7.2-24.5). 18/22 patients permanently discontinued sorafenib and the remaining are still on treatment. The causes of sorafenib discontinuation were tumor progression 14/18, sorafenib-related 2/18 (diarrhea and peripheral arterial thrombosis) and non-sorafenib related AE 2/18 (liver decompensation and pulmonary edema).
Conclusion: This is the largest cohort describing patients with HCC under hemodialysis who received sorafenib treatment. Our data show that median time to the first dose modification, treatment duration, and overall survival were comparable to the results of the non-dialysis population, obtained from large clinical trials and real-world cohorts. However, in these patients, asthenia appears to be the main treatment related adverse event.

FRI-463

Long-term outcomes of irreversible electroporation for hepatocellular carcinoma

Elliot Freeman[1], Helen Kavnoudias[2], Wa Cheung[2], Ammar Majeed[1,3], William Kemp[1,3], Stuart Roberts[1,3]. [1]*Alfred Hospital, Department of Gastroenterology, Melbourne, Australia;* [2]*Alfred Hospital, Department of Radiology, Melbourne, Australia;* [3]*Monash University, Central Clinical School, Department of Medicine, Melbourne, Australia*
Email: s.roberts@alfred.org.au

Background and aims: Irreversible electroporation (IRE) is a relatively novel non-thermal ablation technique which has been shown to be both safe and efficacious for soft tissue tumours including hepatocellular carcinoma (HCC), not amenable to standard thermal ablative therapy. Our group has previously reported on our initial experiences with IRE in HCC patients, and the aim of this study was to report longer-term outcome data with this treatment modality.
Method: We identified all patients at our hospital who underwent IRE for HCC between 2008 and 2017 and analysed their clinical and demographic data until December 31, 2017. All patients had undergone multi-disciplinary team review with IRE determined as the most suitable treatment based on tumour size and location near solid organ or vascular structures. Our primary outcomes were complete ablation rates and local recurrence-free survival (RFS) based on follow-up imaging in patients who had a complete response.
Results: Overall, 22 patients (77% males, mean age 66.6 years) received IRE therapy to 30 HCC lesions with a mean size of 2.4 ± 1.0 cm during the study period. Twenty (66.7%) lesions were adjacent to important structures or organs. Twenty-five (83.3%) lesions were successfully ablated after one (n = 23) or two (n = 2) procedures. Lesion size of ≤ 2 cm was a significant predictor of successful ablation (p = 0.014). The mean follow-up time was 22.2 months from the first computed tomography scan confirming complete response using mRECIST. The mean local RFS was 64.9 months (95% CI 43.9-85.8) with a 12-month local RFS of 89%. No serious procedure related complications were observed.

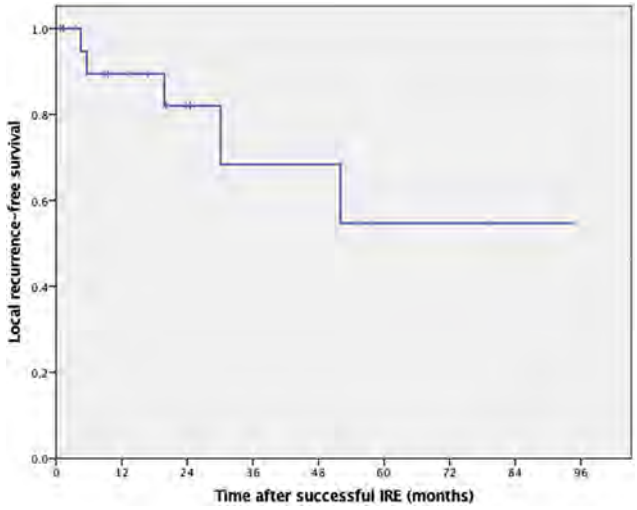

Figure: Kaplan-Meier estimated local RFS curve of 25 HCC lesions with successful IRE

Conclusion: IRE appears to be a safe and efficacious local ablative method for HCC, with high rates of complete response and good long-term local RFS. Further studies comparing this technique to microwave ablation and radiofrequency ablation are warranted.

FRI-464

Percutaneous microwave is better than radiofrequency ablation to obtain complete response in cirrhotic patients with very early and early hepatocellular carcinoma

Michela Ciruolo[1], Elena Mosso[1], Patrizia Carucci[1], Emanuela Rolle[1], Simone Vola[1], Alessandra Risso[1], Enrica Migliore[2], Giorgio Maria Saracco[1], Silvia Gaia[1]. [1]*Gastroenterology and Hepatology Unit, Città della Salute e della Scienza University-Hospital, Turin, Italy;* [2]*Unit of Cancer Epidemiology, Città della Salute e della Scienza University-Hospital and Center for Cancer Prevention (CPO), Turin, Italy*
Email: silvia.gaia74@gmail.com

Background and aims: Percutaneous thermal ablations are widely employed treatments for hepatocellular carcinoma (HCC). It has been proved that complete necrosis in early HCC and cirrhosis is related to a better survival. We compared the efficacy of RFA and MW to obtain complete response (CR) in patients with HCC.
Method: This retrospective observational study was carried out on a cohort of 227 adult cirrhotic patients with a first diagnosis of early HCC (single node ≤ 50 mm or ≤ 3 nodules ≤ 35 mm), consecutively treated with RFA or MW between January 2013 and July 2018 at our Gastro-hepatology Unit. Diagnosis and treatment allocation followed EASL guidelines. The choice of RFA or MW was reliant on operators and local availability. Other treatments and combined therapies were excluded. Complete response (CR) was evaluated with multiphasic contrast-enhanced computed tomography (CT) or Magnetic Resonance Imaging (MRI) at 5-7 weeks after treatment and in the follow-up, relying on mRECIST criteria.
Results: 227 subjects (M/F 163/64, viral/non viral etiology 181/46, median age 63 years [IQR 56-73]) were included. A total of 295 nodules treated with RFA (212, 72%) or MW (83, 28%) was evaluated. However, a homogeneous subgroup of 184 patients with 220 comparable nodules in terms of diameter (15-35 mm) was considered. The two groups were also homogeneous for age, BMI, Child Pugh score, smoke and alcohol habits, complex position, ultrasound visibility and number of nodules per each patient. Overall, a complete response was achieved in 54/58 (93%) HCC after MW and in 126/158 (80%) HCC after RFA (OR 3.43; IC95% 1.14-10.3, p = 0.028). In 15-20 mm nodules, the two procedures were not significantly different (OR 3.41; IC95% 0.40-29.2, p = 0.264), however in 21-35 mm nodules MW was significantly superior in obtaining CR compared to RFA (OR 3.70; IC95% 1.00-13.7, p = 0.05). The rate of CR was inversely proportional to the number of nodules, but without statistical significance. Multivariate Cox-proportional hazard regression showed that MW was an independent predictor of CR in HCC nodules (OR 3.92, IC95% 1.26-12.2, p = 0.018).
Conclusion: In this study MW appeared to be superior to RFA to induce complete response in patients with very early and early HCC with major evidence in bigger nodules (21-35 mm). Further studies are ongoing to confirm these findings and to evaluate the effect on survival.

FRI-465

The INCRNA H19 is an oncogenic driver of HCC in chronic inflammation-mediated mouse model

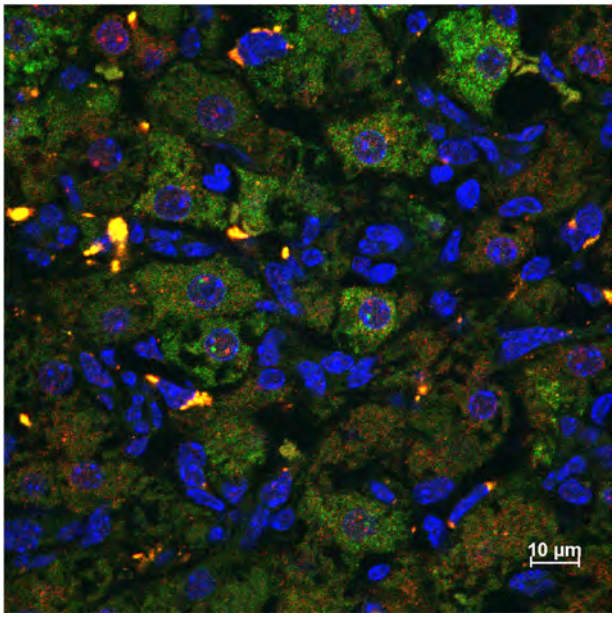
Lika Gemaev[1], Lina Mizrahi[1], Orit Pappo[2], Devorah Olam[1], Luisa Dandolo[3], Stefano Caruso[4], Jessica Zucman-Rossi[4], Daniel S Goldenberg[1], Eithan Galun[1]. [1]*Hadassah Hebrew University Medical Center, The Goldyne Savad Institute of Gene Therapy, Jerusalem, Israel;* [2]*Hadassah Hebrew University Medical Center, Pathology, Jerusalem, Israel;* [3]*Cochin, Genetics and Development, Paris, France;* [4]*University Paris Descartes, Inserm UMR, Paris, France*
Email: eithang@hadassah.org.il

Background and aims. H19 is paternally imprinted and maternally expressed long non-coding RNA (lncRNA). H19 is an oncofetal RNA that is widely expressed in the embryo, is repressed at birth in most tissues, and is re-expressed in many cancer types, including HCC. The role of H19 in tumor initiation and progression has long been a

subject of controversy. The object of our study was to examine the role of H19 in chronic inflammation-mediated hepatocarcinogenesis using double knock out (dKO) Mdr2-KO/H19-KO mouse model and to elucidate the associated molecular mechanisms. The Mdr2 knock out (Mdr2-KO) mouse is a well-established model of chronic cholangitis and hepatitis, which results in HCC development. Previously, we have detected H19 is expressed in the liver of adult Mdr2-KO females.

Methods. We have transferred the H19 delta3 mutation (a 3-kb deletion of the H19 encoding region) from the 129Sv to C57BL/6 (B6) strain and generated the B6 Mdr2-KO/H19-KO (dKO) mice. Following spontaneous tumor development at the age of 16 months, female Mdr2-KO and dKO mice were sacrificed, tumors were counted and non-tumor (NT) and tumor (T) liver tissues were collected for analysis. Expression levels of the H19 and Igf2 genes were determined by real-time qRT-PCR. Cellular localization of H19 lncRNA was determined by single-molecule RNA-FISH (smRNA-FISH).

Results. Tumor incidence and tumor load were both significantly decreased in the liver of dKO vs. Mdr2-KO females. The expression levels of H19 and Igf2 were variable in non-tumor liver tissues of Mdr2-KO females and were significantly down-regulated in most matched tumors. Immunohistochemical staining revealed about two-fold reduction of Ki67-positive hepatocytes in non-tumor liver tissue of dKO vs. Mdr2-KO females. SmRNA-FISH demonstrated that H19 was expressed in a small fraction of hepatocytes (co-localized with Pck1 mRNA) which appeared sporadically, mainly in the zone 2. At early age, dKO mice had lower activity of liver enzymes in the blood compared to Mdr2-KO mice, pointing to a reduced injury of hepatocytes and cholangiocytes in the absence of H19. In human HCC samples (Nault et al., Gastroenterology 2015), H19 expression negatively correlated with activating mutations in the CTNNB1 gene (encoding β-catenin).



Picture: **H19 RNA in a non-tumorous liver of a 15-month-old B6 Mdr2-KO female mice**. H19 is marked with a "green" RNA probe and Pck1 is marked with a "red" RNA probe. There are at least three hepatocytes in this picture that have both one green dot and two red dots in their nuclei. Cytoplasmic H19 staining is also prominent. Every dot in the cytoplasm is one RNA molecule. This teaches to the prominence of H19 in chronic inflamed liver in the "pre-tumorous" liver.

Conclusions. Our results suggest that the global effect of lncRNA H19 in development of chronic inflammation-mediated HCC in the Mdr2-KO mouse model is not tumor suppressive, but rather pro-oncogenic.

FRI-466

A single centre experience of transarterial radioembolisation using Rhenium 188 for treatment of liver space occupying lesions

Jeffey George[1], brijesh ray[2]. *[1]Aster Medcity, Kochi, India; [2]Aster medcity, Kochi, India*
Email: kevinrose320@icloud.com

Background and aims: Transarterial radioembolisation (TARE) is a treatment modality for Hepatocellular cancer as a bridging treatment before transplant or as a mainstay treatment in hepatocellular cancer with diffuse intrahepatic spread. It can be a salvage therapy in unresectable hepatocellular cancer due to poor liver reserves, performance status and when comorbid conditions prevent surgery in portal vein thrombosis. Re 188 is a high energy beta emitter isotope from Tungsten 188/Rhenium generator. Re-188 HDD (Lipiodol) (4-hexadecyl-1, 2, 9, 9-tetramethyl-4, 7-diaza-1, 10-decanethiol) is used for hepatocellular cancer treatment.

Method: Inclusion criteria-hepatocellular cancer Barcelona Clinic Liver Cancer (BCLC) B and C**,** portal vein thrombosis, failure of transarterial chemoembolization, large tumor unilobar or bilobar with adequate liver reserves, cholangiocarcinoma and diffuse disease with oligometastasis. Total of 35 patients were included, 27 were BCLC C with portal vein thrombosis, 4 patients did not have portal vein thrombosis. Non cirrhotic hepatocellular cancer with portal vein thrombosis in 2 patients and inoperable large cholangiocarcinoma in 2 patients. Tumor size < 5 cm in 6 patients, tumor > 5 cm in 20 and diffuse disease in 9 patients. Procedure was done by superselective cannulation, angiogram revealed tumor blush, adequate dose of Rhenuim was injected and feeding vessel embolised with gel foam. Response to therapy was observed after 6 weeks by Triple phase CT/MRI scan.

Results: As per m RECIST criteria, good response was noted in 14.3% (n = 5), partial response 11.4% (n = 4), stable disease in 28.57% (n = 10), progressive disease 22.8% (n = 8), lost to follow-up in 14.2% (n = 5) and response early to comment in 8.6% (n = 3). Time to progression was 4 months in patients (n = 3) who initially has a partial response/stable disease. Tumor rupture was noted in 2 patients. Doses of Rhenium up to 3 mci/ml were tolerated without much side effects. Response was largely determined by CHILD stage, volume of lesion and amount of activity administered. All patients with good and partial response were followed up for 10 months. Treatment side effects included mild fever (n = 11), transaminits (n = 21), mild abdominal pain (n = 3), rise in serum bilirubin (n = 17) and decompensation (n = 3).

Conclusion: Rhenium Transarterial radioembolisation is an effective approach in centres where Yttrium TARE is not feasible due to its attractive physical properties, simpler procedure and at one third of the cost.

Background and aims: The optimal time-point of radiological response assessment remained controversial in predicting outcomes of patients with unresectable hepatocellular carcinoma (HCC) undergoing repeated transarterial chemoembolization (TACE), which may be affected by tumor burden. We aim to evaluate the prognostic values of not only the initial and best response, defined as complete and partial response (CR and PR), especially in different tumor characteristics, but also the time-point of achieving response.
Method: Between January 2010 and May 2016, 1549 treatment-naïve patients with unresectable HCC, well-preserved liver function and performance status 0-1 score undergoing TACE were recruited from 17 Chinese academic hospitals. Overall survival (OS) was analyzed and correlated with response, determined with modified Response Evaluation Criteria in Solid Tumors (mRCIST) criteria, and time-dependent Cox regression analysis was performed for multivariate analysis.
Results: Time-dependent multivariable analysis exhibited that both initial and best response had independent prognostic values (both $P < 0.001$) in patients with low and intermediate tumor burden (sum of tumor size and number ≤ 6, > 6 but ≤ 12). Whereas the best response, rather than initial response could predict OS in high tumor burden patients (tumor size + number > 12) ($p = 0.537$, $P < 0.001$, respectively). All these findings were consistent in different subsets. Patients who achieved initial CR or subsequent CR after repeated TACE (41.8 and 48.2 months, respectively) showed a significant higher OS than those with subsequent PR or persistent non-response (30.4 or 14.1 months, respectively, $P < 0.001$).
Conclusion: Particularly, the current study indicated that initial response was not always a predictor for OS. Seeking complete response regardless of time-points was determinative for favorable prognostication. Further validations still remain warranted.

FRI-468

Identifying optimal candidates for combining transarterial chemoembolization and sorafenib in patients with unresectable hepatocellular carcinoma: A multicenter observational study

Email: hangh@fmmu.edu.cn

Background and aims: The benefits of combining transarterial chemoembolization (TACE) and sorafenib (TACE-S) over TACE alone in unresectable hepatocellular carcinoma (HCC) remains controversial; yet it should be noted that "unresectable HCC" are highly heterogeneous regarding to the baseline characteristics. Here, we aimed to investigate the predictors of survival benefits from added sorafenib and identify the optimal candidates for TACE-S.
Method: The multicenter observational study was conducted in seventeen Chinese tertiary hospitals for patients with unresectable, liver-confined HCC. Eligible patients with Eastern Cooperative Oncology Group performance status of 1 or less and Child-Pugh score of 7 or less were treated with TACE or TACE-S. Interactions between treatments and baseline variables were evaluated to find the predictors for survival benefits, based on which the patients were stratified. Multivariate models adjusted for baseline factors or propensity score were used to compare the overall survival (OS) and time-to-tumor progression (TTP).
Results: From January 2009 to December 2015, 1719 consecutive patients receiving TACE (n = 1406) or TACE-S (n = 313) were enrolled. Overall, though TACE-S improved TTP compared with TACE (adjusted hazard ratio [HR] 0.77, P = 0.013; Figure 1A), no difference of OS was observed (adjusted HR 0.92, P = 0.283; Figure 1B). Nevertheless, the tumor burden (sum of the maximum diameter of largest tumor [cm] and tumor number) and ALBI (Albumin-Bilirubin) score independently predicted the survival benefits from added sorafenib (interaction $P < 0.001$; Figure 1C and 1D). For patients with either moderate tumor burden (between 7 and 13) or low ALBI score (no more than −2.8), TACE-S significantly prolonged OS (adjusted HR 0.74, P = 0.005; Figure 1E) compared to TACE alone, whereas its superiority disappeared in the others (adjusted HR 1.15, P = 0.290; Figure 1F).
Conclusion: Not all the unresectable-HCC patients but those with moderate tumor burden or low ALBI score would get survival benefits

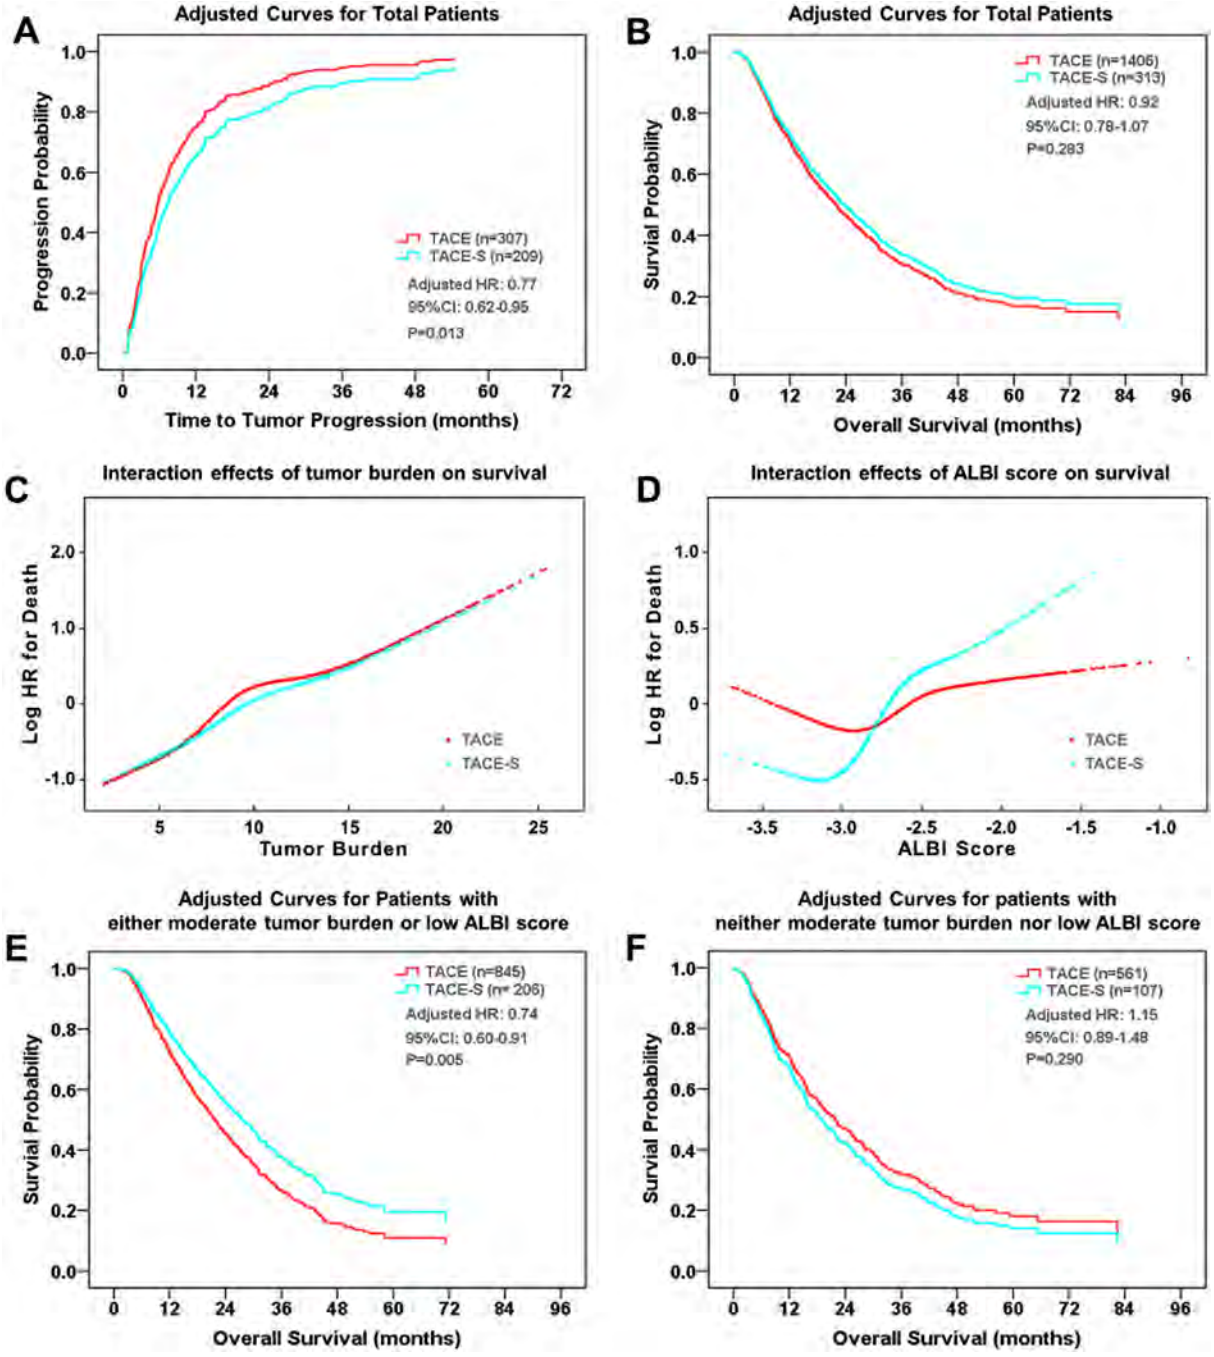

Figure: (abstract FRI-468)

from TACE-S compared to TACE alone. Future randomized-controlled trials focused on the subset are needed.

FRI-469

Vitamin K dosing could improve anti-cancer outcome of transarterial chemoembolization for patients with hepatocellular carcinoma-an open label, randomized, phase II study

Yoshimichi Haruna[1], Takayuki Yakushijin[2]. [1]*Osaka General Medical Center, Department of Laboratory Medicine, Liver Cancer Center, Osaka, Japan;* [2]*Osaka General Medical Center, Department of Gastroenterology and Hepatology, Liver Cancer Center, Osaka, Japan*
Email: apple-123-grape@ab.auone-net.jp

Background and aims: The ischemic surroundings make hepatocellular carcinoma (HCC) cells increase production and release of des-γ-carboxy prothrombin (DCP). There are many reports that the DCP is a paracrine angiogenetic factor as well as an autocrine tumor growth factor and that it enhances HCC growth. It was shown that excess dosing of vitamin K drastically declines the DCP production in tumor cells. We previously reported that vitamin K dosing enhanced anti-tumor action of sorafenib by diminishing DCP production of HCC. In this study, we aimed to clarify whether the vitamin K dosing could augment ischemic cell damage caused by TACE.

Method: Forty-five patients with BCLC stage B of HCC were enrolled. Patients were randomly assigned (1:1) to receive TACE + vitamin K dosing (vitamin K2: Glakay, Eizai Co., Ltd., Tokyo, Japan) or receive

TACE alone. In 22 patients, the vitamin K was dosed orally, 45 mg daily, from the day of TACE until 28 days after. Randomization was stratified by TACE-naïve or not, and by tumor size/number (or 5 cm/ one tumor vs others). Tumor necrosis by TACE was evaluated by dynamic CT or EOB-MRI 4weeks after TACE according to RECICL as well as modified RECIST. The treatment effect was classified into four categories: TE4 (100% necrosis), TE3 (50%-99% necrosis), T2 (the rest of T4, T3 and T1) and T1 (greater than 25% tumor growth) by the RECICL.

Results: TACE + vitamin K dosing showed the following outcome: 9 patients of TE4, 12 of TE3, 1 of TE2 and none of TE1, although the outcome of TACE alone was unfavorable; 5 of TE4, 9 of TE3, 6 of TE2 and 3 of TE1 (p = 0.015). The evaluation by modified RECIST also demonstrated better outcome of TACE + vitamin K group than TACE alone group; CR: PR: SD: PD was 8: 12: 2: 0 vs 5: 9: 6: 3 (p = 0.018). Therefore, effective rates were significantly higher in TACE + vitamin K group than in TACE alone group (91.0% vs 65.2%, respectively, P = 0.019). Four weeks after TACE, in TACE + vitamin K group, 21 of 22 patients (95.5%) showed the DCP level decline into normal range, whereas only 7 of 23 (30.4%) had decline to the normal range (p = 0.001). Arterial embolization causes massive necrosis of tumors. However, in surrounding portions of the necrotic areas or in tumors with insufficient embolization, viable HCC cells under ischemic situation seem to produce excess DCP and survive with enhanced angiogenesis induced by the DCP. Vitamin K dosing could jeopardize the survival of the viable tumor cells by suppressing the DCP production.

Conclusion: Vitamin K, a nontoxic agent, could improve the outcome of TACE by suppressing DCP production.

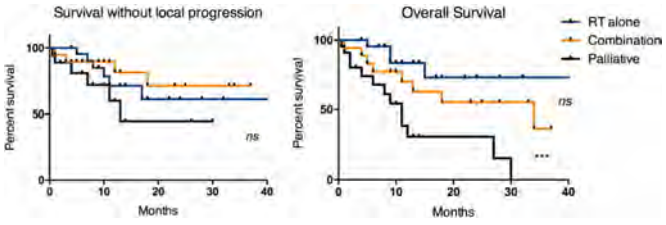
Email: clemenceho@hotmail.com

Background and aims: Recent data suggest that EBRT could be an efficient and safe local treatment of HCC. Yet, RT alone or in a combined strategy is rarely used for HCC patients.

Methods: We retrospectively analysed all patients with any stage of HCC who received RT as a sole therapy or combined with other treatments. We reviewed charts of 66 patients treated between 01/11 and 09/18. Indications of RT were contraindication or technical issues for others local therapies, remaining active lesions after first local therapy or heavy comorbidities not allowing systemic treatments. We aimed to evaluate outcome and safety.

Results: Mean age was 70 ± 1 years, women 13 (20%), men 53 (80%). 61pts (92%) were cirrhotic among which 56% were Child A, B in 42% and C in 2%. The BCLC stage was A in 41%, B in 15%, C in 41% and D in 3% of pts. Median tumor size was 41 mm. 19 (29%) patients were naïve of treatment, 30 (64%) previously received one another HCC treatment and 17 (36%) received > 1 previous treatment. RT was indicated as unique treatment, complementary treatment and as palliative therapy in 38%, 30%, and 32%, respectively. The median dose delivered was 42 Gray (Gy) with median of dose per fraction of 5 Gy, using 3D-conformal RT planning in 30% and stereotactic-body RT in 70% of pts. The median follow-up was 10.5 mths. 3 months after the end of RT, there were 17% complete responses (CR), 44% partial responses (PR), 35% tumor stability (TS) and 4% tumoral progression (TP). During overall follow-up, we observed 35% CR, 40% PR, 21% TS and only 4% TP. There was no statistical difference in terms of response between RT as unique treatment (21/23 patients) or combination treatment (13/20 patients) (p = 0.06). Among the 43 responders, response criteria were based on RECIST, mRECIST or both in 19%, 46% and 35% of cases, respectively. In the follow-up, 16 (24%) patients had no relapse, and among them, five patients underwent LT. 21% of patients had a local relapse after a median of 8.5 months, 53% had an intra-hepatic relapse at a median of 5.5 months and 19% had a metastatic relapse at a median of 4 months. 25 patients had subsequent treatment for a relapse. Tumor size was not statistically different in patients with or without local relapse (Mann-Whitney test, p = 0.07). RT was well tolerated; principal adverse events were asthenia (44% of patients), gastro-intestinal symptoms (14%), mild and transitory elevation of transaminases (9%) and signs of cirrhosis decompensating (9% of patients, requiring interruption of treatment). At the end of the study, 59% of patients were alive. Median overall survival was 34 months in the curative group and 11 months in the palliative group (Log-rank test, p = 0.0003).



Conclusion: RT should be considered as an effective and safe therapy alone or in combination in all stages of HCC and could be proposed for cirrhotic patients that present contraindication or failure for all others therapies.

FRI-471

Regorafenib may enhance efficacy of anti-program cell death-1 therapy in hepatocellular carcinoma through modulation of macrophage polarization

Chia-Wei Chen[1], Da-Liang Ou[1], Chia-Lang Hsu[2], Li Lin[1], Ann-Lii Cheng[3], Chiun Hsu[1,4]. *[1]National Taiwan University College of Medicine, Graduate Institute of Oncology, Taipei, Taiwan; [2]National Taiwan University Hospital, Medical Research, Taipei, Taiwan; [3]National Taiwan University Cancer Center, Taipei, Taiwan; [4]National Taiwan University Hospital, Oncology, Taipei, Taiwan*
Email: hsuchiun@gmail.com

Background and aims: Many multi-kinase inhibitors are being tested for potential synergistic antitumor efficacy with anti-PD1 therapy in HCC. In addition to their anti-angiogenic property, direct immune modulatory effects of these kinase inhibitors were not clearly defined.

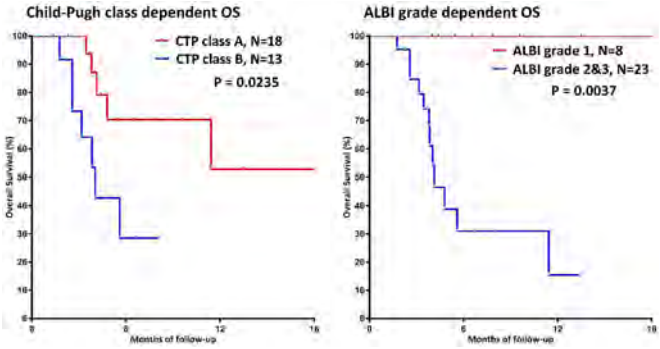
Method: An orthotopic HCC model, generated by implanting BNL/MEA liver cancer cells into the subcapsular space of BALB/c mice, was used to evaluate in vivo treatment efficacy and safety of regorafenib and anti-PD1 therapy, alone or in combination. Expression patterns of immune-related genes in tumor samples after drug treatment were analyzed by RNA-Seq. Extent of macrophage polarization after regorafenib treatment was measured by expression of M1-related (TNFa, IL6) or M2-related genes (Arg1, CD206) in bone marrow-derived macrophages (BMDMs) using quantitative PCR, ELISA, or flow cytometry. The changes in T cell function after co-culture with

regorafenib-treated BMDMs were examined by cytokine assay, expression of T-cell related genes, and flow cytometry.
Results: Regorafenib 5 mg/kg/day, which corresponded to about half of the human dosage for clinical use, may produce synergistic antitumor efficacy with antiPD1 in terms of tumor regression and animal survival. Immune-related genes induced by regorafenib, independent of its anti-angiogenic effects, included genes related to T cell activation (IL2ra, CD69, Tespa1) and myeloid differentiation (Ccr7, Ly6c2, Tnf, Slfn4). This was consistent with increasing tumor-infiltrating interferon+/CD8+ T cells and M1 macrophages in regorafenib-treated tumors. Regorafenib at sub-micromolar range may induce M1 polarization in vitro. Co-culture of regorafenib-treated BMDMs increased proliferation and activation of CD8+ T cells, whereas direct exposure to regorafenib at same concentrations had negligible effects on T cell proliferation or function.
Conclusion: Low-dose regorafenib may modulate macrophage polarization, increase T cell activation, and thereby enhance efficacy of anti-PD1 therapy for HCC. Optimization of regorafenib dosage for rational design of combination therapy regimen may improve the therapeutic index in the clinic.

FRI-472
ALBI grade determines survival of nivolumab-treated patients with advanced hepatocellular carcinoma: a real-world observational study

Pei-Chang Lee[1], ChiehJu Lee[1], Ming-Chih Hou[1], Yee Chao[2], Yi-Hsiang Huang[1,3]. *[1]Taipei Veterans General Hospital, Division of Gastroenterology and Hepatology, Taipei, Taiwan; [2]Taipei Veterans General Hospital, Cancer Center, Taipei, Taiwan; [3]National Yang-Ming University, Institute of Clinical Medicine, Taipei, Taiwan*
Email: yhhuang@vghtpe.gov.tw

Background and aims: Immunotherapy with checkpoint inhibitor is a promising and FDA-approved treatment for advanced hepatocellular carcinoma (HCC), mainly after sorafenib failure. The treatment response of Nivolumab (anti-programmed cell death-1, PD-1) in real-world setting as the first line or second line treatment for advanced HCC was rarely reported. In addition, factors associated with treatment outcomes were unclear.
Method: From May 2017, 37 patients had received nivolumab treatment for advanced HCC in Taipei Veterans General Hospital. Among them, 31 patients with evaluable radiographic images following treatment before the date of data cut were enrolled for clinical assessment. Factors associated with survival were analyzed.
Results: Majority (80.6%) of the patients were in BCLC stage C, followed by 16.1% BCLC B. Twenty (64.5%) patients were sorafenib failure and 11 (35.5%) were sorafenib naïve. At the date of data cut, the disease control rate was 41.9% including 1 (3.2%) complete response, 5 (16.1%) partial responses, and 7 (22.6%) stable diseases. Median time to response was 61 days (IQR 40-64 days), and the median duration of response was 9.6 months (IQR 1.4-11.0) for responders. The median overall survival (OS) was 11.4 months (95% C.I. 1.9-21.0). Patients within Child-Pugh A (n = 18) had better OS than those at Child-Pugh B (n = 13) (median OS: not yet reached vs. 4.0 months, p = 0.023). The median OS was 11.4 months in sorafenib-failure cases; whereas, the median OS in sorafenib-naïve patient was not yet reached (p = 0.990). All patients at ALBI grade 1 status were still alive at the date of data cut and had significantly longer OS than those at ALBI grade 2 or 3 (median OS: not yet reached vs 4.1 months, p = 0.004). No factor was identified associated with treatment response. Till the date of data cut, 9 patients still kept ongoing nivolumab treatment. Grade 3/4 treatment-related adverse events were observed in 7 patients (3 ALT elevation, 6 AST elevation, and 2 hyperbilirubinemia). Besides, only one patient developed grade 2 immunotherapy-related pneumonitis.



Conclusion: ALBI grade 1 confers excellent survival under immunotherapy for advanced HCC. The treatment response of nivolumab was equivalent between sorafenib-naïve and sorafenib-experienced patients.

FRI-473
Safety and effectiveness of regorafenib in recurrent HCC after liver transplantation and progression on sorafenib: A real-life multicentre study

Email: massimo.iavarone@gmail.com

Background and aims: Regorafenib improves the overall survival (OS) of sorafenib-tolerant patients who develop progression and it is the first second-line systemic treatment approved by EMA and FDA for hepatocellular carcinoma (HCC). However, there is no data of regorafenib in patients with HCC recurrence after liver transplantation (LT). Thus, the aim of this study is to evaluate the safety and outcomes of regorafenib in this population.

Method: This is a retrospective, multicentre and international study, including regorafenib-treated LT patients. The baseline characteristics and evolutionary events during sorafenib/regorafenib treatment were collected. Patients' management and radiological evaluations were performed according to centres' policy.
Results: From 2015 to 2018, 28 LT patients (57 years, 68% males, 54% performance status 1) from Europe and Latin-America were included. Median time from LT to regorafenib initiation was 3.9 (1.1-18.5) years, median time on sorafenib was 11.3 (0.7-76.4) months and from sorafenib discontinuation to regorafenib initiation was 14 (1-591) days. During regorafenib treatment (6.3 months), all patients had at least 1 adverse event (AE) of any grade, the most common grade 3/4 AEs were fatigue (25%) and dermatological reaction (18%). While no liver rejection episodes were observed, plasma levels of immunosuppressive drugs increased in 5 patients. Twenty-four patients developed radiological tumor progression: the most frequent patterns of progression were extra-hepatic growth (38%) and new extra-hepatic lesions/new vascular invasion (33%). Median OS from regorafenib initiation and sorafenib-regorafenib sequence were 12.9 (CI 95%; 6.7-19.1) and 38.4 (CI 95%; 18.5-58.4) months, respectively.
Conclusion: This is the first evidence that regorafenib is safe in patients after LT. The impact of sequential sorafenib-regorafenib treatment on OS in this population seems similar to the reported in no-LT patients.

FRI-474
AGT gene polymorphisms predict early dose modification of sorafenib for dermatological adverse events: towards tailored medicine for patients with hepatocellular carcinoma
Massimo Iavarone[1], Enrico Galmozzi[1], Annalisa De Silvestri[2], Andrea Casadei Gardini[3], Fabio Piscaglia[4], Giorgia Marisi[5], Floriana Facchetti[1], Luca Faloppi[6], Luca Ielasi[4], Francesca Benevento[4], Mario Scartozzi[6], Stefano Cascinu[7], Angelo Sangiovanni[1], Carmine Tinelli[2], Pietro Lampertico[1]. *[1]C.R.C. A.M. and A. Email: massimo.iavarone@gmail.com

Background and aims: Sorafenib (SOR) is the standard of care of patients with advanced hepatocellular carcinoma (HCC). However, no biomarker exists able to predict treatment duration (TD) and overall survival (OS). It has been recently shown that the AGT gene polymorphisms (SNPs) can predict the early (< 2 months) occurrence of dermatological adverse events (eDAEs) requiring dose-reduction, which is associated with OS. We aimed to evaluate the ability of eDAE and genetic profile to predict the benefit of SOR in a large population of patients with HCC.
Method: We retrospectively evaluated 221 prospectively enrolled HCC patients treated with SOR (starting dose 800 mg) in five centers in Italy. Clinical and laboratory assessments were done monthly, radiologic tumour re-evaluation every 2-3 months. Treatment was maintained until progression, significant toxicity or patient's decision. Two SNPs (*rs699* and *rs4762*) of the AGT gene were assessed by using the TaqMan end point-genotyping assay. The end points of the study were: identification of baseline and time-dependant predictors of TD and OS and correlation with ATG gene SNPs.
Results: Baseline characteristics of patients included in the analysis were: age 69 years, 83% males, 46% HCV-pos, 86% Child-Pugh (CPT) A, 61% ECOG PS 0, 66% BCLC-C. Genetic distribution of AGT SNPs among the population were: 33% AA, 46% AG and 21% GG for *rs699*; 78% GG, 20% GA and 2% AA for *rs4762*. The median follow-up was 12 months (mos), the median TD 4 months and the OS at 24 months was 32% (CI 95% 26-39). At least one AE developed in 94% of patients; 46% patients required ≥ 1 dose reductions, which was due to AE in 88% and early in 62% of cases. eDAE developed in 26 patients (47% of those with an early reduction due to AE). Predictors of TD by time dependent covariate analysis were CPT (HR 2.11, 95%CI 1.06-4.16, p = 0.033), ECOG PS (HR 1.57, 95%CI 1.07-2.32, p = 0.022), and eDAE (HR 0.61, 95% CI 0.37-1.01, p = 0.05); while for OS were presence of varices (HR 1.40, 95%CI 1.01-1.95, p = 0.045), CPT (HR 2.24, 95%CI 1.13-4.41, p = 0.020), ECOG PS (HR 2.51, 95%CI 1.66-3.79, p < 0.001) and eDAE (HR 0.62, 95% CI 0.35-1.09, p = 0.097). The *rs4762* SNP was an independent predictor of eDAE (HR 3.01, 95% CI 1.14-7.99, p = 0.009), while the risk of eDAE was two-fold higher in carriers of at least one minor allele of both SNPs (p = 0.031).
Conclusion: eDAE during SOR therapy predicted TD and OS and AGT *rs4762* SNP was associated with eDAE occurrence. The AGT *rs4762* SNP could help to tailor treatment strategies in patients with HCC whenever different therapies will be available.

FRI-475
Experience impacts on reasons leading to sorafenib discontinuation and chance of long-term response
Francesco Tovoli[1], Luca Ielasi[1], francesca benevento[1], Angelo Cimino[1], Fabio Piscaglia[1], Luigi Bolondi[1]. *[1]University of Bologna, Department of Medical and Surgical Sciences, Bologna, Italy*
Email: luca.ielasi.kr@gmail.com

Background and aims: Sorafenib is associated with various adverse events (AEs) potentially leading to permanent drug discontinuation. Common sense suggests that cumulative experience over a long timeframe might improve the management of drug-related AEs, with a potential benefit to the patients. However, the actual existence and the full extent of this phenomenon have never been investigated.
Method: We analyzed a large retrospective-prospective database gathering the clinical data of 201 patients from our Centre, who were consecutively prescribed with sorafenib between 2008 and 2017. We divided these patients in two groups according to the start date of sorafenib (2008-2012 vs 2013-2017), comparing clinical, laboratory and tumor characteristics. In particular, we verified: treatment duration, medium daily dose, reason of sorafenib discontinuation (as defined by Iavarone et al, Hepatology 2015), and overall survival (OS).
Results: One-hundred-three and 98 patients started sorafenib in 2008-2012 and 2013-2018, respectively. These groups did not differ in age, sex, performance status, liver function, and tumor staging. Due to more frequent dose reductions, the median average daily dose of sorafenib was lower in the 2013-2018 group (413 vs 518 mg/day, p < 0.001). In parallel, the median treatment duration increased in the same group (145 vs 112 day, p = 0.027), with no remarkable difference in the cumulative drug dose between the two groups (61.6 vs 58.1 g, p = 0.440). The rate of patients permanently stopping sorafenib for intolerance dropped from 23.3% in 2008-2012 to 7.1% in 2013-2017 (p = 0.002). The median OS was similar in the two groups (11.1 vs 11.6 months), but the rate of long-survivors (OS > 3 year) was higher in the 2013-2017 group (23.4 vs 9.7%, p = 0.001). To reduce the influence of deaths due to early progression, we performed a subgroup analysis of patients who achieved disease control as their best radiologic response. In this case, the OS in the 54 patients treated in 2013-2017 was significantly higher compared to that of the 51 patients treated in 2008-2012 (24.4 vs 20.6 months, HR 0.63, 95%CI 0.42-0.96, p = 0.031).
Conclusion: Increased experience in the management of sorafenib-related AEs may lead to increased treatment duration and better outcomes in sorafenib-responsive patients. This factor may be of paramount relevance in the era of sequential treatments based on

tyrosine-kinase inhibitors, as these molecules share a common toxicity-profile.

FRI-476

Repeated surgical resection versus radiofrequency ablation for recurrent hepatocellular carcinoma after surgical resection : A propensity score matching analysis

Chang Ke-Bin[1], I-Cheng lee[1,2], Gar-Yang Chau[3], Ming-Chih Hou[2,4], Yi-Hsiang Huang[1,2,5]. *[1]Taipei Veterans General Hospital, Taipei, Taiwan, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan; [2]National Yang-Ming University, Taipei, Taiwan., Institute of Clinical Medicine, Taipei, Taiwan; [3]Taipei Veterans General Hospital, Department of Surgery, Taipei, Taiwan; [4]Taipei Veterans General Hospital, Taipei, Taiwan, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan; [5]National Yang-Ming University School of Medicine, Faculty of Medicine, Taipei, Taiwan*
Email: popogogoc@gmail.com

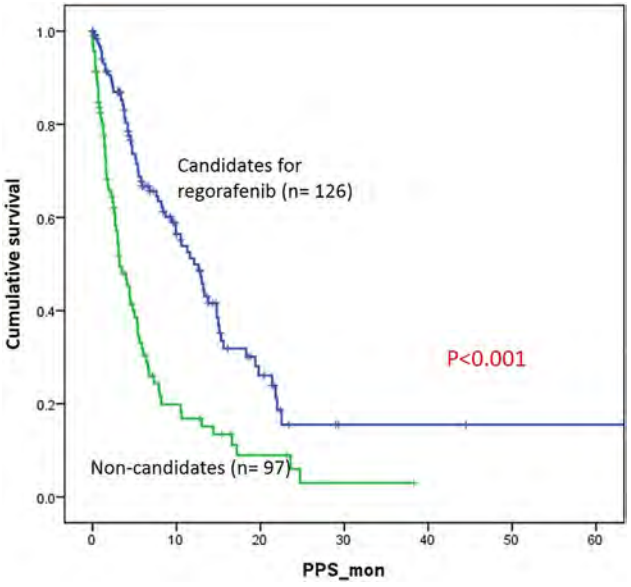
Background and aims: Tumor recurrence rate remains high after curative surgical resection for early stage hepatocellular carcinoma (HCC). Repeated surgical resection and radiofrequency ablation (RFA) are treatment options for recurrent HCC within early stage, but which treatment modality provides better outcomes remains unclear. The aim of this study was to compare the recurrence rate and survival between the two treatment modalities for recurrent HCC.
Method: From August 2007 to September 2017, 158 patients undergoing repeated surgical resection (n = 45) or RFA (n = 113) for recurrent HCC after surgical resection were retrospectively enrolled. Factors associated with recurrence-free survival (RFS) and overall survival (OS) were analyzed.
Results: Patients in the RFA group had significantly smaller tumor size ($p < 0.001$) and lower AFP levels ($p < 0.001$). During a median follow-up period of 44.8 months, 109 (68.9%) cases developed tumor recurrence and 117 (74%) patients died. The complication rate was higher (17.8% vs 3.5%, $p = 0.005$) and the mean hospital stay was longer (13.3 vs 3.6 days, $p = 0.001$) in the repeated surgical resection group versus the RFA group. The median RFS was significantly longer in the surgical resection group than the RFA group (29.2 vs 11.5 months, $p = 0.030$), whereas the median OS was comparable between the surgical resection group and the RFA group (49.9 vs 41.1 months, $p = 0.164$). By multivariate analysis, age > 65 years (Hazard ratio (HR) = 1.55, $p = 0.025$), AFP ≥ 20 ng/ml (HR = 2.28, $P < 0.001$), RFA (vs surgical resection, HR = 2.26, $p = 0.001$) were independent predictors of poorer RFS, while tumor size ≥ 3 cm (HR = 0.54, $p = 0.041$) was the only independent predictor of OS. After propensity score matching, the median RFS remained significantly longer in the surgical resection group than the RFA group (29.2 vs 8.7 months, $p = 0.001$), while the median OS remained comparable between the surgical resection group and the RFA group (49.9 vs 42.9 months, $p = 0.393$). For recurrent tumor within BCLC stage 0, i.e. single tumor < 2 cm, the median RFS and OS were comparable between the surgical resection group and the RFA group (19.2 vs 13.0 months, $p = 0.325$), and (49.9 vs 44.8 months, $p = 0.930$) respectively.
Conclusion: Although surgical resection provides longer RFS than RFA for recurrent HCC after surgical resection, the OS were comparable between repeated surgical resection and RFA.

FRI-477

Factors associated with good postprogression survival in post-sorafenib progressed advanced hepatocellular carcinoma pateitns not eligible for regorafenib

Chang Wook Kim[1], Hee Yeon Kim[1], Do Seon Song[1], U Im Chang[1], Jin Mo Yang[1], Sung Won Lee[1], Hae Lim Lee[1], Sun Hong Yoo[1], Jung Hyun Kwon[1], Soon Woo Nam[1], Pil Soo Sung[1], Jeong Won Jang[1], Hee Chul Nam[1], Jong Young Choi[1], Si Hyun Bae[1], Seung Kew Yoon[1]. *[1]The Catholic University of Korea, Seoul, Korea, Rep. of South*
Email: hee82@catholic.ac.kr

Background and aims: This study aimed to assess the prognostic factors associated with postprogression survival (PPS) in advanced hepatocellular carcinoma (HCC) patients who showed radiological progressive disease (PD) with sorafenib monotherapy, and were not eligible for 2nd-line regorafenib treatment.
Method: A total of 223 patients who were confirmed with radiological PD after sorafenib monotherapy from September 2008 to December 2017 were enrolled. We define those with Child-Pugh class A, ECOG PS 0 or 1 at progression, and who had tolerated sorafenib as candidates eligible for 2nd line regorafenib therapy.
Results: Among 223 patients with PD after sorafenib treatment, 126 (56.5%) patients met eligibility criteria for regorafenib treatment at first radiological confirmation of PD. The median PPS of the candidates for regorafenib treatment (12.1 months) was statistically longer ($p < 0.001$) than that of the non-candidates (3.2 months). Prognostic factor associated with good PPS in non-candidates for regorafenib therapy was absence of macrovascular invasion [hazard ratio = 0.5 (95% confidence interval 0.33-0.76)] at initial radiological PD.



Conclusion: Absence of macrovascular invasion at initial radiological PD may predict good PPS in advanced HCC patients who had progressed after sorafenib monoterapy and were not eligible for regorafenib treatment.

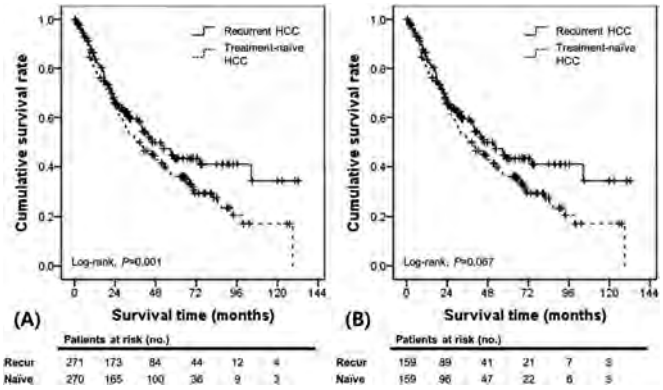
FRI-478

Survival outcomes of TACE in treatment-naive and recurrent HCC after curative resection: A propensity score-matched analysis

David Kim[1], Tae Seop Lim[1], Mi Young Jeon[1], Beom Kyung Kim[1], Jun Yong Park[1], Do Young Kim[1], Sang Hoon Ahn[1], Kwang-Hyub Han[1], Oidov Baatarkhuu[2], Seung Up Kim[1]. *[1]Yonsei University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South; [2]Mongolian National University of Medical Sciences, Department of Infectious Diseases, Ulaanbaatar, Mongolia*
Email: ksukorea@yuhs.ac

Background and aims: Transarterial chemoembolization (TACE) improves the survival of patients with hepatocellular carcinoma (HCC); however, TACE treatment outcomes of patients with treatment-naïve HCC (TN-HCC) and those with recurrent HCC after curative resection (R-HCC) have not yet been compared.
Method: We recruited 448 patients with TN-HCC and 275 patients with R-HCC treated with TACE as first-line anti-cancer treatment.
Results: At first TACE, patients with TN-HCC showed a significantly lower proportion of male gender (74.9% vs. 84.3%), higher proportion

of liver cirrhosis (61.9% vs. 49.3%), higher aspartate aminotransferase (median 48 vs. 31 IU/L) alanine aminotransferase (median 38 vs. 26 IU/L), alpha-fetoprotein (AFP) (median 96.6 vs. 7.7 ng/ml), and total bilirubin (mean 1.0 vs. 0.8 mg/dL) levels, longer prothrombin time (median 1.05 vs. 1.01 international normalized ratio), higher tumor number (mean 2.1 vs. 1.7), larger tumor size (median 3.1 vs. 1.6 cm), and lower proportion of Barcelona Clinic Liver Cancer stage 0-A (55.6% vs. 71.9%) than patients with R-HCC (all $p < 0.05$). Multivariate analysis showed that TACE for TN-HCC (vs. R-HCC) was an independent predictor of mortality (hazard ratio, 1.328; $p = 0.024$) with AFP level and tumor number (all $p < 0.05$). However, treatment outcomes between TN-HCC and R-HCC became statistically similar after propensity score-matched (PSM) analysis using liver cirrhosis, tumor size, and multiple tumors ($p < 0.05$).



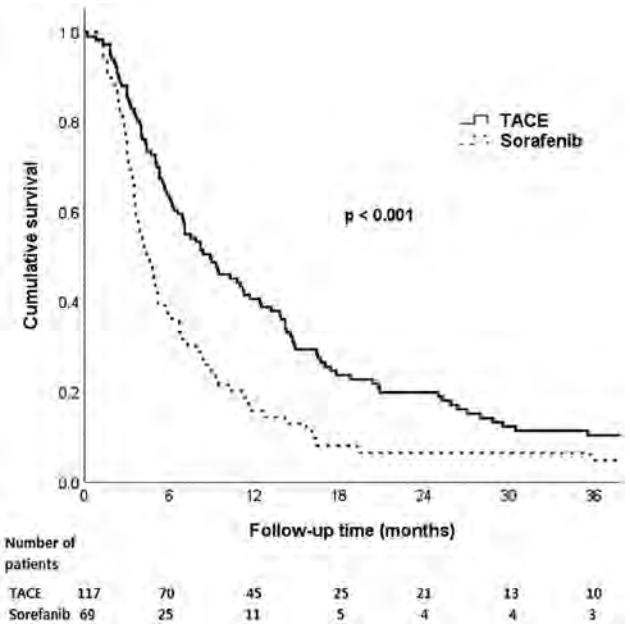
Conclusion: Based on the similar TACE treatment outcomes observed with the PSM analysis, the current TACE treatment guideline for patients with TN-HCC might similarly be applied for patients with R-HCC.

FRI-479

Hepatocellular carcinoma with extrahepatic metastasis: Are there still candidates for transarterial chemoembolization as an initial treatment?

Jihye Kim[1], Dong Hyun Sinn[1], Moon Seok CHOI[1], Wonseok Kang[1], Geum-Yon Gwak[1], Yong Han Paik[1], Joon Hyeok Lee[1], Kwang Cheol Koh[1], Seung Woon Paik[1], Byung Chul Yoo[2]. [1]*Samsung Medical Center, Sungkyunkwan University School of Medicine, Department of Medicine, Seoul, Korea, Rep. of South;* [2]*Konkuk University School of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South*
Email: drmschoi@gmail.com

Background and aims: Currently, sorafenib is indicated for hepatocellular carcinoma (HCC) with extrahepatic metastasis (EHM), and many other systemic agents are becoming available. However, a few HCC patients with EHM still undergo transarterial chemoembolization (TACE) for intrahepatic tumor control. We aimed to investigate whether TACE is appropriate for patients with EHM, and if so, which subgroup may benefit from TACE.
Method: A total of 186 consecutive HCC patients (median: 55 years, male: 86.0%, hepatitis B virus: 81.7%, Child-Pugh Class A: 83.3%) with EHM (nodal metastasis: 60.8%, distant metastasis: 39.2%) between 2010 and 2014 were analyzed. Initial treatment included sorafenib in 69 patients, and TACE in 117 patients.
Results: During a median follow-up of 6.6 months (range: 0.2-94.6 months), mortality was observed in 90.3% (168/186). The median survival was better for patients who received TACE than those treated with sorafenib (8.2 months vs. 4.6 months, $p < 0.001$). However, baseline characteristics varied between patients initially treated with TACE and sorafenib, and the treatment modality was not an independent factor associated with overall survival (hazard ratio: 1.19, 95% confidence interval: 0.81-1.75, $p = 0.36$). In sub-group analysis, TACE was associated with better survival only among younger patients and those with segmental/lobar portal vein invasion.



Conclusion: In HCC patients with EHM, TACE was not an independent favorable prognostic factor compared to sorafenib. The concept of intrahepatic control in HCC patients with EHM may need to be reevaluated in the era of promising systemic therapies, although there can be specific subgroups who still benefit from TACE.

FRI-480

Laparoscopic right hepatectomy is feasible and safe in solitary hepatocellular carcinoma

Jong Man Kim[1], Jinsoo Rhu[1], Gyu-Seong Choi[1], Jae-Won Joh[1].
[1]*Samsung Medical Center, Sungkyunkwan University School of Medicine, Department of Surgery, Seoul, Korea, Rep. of South*
Email: jongman94@hanmail.net

Background and aims: Laparoscopic liver resection has been reported as a safe and effective approach for the management of hepatocellular carcinoma (HCC). However, its perioperative and oncological outcomes have not been evaluated in right hepatectomy (RH) patients. Aim of present study is to compare the outcomes between laparoscopic RH (LRH) and open RH (ORH) in HCC patients.
Method: From January 2013 to August 2017, 345 patients with HCC underwent RH. Patients with portal vein tumor thrombosis, history of preoperative locoregional therapies, multiple tumors, bile duct tumor thrombosis, the history of abdominal operation, and serosal involvement were excluded. 189 patients were selected because of Child-Pugh class A and solitary HCC.
Results: The numbers of ORH and LRH groups were 134 and 55 patients. Among LRH group, four patients (7.3%) converted open conversion due to bleeding (n = 3) and close to the tumor (n = 1). Median tumor size of ORH and LRH was 4.0 cm and 3.5 cm, respectively ($p = 0.086$). Preoperative factors, preoperative AFP levels, and pathologic factors were not different between the two groups. Operation time in ORH group was shorter than in the LRH group (243 min vs. 271 min; $P = 0.032$), but amounts of blood loss in the ORH group was more than in the LRH (300 ml vs. 200 ml; $P < 0.001$). Two patients in the ORH group received red blood cells transfusion, but none in the LRH group were not transfused. Ten patients in the ORH group developed postoperative complications

(Clavien grade I and II), but three patients in the LRH group had postoperative complications (Clavien grade 1 and II). Median hospitalization in the ORH group was longer than in the LRH group (10 days vs. 7 days; P < 0.001). Disease-free survival (DFS) rates and patient survival (PS) rates at 1-, 2-, and 3-year were 92.1%, 89.2%, 87.4% and 95.3%, 92.4%, 90.2% in the ORH group and 100%, 94.1%, 94.1% and 100%, 100%, 100% in the LRH group, respectively. The DFS and PS in the LRH group were better than in the ORH group, but the difference did not reach significant levels.
Conclusion: LRH is feasible and safe for solitary HCC patients in experienced center. However, the oncologic outcome of LRH should be needed in further investigations.

FRI-481
Predicting hepatocellular carcinoma recurrence beyond Milan criteria after liver resection for solitary hepatocellular carcinoma
Jong Man Kim[1], Gyu-Seong Choi[1], Nam-Joon Yi[2], Kwang-Woong Lee[2], Kyung-Suk Suh[2], Jae-Won Joh[1]. *[1]Samsung Medical Center, Sungkyunkwan University School of Medicine, Department of Surgery, Seoul, Korea, Rep. of South; [2]Seoul National University College of Medicine, Division of HBP Surgery, Department of Surgery, Seoul, Korea, Rep. of South*
Email: jongman94@hanmail.net

Background and aims: Several hepatectomy patients with HCC who are initially transplantable (within MC) developed untransplantable HCC recurrence (beyond MC) after primary curative liver resection. The purpose of our study is to identify the risk factors of untransplantable hepatocellular carcinoma (HCC) recurrence after primary curative resection of solitary HCC and solitary HCC within Milan criteria (MC).
Method: We retrospectively reviewed 592 patients with recurrent HCC who underwent liver resection due to solitary HCC between 2005 and 2011.
Results: All patients were Child-Pugh class A. At primary curative hepatectomy, 411 patients (69.4%) were diagnosed with HCC within MC and 181 patients (30.6%) had HCC beyond MC. The mean time from primary hepatectomy to recurrence was 14 months (range, 1-116 months). At HCC recurrence, 93 patients (15.7%) were diagnosed beyond MC. Multivariate analysis showed that microvascular invasion and a tumor grade of 3 or 4 were closely associated with a high risk of HCC recurrence beyond MC in patients who had hepatectomy for solitary HCC. Of the 411 patients within MC at primary curative hepatectomy, 54 patients (13.9%) developed HCC recurrence beyond MC. Multivariate analysis also showed that microvascular invasion and a tumor grade of 3 or 4 were closely associated with HCC recurrence beyond MC in these patients.
Conclusion: The present study suggests that the presence of certain unfavorable histological factors in patients who underwent initial liver resection of transplantable HCC within MC with good liver function predicted the development of recurrent HCC beyond MC.

FRI-482
Ideal number of lymph nodes to harvest for intrahepatic cholangiocarcionoma
Sung Hyun Kim[1], Dai Hoon Han[1], Gi Hong Choi[1], Jin Sub Choi[1], Kyung Sik Kim[1]. *[1]Yonsei University College of Medicine, Hepatobiliary and Pancreatic Surgery, Seoul, Korea, Rep. of South*
Email: ohliebe@gmail.com

Background and aims: Although lymph node dissection is recommended during hepatectomy for intrahepatic cholangiocarcinoma (ICC) by the American Joint Committee on Cancer (AJCC) 8th edition, the role of routine lymphadenectomy for ICC is still controversial. Moreover, AJCC recommends that at least 6 lymph nodes should be harvested during the lymphadenectomy. However, there is no clear evidence about this issue. In this study, we evaluated the minimum number of lymph nodes to harvest for ICC.
Method: Records from 180 patients who underwent radical hepatectomy for intrahepatic cholangiocarcinoma from January 2000 to December 2014 were retrospectively reviewed. The minimum number of lymph nodes to harvest was calculated via comparison of overall survival between N0 and N1 patients based on the Cox proportional hazard model.
Results: Median harvested lymph nodes were 5 [1-12]. About 20 percent (N = 37) of patients didn't undergo lymphadenectomy (Nx group). (**Table**) The Cox proportional hazard model showed that when the minimum number of lymph nodes examined was 6 or more, the hazard ratio between N1 versus N0 patients was statistically significant. (HR 2.18, 95% CI 1.11-4.26) The hazard ratio for N1 patients increased from 2.18 with 6 minimum number of lymph nodes examined to 2.62 with 10 minimum number of lymph nodes examined. (**Figure**)

Table: Basal characteristics of the patients

	N = 180
Age	62.9±9.9
Gender (M:F)	108 : 72 (1.5 : 1)
Hepatitis (B or C viral carrier)	28 (15.6%)
IHD stone	14 (7.8%)
CA 19-9	64.0 [12.2-410.5]
Neoadjuvant therapy	17 (9.4%)
Tumor size (cm)	4.7±2.5
Gross type	
IG	25 (13.9%)
PI	11 (6.1%)
MF	119 (66.1%)
Mixed	25 (23.9%)
Differentiation (N = 174)	
Well	32 (17.8%)
Moderately	82 (45.6%)
Poorly	55 (30.6%)
Undifferentiated	5 (2.8%)
LVI	111 (61.7%)
PNI	61 (33.9%)
Harvested LN	5 [1-12]
T stage	
T1	28 (15.6%)
T2	93 (51.7%)
T3	56 (31.1%)
T4	3 (1.7%)
N stage	
N0	92 (51.1%)
N1	51 (28.3%)
Nx	37 (20.6%)
TNM stage	
I	26 (14.4%)
II	63 (35.0%)
III	38 (21.1%)
IV	53 (29.4%)
Adjuvant therapy	71 (39.4%)
Median follow-up (months)	64.0 [54.3-73.7]

Conclusion: Intrahepatic cholangiocarcinoma patients undergoing radical resection should ideally have at least 6 lymph nodes harvested to be accurately staged.

FRI-483

Endoscopic biliary drainage in patients with cholangiocarcinoma: Polyethylene versus self-expanding metal stents

Torsten Voigtländer[1], Schweitzer Nora[1], Von Hahn Thomas[1], Michael P. Manns[1], Arndt Vogel[1], Martha Kirstein[1]. [1]*Hannover Medical School, Hannover, Germany*
Email: kirstein.martha@mh-hannover.de

Background and aims: Endoscopic biliary drainage is the standard of care for patients with cholangiocarcinoma (CCA)-induced, obstructive jaundice. Self-expanding metal stents are supposed to be superior to polyethylene stents in terms of reduction of interventions and costs. So far, there are only few real-life data with respect to survival in this patient cohort.
Method: In this study, we retrospectively analyzed 422 patients with CCA treated with endoscopic biliary drainage from 2000 to 2015 at Hannover Medical School, Germany. The aim of this study was to assess whether metal stenting reduces the frequency of interventions and influences survival in a large, real-life cohort compared to polyethylene stenting.
Results: Overall, 422 patients with CCA treated with endoscopic biliary drainage were included in this study. Indication for endoscopic biliary drainage was most often obstructive jaundice (n = 397; 94.1%). Among these patients, 20 patients (5%) were initially treated with a metal stent, and 38 (9.6%) received a metal stent in the subsequent course. Median number of interventions per month was 2.4-fold reduced following metal stenting in patients, which have initially received polyethylene stents. Patients first treated with a metal stent had a more advanced tumor stage and a significantly shorter median overall survival (mOS) compared to patients who received a metal stent subsequently (7.5 vs. 15.2 months; p = 0.019). There was no difference in mOS for metal vs. polyethylene stenting following a propensity score match for the confounders curative resection and chemotherapy (13.2 vs. 13.7 months, p = 0.555).
Conclusion: Our data confirm that metal stenting reduces the frequency of interventions, but does not influence OS. Metal stenting should be considered particularly in patients with a good prognosis and a prolonged life expectancy.

FRI-484

The early clinical response at 2 weeks of lenvatinib therapy for patients with advanced HCC

Teiji Kuzuya[1], Masatoshi Ishigami[1], Takanori Ito[1], Yoji Ishizu[1], Takashi Honda[1], Mitsuhiro Fujishiro[1]. [1]*Nagoya University Hospital, Gastroenterology and Hepatology, Nagoya, Japan, Japan*
Email: tkuzuya@med.nagoya-u.ac.jp

Background and aims: We previously reported that the disappearance of arterial tumor enhancement on CE-CT and the decrease in AFP levels after 2 weeks of sorafenib therapy were significant predictors of better survival for patients with advanced HCC. Lenvatinib has recently become available as a first line tyrosine-kinase inhibitor for unresectable HCC. The aim of this study was to investigate the early clinical response at 2 weeks of lenvatinib therapy for patients with advanced HCC.
Method: Between March and October 2018, a total of 23 patients who received lenvatinib as a first-line therapy were retrospectively enrolled to evaluate the early clinical response. Subjects were as followed; male/female, 15/8 cases; BCLC Stage (B/C), 10/13 cases; portal vein tumor thrombosis (Vp 0/2/3/4), 14/1/5/3 cases; tumor liver occupancy rate (50% > / > 50%), 15/8 cases; Child-Pugh score (CPS 5/6/7), 12/9/2 cases; ECOG-PS (0/1), 15/8 cases. The median AFP level was 44 ng/ml (2-54276). CE-CT images were taken at baseline, after 2 weeks and after 6 weeks of lenvatinib treatment. The antitumor responses were evaluated according to the modified RECIST. An AFP response was defined as a decline > 20% from baseline after 2 to 6 weeks of treatment in patients with > 20 ng/ml of AFP levels at baseline.
Results: At 2 weeks of lenvatinib therapy, the antitumor responses according to modified RECIST (CR/PR/SD/PD) were 0/12/11/0 cases (response rate, 52.2%; disease control rate, 100%). The response rates were as followed: 50% in 8 patients with Vp3 or 4 and 62.5% in 8 patients with > 50% of tumor liver occupancy rate, respectively. At 2 weeks, 16 patients were included for AFP response evaluation, and 13 of those patients (81.3%) were classified as AFP responders. At 6 weeks of lenvatinib therapy, the antitumor responses (CR/PR/SD/PD) were 0/8/9/0 cases (response rate, 47.0%; disease control rate, 100%; 6 cases were not taken). The response rates were as followed: 57.1% in 7 patients with Vp3 or 4; 60.0% in 5 patients with > 50% of tumor liver occupancy rate, respectively. At 6 weeks, 11 patients were included for AFP response evaluation, and 8 of those patients (72.7%) were classified as AFP responders. In 15 patients (88.2%), antitumor responses at 2 weeks by modified RECIST were consistent with those at 6 weeks. Regarding the deterioration of liver function, cases with the 2 points increase of CPS were as followed: 2 patients (8.7%) at 2 weeks; 1 (5.9%) patient at 6 weeks, respectively. Only one patient discontinued lenvatinib therapy within 6 weeks due to adverse events. Median duration of lenvatinib administration was 200 days.
Conclusion: In our initial experience, treatment response of lenvatinib therapy for patients with advanced HCC was favorable efficacy and acceptable tolerability. The early clinical response at 2 weeks may be a useful to evaluate the antitumor response of lenvatinib therapy.

Laparoscopic liver resection vs. Percutaneous radiofrequency ablation for small single nodular HCC: Comparison of treatment outcome

Dong Ho Lee[1], Jeong Min Lee[1], Jin Woong Kim[2], Min Woo Lee[3], Jong Man Kim[4]. [1]*Seoul National University Hospital, Radiology, Seoul, Korea, Rep. of South;* [2]*Chonnam National University Medical School, Radiology, GwangJu, Korea, Rep. of South;* [3]*Samsung medical center, Radiology, Seoul, Korea, Rep. of South;* [4]*Samsung medical center, Surgery, Seoul, Korea, Rep. of South*
Email: dhlee.rad@gmail.com

Background and aims: The treatment outcome of percutaneous radiofrequency ablation (p-RFA) or laparoscopic liver resection (LLR)

have not been fully compared. The aim of this study was to compare LLR with p-RFA as first-line treatment in patients with small single nodular HCC ≤ 3 cm.

Method: From January 2014 to December 2016, a total of 566 patients with single nodular HCC ≤ 3 cm treated by either LLR (n = 251) or p-RFA (n = 315) were included. The recurrence-free survival (RFS) and

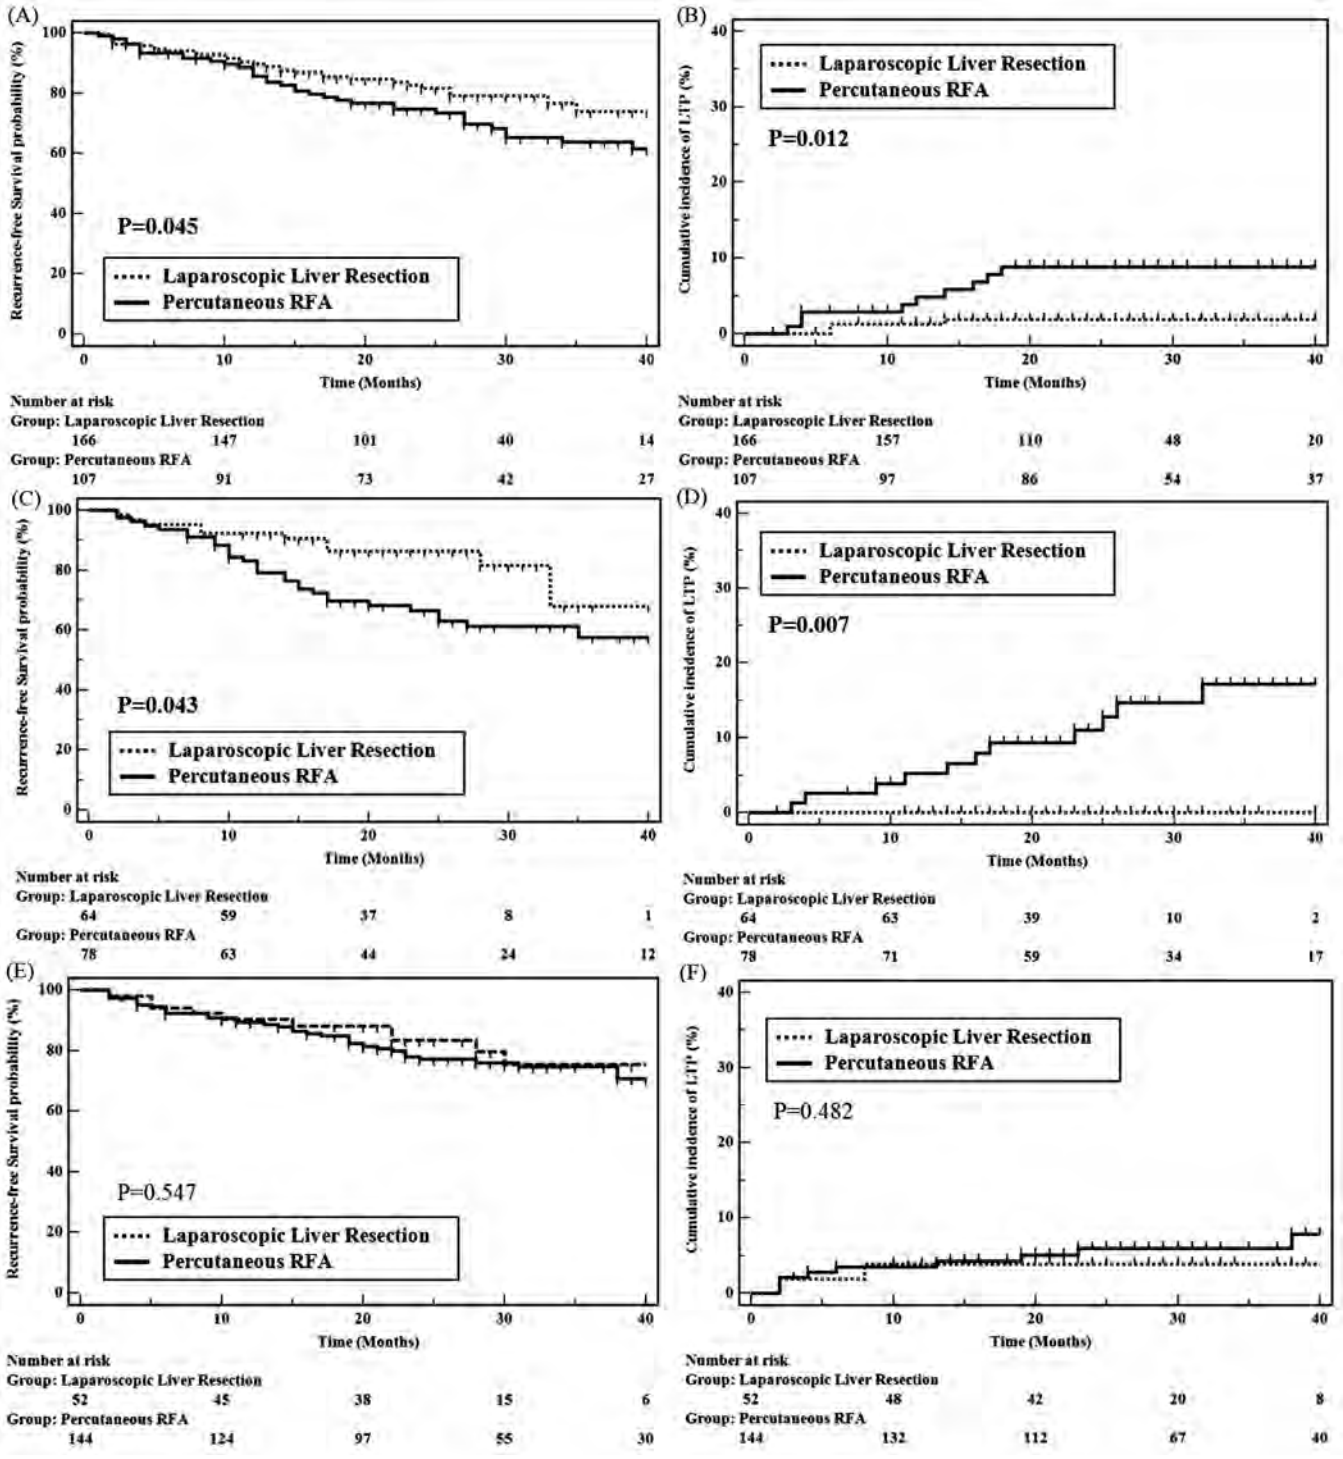

Figure: Estimation of recurrence-free survival and cumulative incidence of local tumor progression according to the tumor location. (A) Kaplan-Meier estimation of recurrence-free survival after laparoscopic liver resection for subcapsular tumor were compared with percutaneous RFA. (B) Cumulative incidence of local tumor progression after laparoscopic liver resection for subcapsular tumor was compared with percutaneous RFA. (C) Kaplan-Meier estimation of recurrence-free survival after laparoscopic liver resection for perivascular tumor were compared with percutaneous RFA. (D) Cumulative incidence of local tumor progression after laparoscopic liver resection for perivascular tumor was compared with percutaneous RFA. (E) Kaplan-Meier estimation of recurrence-free survival after laparoscopic liver resection for non-subcapsular and non-perivascular tumor were compared with percutaneous RFA. (F) Cumulative incidence of local tumor progression after laparoscopic liver resection for non-subcapsular and non-perivascular tumor was compared with percutaneous RFA.

cumulative incidence of local tumor progression (LTP) were estimated using Kaplan-Meier methods, and compared using log-rank test. Treatment outcome of two treatment modalities were compared in subgroup of patient according to the tumor location.

Results: The 3-year RFS after LLR was 74.4%, and significantly higher than p-RFA of 66.0% (p = 0.013), due to significantly lower cumulative incidence of LTP (2.1% at 3-year after LLR vs. 10.0% after p-RFA, P < 0.001). LLR provided significantly better local tumor control than p-RFA for subscapular tumor (3-year LTP rate of 1.9% vs. 8.8%, P = 0.012), as well as perivascular tumor (3-year LTP rate of 0.0% vs. 17.2%, P = 0.007). Regarding tumor located in liver antero-lateral portion, the cumulative incidence of LTP after LLR was significantly higher than p-RFA (3-year LTP rate of 0.0% vs. 10.7%, P < 0.001). However, there was no significant difference in LTP rates between LLR and p-RFA for non-subcapsular and non-perivascular tumor (p = 0.482) and for tumor in postero-superior liver portion (p = 0.380).

Conclusion: LLR could provide significantly better local tumor control and would be better for subcapsular or perivascular tumor as well as tumor located in antero-lateral portion of the liver than p-RFA.

FRI-486

Serum cytokines and chemokines correlated with tumor recurrrence and survival after surgical resection for overt and occult HBV-related hepatocellular carcinoma

I-Cheng Lee[1], Ming-Chih Hou[1], Yi-Hsiang Huang[1]. [1]*Taipei Veterans General Hospital, Taipei, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan*
Email: iclee@vghtpe.gov.tw

Background and aims: Serum cytokines and chemokines might reflect host anti-viral and anti-tumor immunity and could be potential biomarkers to predict outcomes of HBV-related hepatocellular carcinoma (HCC). The aim of this study was to evaluate the predictive value of serum cytokines and chemokines and outcomes of overt and occult HBV-related HCC after surgical resection.

Method: Serum samples of 80 HBsAg-positive HCC patients (overt HBV group) and 80 HBsAg-negative, HBV DNA-negative, intrahepatic HBcAg-positive HCC patients (occult HBV infection (OBI) group) were obtained from the Taiwan Liver Cancer Network. Serum levels of interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), transforming growth factor-β (TGF-β), interleukin-6 (IL-6), IL-10, IL-22, CXCL9, IP-10 and CCL5 were measured by Multiplex ELISA Cytokine Arrays. Factors associated with recurrence-free survival (RFS), early recurrence within 2 years of surgery, late recurrence after 2 years and overall survival (OS) were analyzed.

Results: The OBI group had significantly older age, larger tumor size, lower serum IL-6, IL-10, IL-22, CXCL9, CCL5 levels and higher TGF-β levels. Serum HBV DNA levels significantly correlated with serum levels of ALT, AST, IL-10, IL-6, CXCL9, CCL5, IL-22 and TGF-β, while tumor size significantly correlated with serum levels of AST, AFP, CXCL9, CCL5, IL-22 and TGF-β. During a median follow-up period of 71.9 months, 102 (63.7%) cases developed tumor recurrence and 70 (43.8%) patients died. By multivariate analysis, IL-6 > 14 pg/ml (hazard ratio (HR) = 1.898, p = 0.008) and tumor stage I-II (HR = 0.228, p < 0.001) were independent predictors of RFS. Tumor size > 5 cm (HR = 2.270, p = 0.003), presence of multiple tumors (HR = 2.602, p = 0.002) and presence of microvascular invasion (HR = 3.243, p = 0.007) were independent predictors of early recurrence. IL-22 > 25 pg/ml (HR = 3.608, p = 0.038), HBV DNA > 10^6 IU/ml (HR = 20.237, p = 0.001) and presence of cirrhosis (HR = 3.239, p = 0.043) were independent predictors of late recurrence. IL-6 > 14 pg/ml (HR = 3.382, p = 0.003), presence of microvascular invasion (HR = 3.206, p = 0.017) and tumor stage I-II (HR = 0.070, p < 0.001) were independent predictors of OS.

Conclusion: Serum cytokine and chemokine levels correlated with HBV viral load and tumor size, suggesting their role of host anti-viral and anti-tumor immunity. IL-6 significantly correlated with RFS and OS and could be a useful biomarker to predict outcomes of HBV-related HCC after surgical resection.

FRI-487

A new prognosis prediction model in patients with hepatocellular carcinoma after Yttrium-90 radioembolization

Jae Seung Lee[1], Han Ah Lee[2], Mi Young Jeon[1,3], Tae Seop Lim[1,3], Beom Kyung Kim[1,3], Jun Yong Park[1,3], Do Young Kim[1,3], Sang Hoon Ahn[1,3], Kwang-Hyub Han[1,3], Yeon Seok Seo[2], Seung Up Kim[1,3]. [1]*Yonsei University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South;* [2]*Korea University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South;* [3]*Severance Hospital, Yonsei Liver Center, Seoul, Korea, Rep. of South*
Email: ksukorea@yuhs.ac

Background and aims: Few studies have reported the treatment outcomes of trans-arterial radioemoblization (TARE) using Yttrium-90 (90Y) for hepatocellular carcinoma (HCC). We established and validated a new prognosis prediction model for patients with HCC treated with TARE.

Method: Between 2010 and 2017, 113 and 35 patients with intrahepatic HCC treated with TARE were selected for training and validation cohorts, respectively. The modified RECIST (mRECIST) criteria were used for response evaluation at 1, 3 and 6 months after TARE.

Results: In the training cohort, the median age was 64.1 years (92 male and 19 female) and the median survival after TARE was 50.3 months. A new prediction model for TARE (Y-scoring system) was established from the training cohort using five variables including low serum albumin (< 3.5 g/dL; hazard ratio [HR] = 5.446), high alpha-fetoprotein (AFP, >200 ng/ml; HR = 5.071), and tumor number ≥3 (HR = 2.933), portal vein thrombosis (HR = 4.915), and hepatic vein invasion (HR = 8.500), and two on-treatment variables including no des-gamma-carboxy prothrombin response (HR = 15.346) and progressive disease at 3 months after TARE (HR = 4.154), which were independently associated with mortality (all P < 0.05). The predictive accuracy of the Y-scoring system to predict 6 (area under curve [AUC] = 0.845), 9 (AUC = 0.868), and 12 months mortality (AUC = 0.886) after TARE was acceptable (all P < 0.05). In the validation cohort, the predictive accuracy of the Y-scoring system was similarly maintained (AUC 0.737-0.901 at 6 to 12 months).

Figure: Hazard ratios of independent risk factors, corresponding rounded risk score and predictive accuracy of candidate Y-scoring system to predict 6-12 months mortality. CI, confidence interval; AUC, area under the ROC curve.

Risk factors	Univariate	Multivariate analysis		Scoring
	P value	*P* value	Hazard ratio (95% CI)	
Serum albumin < 3.5 g/dL	< 0.001	0.001	5.446 (2.004-14.798)	2
Alpha-fetoprotein, baseline > 200 ng/ml	0.026	0.001	5.071 (1.949-13.196)	2
Three or more tumors	0.012	0.029	2.933 (1.116-7.706)	1
First order branch portal vein thrombosis	0.008	0.032	4.915 (1.147-21.066)	2
Hepatic vein invasion	0.014	0.003	8.500 (2.051-35.226)	3
No DCP response at 3 months	< 0.001	< 0.001	15.346 (4.424-53.235)	5
Progression by mRECIST criteria at 3 months	0.004	0.008	4.154 (1.453-11.872)	1

Cohorts	Time points after TARE	Total patients	Mortality	AUC (95% CI)	P value
Training	at 6 months	113	9 (8.0)	0.845 (0.684-1.000)	0.002
	at 9 months	102	12 (11.8)	0.868 (0.728-1.000)	0.001
	at 12 months	92	17 (18.5)	0.886 (0.797-0.975)	< 0.001
Validation	at 6 months	35	11 (31.4)	0.901 (0.767-1.000)	0.005
	at 9 months	32	15 (46.9)	0.818 (0.609-1.000)	0.017
	at 12 months	32	18 (56.2)	0.737 (0.516-0.958)	0.074

Conclusion: Our new predictive model can be used to stratify different prognoses for patients with HCC treated with TARE. Further validation from a large cohort is required.

FRI-488

Prognostic value of tumor markers after a complete response to transarterial chemoembolization in patients with recurrent hepatocellular carcinoma following curative resection

Jae Seung Lee[1], Mi Young Jeon[1,2], Tae Seop Lim[1,2], Beom Kyung Kim[1,2,3], Jun Yong Park[1,2,3], Do Young Kim[1,2,3], Sang Hoon Ahn[1,2,3], Kwang-Hyub Han[1,2,3], Seung Up Kim[1,2,3]. [1]*Yonsei University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South;* [2]*Severance Hospital, Yonsei Liver Center, Seoul, Korea, Rep. of South;* [3]*Yonsei University College of Medicine, Institute of Gastroenterology, Seoul, Korea, Rep. of South*
Email: ksukorea@yuhs.ac

Background and aims: The Prognostic values of alpha-fetoprotein (AFP) and des-gamma-carboxy prothrombin (DCP) are well-known. We investigated the prognostic contribution of tumor markers in patients who achieved a complete response (CR) to trans-arterial chemoembolization (TACE) for recurrent hepatocellular carcinoma (HCC) following complete resection.
Method: Between 2004 and 2017, 316 patients achieved a CR, based on the modified RECIST criteria, after repeated TACE for recurrent HCC following curative resection. Cox's regression analysis was performed to identify prognostic factors for overall survival (OS).
Results: The median age of the study population (269 males and 47 females) was 59.6 years. During the follow-up period, from the time of achieving a CR after TACE, the mean OS was 84.6 months, with 131 (41.5%) deaths occurring, and the mean PFS was 30.1 months, with 255 (80.7%) cases of recurrence. Of the total cohort, 265 (83.9%) and 42 (13.3%) patients obtained a CR at the first and the second TACE treatments, respectively. The AFP and DCP levels at the time of CR (median 4.8 ng/ml and 23.0 mAU/ml, respectively) both exhibited a linear relationship with OS in univariate Cox analysis (p = 0.040 and 0.009, respectively). Patients with elevated AFP (> 20 ng/ml, 58 [19.7%]) or DCP (> 40 mAU/ml, 47 [22.9%]) exhibited significantly low OS than those with normal values (86.5 vs. 71.3 months, P = 0.045 for AFP; 91.8 vs. 45.6, P < 0.001 for DCP, respectively). In a multivariate analysis, DCP at the time of CR was significantly predictive of mortality (hazard ratio [HR] = 2.646, P < 0.001), whereas AFP at the time of CR was not significantly predictive (p = 0.488). Two other variables exhibited only a tendency to be predictive; the time interval between the liver resection and the first following TACE (HR = 0.986, P = 0.053) and achieving CR after more than three TACE treatments (HR = 2.902, P = 0.050).

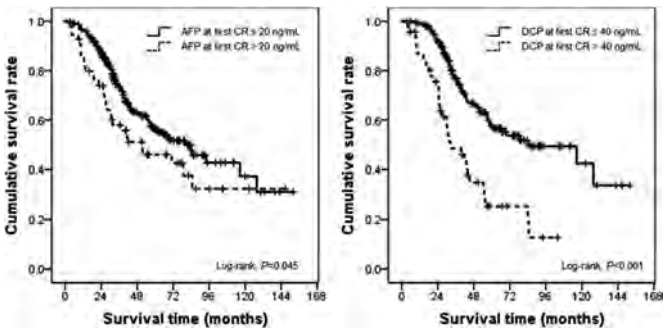

Figure: Kaplan-Meier analyses for overall survival of the patients with elevated tumor markers at the time of achieving CR.

Conclusion: The DCP level at the time of achieving a CR to TACE for recurrent HCC following curative resection was independently predictive of mortality. Thus, for a more refined risk stratification, not only radiological evaluation based on mRECIST criteria, but also the DCP response must be considered.

FRI-489

Downstaging by 90-yttrium radioembolization of unresectable locally advanced hepatocellular carcinoma: A single center experience

Carolina Martelletti[1], Margherita Diotallevi[1], Amedeo Calvo[2], Nadia Russolillo[3], Alessandro Ferrero[3], Rodolfo Rocca[1], Marco Tabone[1]. [1]*Mauriziano Hospital, Division of Gastroenterology, Torino, Italy;* [2]*Mauriziano Hospital, Vascular and Endovascular Surgery Unit, Torino, Italy;* [3]*Mauriziano Hospital, Department of Surgery, Torino, Italy*
Email: martelletticarolina@gmail.com

Background and aims: Only one third of patients may benefit of potentially curative treatments at the time of their first diagnosis due to advanced disease. Tumor downstaging by loco-regional treatments may change unresectable HCC into a resectable tumor, providing the best chance of survivals. Increasing literature evidences suggest a role for radioembolization in downstaging locally advanced hepatocellular carcinoma.
Method: From june 2011, we treated all the patients with first diagnosis of unresectable hepatocellular carcinoma and portal vein thrombosis with 90-yttrium resin microspheres (Sir-Spheres®-Sirtex Europe) intrahepatic iniection with the aim to rescue them to a curative surgical treatment. A 3-years enrollment period and a 5-years follow-up were planned in order to adequately investigate survivals.
Results: Among the 24 enrolled patients (87% males, mean age 70 years) following radioembolization, 5 patients (group1) became eligible to surgical treatment, 8 patients (group 2) obtained partial response or stable disease without achieving eligibility for surgical treatment, while 11 patients (group 3) showed progression of HCC despite radioembolization. High tumor absorbed radiation doses (454 ± 157 Gy vs 248 ± 144 and 138 ± 63 respectively, p = 0.005) and low serum AFP levels (53 ± 86 ng/ml vs 1447 ± 2337 and 4603 ± 8619 p = 0.05) were the only variables significantly associated to successful downstaging of tumor. Median survivals were 70 ± 30, 24 ± 14 and 11 ± 4 months in the three groups respectively. No significant side effects were registered.
Conclusion: In our institution, after radioembolization about 20% of unresectable locally advanced hepatocellular carcinoma have been rescued to surgery This sequential strategy has provided long survivals otherwise impossible with an excellent safety profile.

FRI-490

The real world practice of systemic therapies in patients with advanced hepatocellular carcinoma in Japan: what has changed since lenvatinib approval?

[1]*Graduate School of Medicine, Chiba University, Department of Gastroenterology, Chiba, Japan;* [2]*Asahi General Hospital, Department of Gastroenterology, Chiba, Japan;* [3]*Nippon Medical School, Chiba Hokusoh Hospital, Department of Gastroenterology, Chiba, Japan;* [4]*Kimitsu Chuo Hospital, Department of Gastroenterology, Chiba, Japan;* [5]*Funabashi Municipal Medical Center, Department of Gastroenterology, Chiba, Japan;* [6]*National Hospital Organization Chiba Medical Center, Department of Gastroenterology, Chiba, Japan;* [7]*Matsudo City General Hospital, Department of Gastroenterology, Chiba, Japan*
Email: sadahisa@me.com

Background and aims: Lenvatinib, the third tyrosine kinase inhibitor (TKI) after sorafenib and regorafenib, has been used in the treatment of advanced hepatocellular carcinoma (HCC) in Japan since March 2018. We attempted to investigate the latest treatment of TKIs in

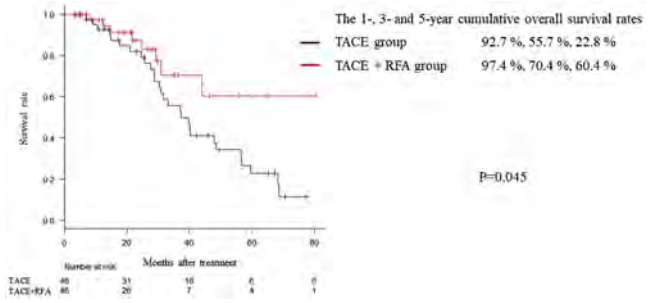
patients with advanced HCC from Japanese field practice and clarify the clinical issues of the era of "multi TKIs."
Method: Between March 26, 2018 (the date of lenvatinib approval) and the end of August 2018, we retrospectively collected data on advanced HCC patients who were administrated TKI (sorafenib, lenvatinib, or regorafenib) as the first-line systemic therapy and were then converted to TKI after the other (i.e., second or later lines) from 7 Japanese institutions. Radiological assessments were evaluated according to both the Response Evaluation Criteria in Solid Tumors (RECIST) and the modified Response Evaluation Criteria in Solid Tumors (mRECIST).
Results: A total of 104 patients received TKI therapy, of which 86 were men (83%), and the median age of the patients was 72 years. The most frequent etiology was hepatitis C virus (44%), followed by hepatitis B virus (14%), and alcohol abuse (27%). Of the 66 patients administrated with TKI as the first-line treatment of systemic chemotherapy, 47 (71%) were treated with lenvatinib. Among the patients who started TKIs as the first-line, the overall response rate (ORR) according to mRECIST was 43% for lenvatinib and 5% for sorafenib and that according to RECIST was 19% and 5%, respectively. The decreasing rate of α-fetoprotein value of ≥ 20% in these patients was 44% in lenvatinib and 23% in sorafenib. Of the 38 patients who received TKI as the second-line or later treatment, 17 patients (45%) were administered lenvatinib and 18 (48%) sorafenib. The ORR according to mRECIST in the second-line or later cohort was 45%. Regorafenib was administrated in 17 patients in this study (1 patient after lenvatinib and sorafenib, and 16 patients after sorafenib). Of 104 patients, 49 patients (47%) used ≥ 2 TKIs and 22 patients (21%) used 3 TKIs by the end of the observation period.
Conclusion: Lenvatinib has become the first alternative drug in the front line for advanced HCC patients in Japan. Since the ORR of lenvatinib in the first-line and second- or later lines patients were almost equal, lenvatinib may have a potential for use as not only the first-line drug but also as the second- or later-lines drug. "Using up all TKIs in patients' clinical courses" may be the treatment strategy during the era of "muti-TKIs" in patients with advanced HCC, although 21% of patients received all 3 TKIs by the end of the observation period.

FRI-492
Long-term outcome according to initial treatment modality in multiple hepatocellular carcinoma within the Milan criteria
Joo Hyun Oh[1], Dong Hyun Sinn[1], wonseok Kang[1], Geum-Yon Gwak[1], Yong-Han Paik[1], Joon Hyeok Lee[1], Kwang Cheol Koh[1], Seung Woon Paik[1], Moon Seok Choi[1]. [1]*Samsung medical center, Department of medicine, Seoul, Korea, Rep. of South*
Email: drms.choi@samsung.com

Background and aims: Although surgical resection is usually considered for a single tumor, several reports suggested that resection can be considered for multiple tumors and may provide a better outcome. We analyzed whether resection can provide a better long-term outcome for patients with multiple hepatocellular carcinomas (HCCs) within the Milan criteria.
Method: A total of 276 consecutive patients with multiple HCCs within Milan criteria and had preserved liver function, defined by Child-Pugh class A, who underwent resection (n = 48), radiofrequency ablation (RFA) (n = 87) or transarterial chemoembolization (TACE) (n = 141), as an initial treatment, between January 2009 and December 2013 were analyzed. Propensity score matching was conducted based on tumor size, tumor number, and ALBI grade (n = 138).
Results: The 5-year overall survival (OS) (93.7%, 68.1%, 59.4%, p < 0.001) and recurrence-free survival (RFS) (58.5%, 19.6%, 7.5%, p < 0.001) was better in resection group than RFA or TACE group. In multivariable analysis, initial treatment modality was independent factor associated with OS and RFS. However, patients who underwent resection had more preserved liver function and had different tumor characteristics compared to those received RFA or TACE. With similar baseline characteristics generated in the propensity score model, there was no significant difference in 5-year OS in patients who received resection and RFA (93.4% vs. 84.5%, p = 0.30), but better OS than TACE (61.6%, p = 0.001). The 5-year RFS was better for patients who received resection than RFA or TACE (59.3%, 24.5%, and 7.2%, respectively, p < 0.001).
Conclusion: Our findings suggest that resection can provide better long-term outcome than RFA or TACE in multiple HCC patients within the Milan criteria, indicating that resection can be considered as a first-line option if selected appropriately.

FRI-493
Efficacy of combination therapy with transcatheter arterial chemoembolization and radiofrequency ablation for intermediate-stage hepatocelluar carcinoma
takuya okamoto[1], kei endo[1], Yasuhiro Takikawa[1]. [1]*Iwate Medical University School of Medicine, Division of Hepatology, Department of Internal Medicine, morioka, Japan*
Email: watertankman2n@gmail.com

Background and aims: Transcatheter arterial chemoembolization (TACE) is the standard therapy for patients with intermediate-stage hepatocellular carcinoma (HCC). With development of systemic chemotherapy, TACE might be limited to cases that require radical treatment. However, TACE is not regarded as a curative treatment; therefore, addition of radiofrequency ablation (RFA) to TACE (TACE +RFA) might gain importance in clinic. However, the efficacy of TACE +RFA for intermediate-stage HCC remains unclear, due to highly diverse patient characteristics. This retrospective cohort study aimed to determine whether combination therapy with RFA and TACE was superior to TACE monotherapy for intermediate-stage HCC and identify cases in which this technique was the most effective.
Method: We selected patients with Barcelona Clinic Liver Cancer classification (BCLC) intermediate (BCLC-B) stage HCC who met the following eligibility criteria: (1) ≥ 20 years of age, (2) receiving initial therapy, (3) ≤ 7 tumors, and (4) maximum tumor diameter < 5 cm. In order to avoid selection bias, we excluded patients with HCC having more than 8 tumors or maximum diameter exceeding 5 cm. We performed propensity score matching (PSM) using potential confounding factors (e.g. age, sex, Child-Pugh score, maximal tumor size, tumor number, AFP, PIVKA-II, and etiology of chronic liver) All subsequent analysis was performed post propensity score matching. We retrospectively compared the cumulative overall survival rate and recurrence-free survival rate between the TACE+RFA and TACE groups. The study complied with the provisions of the Declaration of Helsinki and was approved by the Ethics Committee of our institution.
Results: Among the 103 patients, 92 were selected using PSM. The cumulative overall survival rates at 1, 3 and 5 years for the TACE+RFA group were 97.4%, 70.4% and 60.4%, respectively, which were significantly higher than those for the TACE group (92.7%, 55.7% and 22.8%, respectively, p = 0.045). The recurrence-free survival rates at 0.5, 1 and 2 years for the TACE+RFA group were 80.0%, 58.6% and 33.3%, respectively, which were significantly higher than those for the TACE group (34.5%, 8.8% and 2.9%, respectively, p < 0.01). The multivariate analysis identified AFP ≧100 (hazard ratio, 2.40; 95% CI, 1.28-5.90; p = 0.009) and TACE group classification (hazard ratio, 2.47; 95% CI, 1.11-5.49; p = 0.03) as independent risk factors predicting mortality. For the sub-group with α-fetoprotein (AFP) < 100 ng/ml, the TACE+RFA group demonstrated a significantly improved prognosis than the TACE group (p = 0.036).



Conclusion: Addition of RFA to TACE demonstrated a significantly improved prognosis and recurrence-free survival compared to TACE monotherapy in patients with intermediate HCC, and is recommended in cases with maximum tumor diameter < 5 cm, tumor number < 8, and AFp < 100.

FRI-494

Practice patterns and outcomes of transarterial chemoembolization in patients with hepatocellular carcinoma who were ineligible and eligible for transarterial chemoembolization at inclusion: Global OPTIMIS exploratory analysis

Markus Peck-Radosavljevic[1,2], Han Chu Lee[3], Masatoshi Kudo[4], Keiko Nakajima[5], Inga Bayh[6], Ann-Lii Cheng[7], Jean-Luc Raoul[8].

Email: markus@peck.at

Background and aims: Transarterial chemoembolization (TACE) is used to treat unresectable hepatocellular carcinoma (HCC) and is often administered outside of the recommended guidelines. It is critical to assess patient (pt) eligibility prior to TACE and to assess pts after TACE failure to ensure eligibility for subsequent effective therapies. Here we report results from an exploratory analysis of practice patterns and outcomes in TACE-ineligible and TACE-eligible pts.

Method: OPTIMIS was an international, prospective, non-interventional study evaluating pts with unresectable HCC for whom a decision to treat with TACE was made at study entry. In this analysis, TACE ineligibility was defined according to our study protocol-specified criteria based on international guidelines and consensus. Radiological tumour response was determined by investigator assessment. Liver function deterioration was determined in pts with available laboratory values.

Results: Globally, 1650 pts received TACE, including 636 pts (39%) who were TACE ineligible at inclusion. Of those, both extrahepatic spread and portal vein thrombosis were present in 19% of pts. In TACE-ineligible pts, the median time from first TACE to discontinuation was 1.2 months and 47% of pts only received 1 TACE, while 4% received ≥ 6. Complete response (CR), partial response (PR) and progressive disease (PD) rates to first TACE were 8%, 25% and 23%, respectively. After first TACE, chronic deterioration of bilirubin and albumin (CTCAE grade worsening 31-90 days post TACE) was noted in 15% and 38% of pts, respectively. Overall survival (OS) from the time of first TACE was 16.3 months in TACE-ineligible pts. At inclusion, 1014 pts (61%) were TACE eligible. In TACE eligible pts, the median time from first TACE to discontinuation was 4.2 months and 34% of pts only received 1 TACE, while 10% received ≥ 6. CR, PR and PD rates to first TACE were 17%, 27% and 16%, respectively. Chronic bilirubin and albumin deterioration after first TACE was noted in 9% and 25% of pts, respectively. OS from first TACE was 40.1 months in TACE-eligible pts.

Conclusion: These results indicate that a considerable number of pts with HCC in real-world practice are treated with TACE despite not being adequately indicated. Median OS was 16.3 and 40.1 months in TACE-ineligible and TACE-eligible pts, respectively. These data also highlight the importance of careful pt selection for TACE.

FRI-495

Post transarterial chemoembolization fever can predict poor survival in patients with TNM stage I hepatocellular carcinoma

Chien-Wei Peng[1,2], Wei Teng[1,2], Yi-Chung Hsieh[1,2,3], Rachel Wen-Juei Jeng[1,2,3], Chien-Hao Huang[1,2,3], Kar-Wai Lui[3,4], Chen-Fu Hung[3,4], Yi-Cheng Chen[1,2,3], Chen-Chun Lin[1,2,3], Chun-yen Lin[1,2,3], Shi-Ming Lin[1,2,3], I-Shyan Sheen[1,2,3]. *[1]Chang Gung Memorial Hospital, Liver Research Unit, Taipei city, Taiwan; [2]Chang Gung Memorial Hospital, Linkou branch, Department of Gastroenterology and Hepatology, Taoyuan city, Taiwan; [3]Chang Gung University, Taoyuan city, Taiwan; [4]Chang Gung Memorial Hospital, Linkou branch, Department of Radiology, Taoyuan city, Taiwan*
Email: rachel.jeng@gmail.com

Background and aims: Transarterial chemoembolization (TACE) is the standard of care for intermediate stage hepatocellular carcinoma (HCC) patients. The post-embolization fever (PEF), occurred within 3 days after TACE, is observed in 20-73% patients. However, whether PEF is a predictor of poor survival after TACE is still controversial. Thus, we aimed to investigate the clinical significance of PEF on survival in different TNM stages HCC patients.

Method: From January 2010 to January 2016, a total of 820 patients were enrolled into analysis after exclusion of patients with Barcelona Clinic Liver Cancer (BCLC) stage D, TNM stage IV, double cancers, tumor rupture, adjuvant therapy with operation or ablation, combined other cancer treatments, and lost follow-up after first or second TACE. Survival analysis was performed with Kaplan-Meier curve and log rank test. Cox regression analysis was applied for predictors of survival after first TACE and logistic regression analysis for risk factors of PEF. Statistical analysis was done by the SAS software, version 9.4 (SAS institute, Inc., Cary, NC, USA).

Results: Patients in TNM stage I, II and III were 225, 335 and 260 respectively. The two-year overall survivals between PEF and non-PEF patients were 67.87% vs. 84.11% (p = 0.006), 72.62% vs. 76.76% (p = 0.144), 43.81% vs. 48.96% (p = 0.301), 73.32% vs. 58.11% (p < 0.001) in groups of TNM stage I, II, III and all patients. TNM stage III (adjusted HR: 2.360, P < 0.001), infiltrative type HCC (adjusted HR: 2.446, P < 0.001), higher N/L ratio (adjusted HR: 1.115, P < 0.001), ALBI grade≧2 (adjusted HR: 1.384, P = 0.037) and AFP level≧20 ng/ml (adjusted HR: 1.748, P < 0.001) were independent predictors for overall survival in all patients by the Cox regression analysis. In patients of TNM stage I, PEF (adjusted HR: 2.663, P = 0.016), WBC < 4000/uL (adjusted HR: 0.285, P = 0.014), and higher N/L ratio (adjusted HR: 1.295, P = 0.004) ratio were independent predictors for survival. Only tumor size≧5 cm (adjusted OR: 3.691, P = 0.001) was independent predictor for PEF in TNM stage I HCC patients.

Conclusion: HCC Patients have poor two-year overall survival if PEF presence after 1st TACE treatment. A significant impact of PEF on survival was only observed in TNM stage I HCC patients but not in stage II nor III. PEF, WBC count and high N/L ratio are independent predictor for survival in TNM stage I HCC patients receiving TACE. Larger tumor size can predict occurrence of PEF in TNM stage I HCC patients.

CIBERehd, Gastroenterology and Hepatology, Madrid, Spain; [4]Hospital Universitario Ramón y Cajal. CIBERehd, Gastroenterology and Hepatology, Madrid, Spain; [5]Hospital Universitario La Paz. CIBERehd, Gastroenterology and Hepatology, Madrid, Spain*
Email: joseluis.calleja@uam.es

Background and aims: There is still controversy about the effect of Direct Acting Antivirals (DAA) on the early recurrence of Hepatocellular Carcinoma (HCC) in patients with complete response. The objective was to analyze the recurrence rate in patients with HCC who have received DAA and compare it with a control group who did not received antiviral treatment.

Method: Retrospective, observational and multicentric study in 5 tertiary hospitals in Madrid. Patients were selected from the Registry of Use of Antiviral Agents for HCV of Sermas (RUA-HCV) from November 2015-April 2016, all patients with HCC treated with surgery or ablation in complete response with at least 1-year of follow-up from the beginning of the DAA (Cohort A) and was compared with a consecutive historical group in the same centers that did not receive antiviral treatment (Cohort B). Clinical, oncological and radiological baseline and follow-up data were collected during DAA until the last visit in their clinical history.

Results: We analyzed 665 patients treated with DAA registered in RUA-HCV. Finally, Cohort A, included 76 patients, mean age 66 years (SD9.2), males 57.9%, HIV co-infection 5.8%, diabetes mellitus 27.6%. BCLC 0: 28.9%, A: 65.8%, B: 5.3%. In control group, 57 patients with no antiviral treatment were included, mean age 65.3 (SD12.8), males 73.7%, HIV co-infection 16%, diabetes mellitus 31.6%. BCLC 0: 12.3%, A: 82.5%, B: 5.3%. The median follow-up from the beginning of DAA was 15 months and 25 months in control group. There were no statistically significant differences between recurrence at 3, 6, 12 and 18 months in Cohort A/B: 9.2%/3.5%, 15.8%/19.2%, 30.2%/29, 8%, 38.1%/38.5%, despite the fact that all patients in cohort A obtained a sustained viral response. In Cohort A, a higher recurrence rate was observed in patients treated in the first 12 months after treatment of HCC compared to those who were treated later (85.2% vs. 24.5%) p = < 0.001. In fact, the cumulative probability of recurrence at 12, 18 and 24 months in patients who started DAA at a time ≤ 12 months compared with those who started > 12 months was 25, 5% vs 0%, 42, 9% vs 3, 1% and 56, 3 vs 34% p = 0.001. A propensity score matching was made, not observing changes in the previously obtained results.

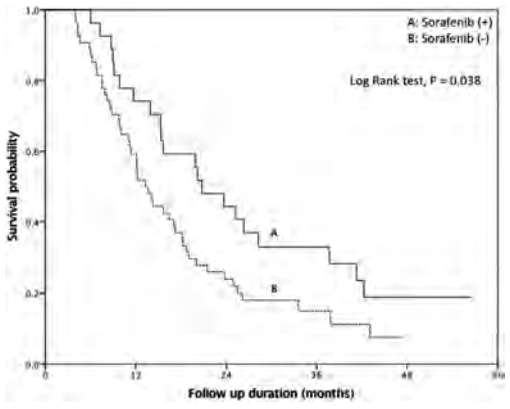
Conclusion: There was no significant differences in terms of recurrence between patients treated with DAA and untreated. However, those patients treated at a time £ 12 months after complete response of HCC treatment showed a significantly higher recurrence than those treated at least 1 year after obtaining the complete response to the HCC.

FRI-497

Shifting to sorafenib is beneficial for hepatocellular carcinoma patients with transarterial chemoembolization refractoriness: A real world experience

Lin Po-Ting[1], Rachel Wen-Juei Jeng[1,2], Yi-Chung Hsieh[1,2], Wei Teng[1,2], Chen-Fu Hung[2,3], Chien-Hao Huang[1,2], Kar-Wai Lui[2,3], Yi-Cheng Chen[1,2], Chen-Chun Lin[1,2], Chun-Yen Lin[1,2], Shi-Ming Lin[1,2], I-Shyan Sheen[1,2]. *[1]Department of Gastroenterology and Hepatology, Chang Gung Memorial Hospital, Linkou branch, Taiwan, Taoyuan, Taiwan; [2]College of Medicine, Chang Gung University, Taiwan, Taoyuan, Taiwan; [3]Department of Radiology, Chang Gung Memorial Hospital, Linkou branch, Taiwan, Taoyuan, Taiwan*
Email: chunyenlin@gmail.com

Background and aims: Transarterial chemoembolization (TACE) is the standard of care for intermediate stage hepatocellular carcinoma (HCC) patients. However, about more than one-third of the patients experience disease in progression post TACE treatment. Sorafenib is the first systemic therapy that shows significant survival benefit in advanced HCC. This study was aimed to investigate whether shifting to sorafenib be beneficial for those experienced TACE refractoriness.
Method: From 2005 to 2016, a total of 656 treatment-naive HCC patients receiving TACE treatment in Chang Gung Memorial Hospital, Linkou medical center were recruited. Based on Japan Society of Hepatology guidelines, we defined TACE refractoriness as progressive disease after two consecutive of TACE treatment within six months. Pre-TACE status including baseline characteristics, tumor staging, tumor burden, and parameters for liver function evaluation were analyzed. All the variables were compared between patients with and without TACE refractoriness.
Results: Among the 656 patients, the median age was 62.5 (27.3-91.5) years old, and 74.5% were male. TACE refractoriness events were documented in 202 patients (30.8%). Patients with advanced tumor stage, tumor number, tumor size, higher alpha-fetoprotein (AFP) level, fever episode after 1st TACE, and elevation of alpha-fetoprotein as well as Child-Turcotte-Pugh score were prone to encounter TACE failure. Multinomial logistic regression analysis revealed that tumor size more than 5 cm, baseline alpha-fetoprotein level more than 200 mg/dl, increase of AFP level more than 20%, and elevation of Child-Turcotte-Pugh score by 2 points between 1st and 2nd TACE were the independent predictive factors for TACE refractoriness. Patients with TACE refractoriness were prone to experience tumor metastasis (42.6% vs. 22.5%, $p < 0.001$) and to have higher mortality rate (5-years: 87% vs. 69%, $p < 0.001$). After documenting TACE refractoriness, patients were either shifting to sorafenib treatment (13.4%) or continuing TACE treatment/best supportive care (78.2%). After one-to-two propensity score matching for these two groups, patients shifting to sorafenib therapy had significantly longer median survival than continuing TACE treatment/best supportive care (20.8 [14.4-27.2] months vs. 13.3 [10.8-15.8] months, $p = 0.038$), though the progression-free survival was similar (9.0 [5.2-10.8] months vs. 6.2 [8.2-17.2], $p = 0.121$).



Conclusion: The incidence of TACE refractoriness was 30.8%. Tumor size, baseline AFP level and Child-Turcotte-Pugh score were good predictors for TACE refractoriness. For patients with TACE refractoriness, shifting to sorafenib gave better survival benefit than continuing TACE treatment/best supportive care.

FRI-498

A current status of therapeutic choice and feasibility for hepato cellular carcinoma patients over 70 years old

Seoung Yoon Rho[1], Kyung Sik Kim[1], Do Young Kim[2], Hyun Woong Lee[2]. *[1]Yonsei University College of Medicine, Surgery, Seoul, Korea, Rep. of South; [2]Yonsei University College of Medicine, Internal Medicine, Seoul, Korea, Rep. of South*
Email: kskim88@yuhs.ac

Background and aims: Benefit of treatment in hepatocellular carcinoma over 70 years old should be greater than the reduction of survival period or maladjustment due to treatment. Based on these perspectives, we investigated how the detailed treatment of hepatocellular carcinoma in elderly patients and overall survival of each treatment modalities.
Method: From January 2003 to December 2005 and January 2008 to December 2014, the National Cancer Center (NCC) and Korean Liver Cancer Study group (KLCSG) collected 3, 006 clinical datas from HCC patients over 70 years old investigating Korea Central Cancer Registry (KCCR) receords at 54 medical centers in south Korea. Using this data we analyzed current treatment modality and overall survival of each modalities in treating HCC patients over 70 years old.
Results: In Period 2003-2005, there were 578 patients and in period 2008-2014, 2428 patients were analyzed. Transarterial therapy (period 2003-2005 : 49.1%, period 2008-2014 : 44.4%) was the most commonly used treatment modality. Among them, Transarterial chemoembolization (TACE) with gelatin sponge occupied largest proportion (96.1%, 65.6%). In overall survival analysis, surgical resection showed statically significant superiority than other treatment modalities ($p < 0.001$), followed by local ablation therapy and transarterial therapy in both periods. Other modalities showed no statistical differences including no treatment. Among transarterial and chemotherapy, there are no statistically significant differences between transarterial therapy modalities except sorafenib. However, there were no statistically significant differences in propensity score matching for surgical resection, local ablation therapy, and transarterial therapy for relatively early stage lesions.

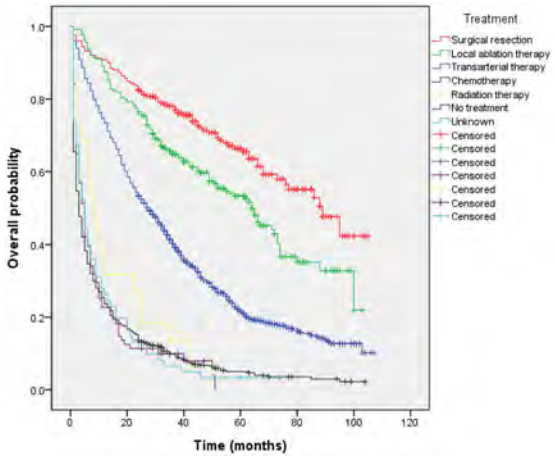


Figure: Overall survival analysis according to treatment modality in Period 2008-2014

In subgroup analysis, there was statistically significant difference between the surgical resection, local ablation therapy, transarterial therapy and the rest of other treatment modalities in the 70-75 year period. However, there was no significant difference between surgical

resection, local ablation therapy, transarterial therapy in the ages of 75-80 years and over 80 years period.
Conclusion: Transarterial therapy was the most commonly used treatment modality in Hepatocellular carcinoma patients over 70 years old. However, surgical resection showed statistically significant superior overall survival rate than other modalities.

Efficacy and hepatic safety of nivolumab treatment in patients with Child-Pugh B disease and advanced hepatocellular carcinoma in CheckMate 040

Bruno Sangro[1], Ana M Matilla[2], Armando Santoro[3], Ignacio Melero[4], Antonio Cubillo Gracian[5], Mirelis Rivera Acosta[6], Su-Pin Choo[7], Anthony El-Khoureiry[8], Ryoko Kuromatsu[9], Bassel El-Rayes[10], Kazushi Numata[11], Yoshito Itoh[12], Francesco Di Costanzo[13], Oxana Crysler[14], María Reig[15], Yun Shen[16], Jaclyn Neely[17], Christine Dela Cruz[16], Carlos Baccan[16], Masatoshi Kudo[18]. *[1]Clinica Universidad de Navarra and CIBEREHD, Pamplona, Spain; [2]Servicio de Digestivo, Hospital General Universitario Gregorio Marañón, Madrid, Spain; [3]Istituto Clinico Humanitas, Rozzano, Italy; [4]Universidad de Navarra, Pamplona, Spain; [5]Hospital de Madrid, Norte Sanchinarro, Madrif, Spain; [6]Fundacion de Investigacion, San Juan, Puerto Rico; [7]National Cancer Center, Singapore, Singapore; [8]USC Norris Comprehensive Cancer Center, Los Angeles, United States; [9]Kurume University Hospital, Fukuoka, Japan; [10]Emory University Winship Center, Atlanta, Georgia; [11]Yokohama City University Medical Center, Yokohama, Japan; [12]Kyoto Prefectural University of Medicine, Kyoto, Japan; [13]AOU Careggi, Florence, Italy; [14]University of Michigan, Ann Arbor, United States; [15]BCLC Group, Liver Unit, Hospital Clinic de Barcelona, CIBEREHD, Barcelona, Spain; [16]Bristol-Myers Squibb, Princeton, United States; [17]Bristol-Myers Suibb, Princeton, United States; [18]Kindai University Faculty of Medicine, Osaka, Japan*
Email: bsangro@unav.es

Background and aims: Most patients (pts) with hepatocellular carcinoma (HCC) are diagnosed at an advanced stage. Pts with Child-Pugh (CP)-B liver function have a poorer prognosis and a historical overall survival (OS) with sorafenib (SOR) of ≈3-5 mo; hence, these pts have a high unmet need for effective and tolerable treatments. Nivolumab (NIVO), a PD-1 inhibitor, is approved in SOR-treated pts with advanced HCC (aHCC) based on data from CheckMate 040 (El-Khoueiry *Lancet* 2017). We present efficacy and hepatic safety data from the CP-B cohort of CheckMate 040, the first prospective immunotherapy study in pts with CP-B aHCC.
Methods: SOR-naïve (n = 25) or -experienced (n = 24) pts with CP-B7-B8 aHCC, with no hepatic encephalopathy or paracentesis within 6 mo or 3 mo of screening, respectively, received NIVO 240 mg IV for 30 min Q2W (flat dose) until unacceptable toxicity/disease progression. The primary end point was objective response rate (ORR) (investigator assessed [INV], using RECIST v1.1). Safety was assessed in all treated pts using NCI CTCAE v4.0.
Results: Median (range) follow-up was 11.8 (6.4-18.0) mo. Of 49 pts analyzed, 28 (57%) had vascular invasion or extrahepatic spread. Baseline CP scores of B7, B8, and A6 were reported in 37 (76%), 11 (22%), and 1 (2%) pt, respectively; 21 (43%) and 8 (16%) pts had HCV or HBV infection, respectively, and 19 (39%) pts had alpha-fetoprotein (AFP) levels ≥ 400 μg/L. INV ORR was 10%, disease control rate (DCR) was 55%, and median duration of response was 9.9 mo; 4 of 5 responders improved from CP-B at baseline to CP-A5 or -A6 status and sustained the improvement for at least 6 mo. Median OS was not reached for pts with a complete/partial response, and was 9.8 mo for pts with stable disease (SD) and 6.8 mo for pts with progressive disease, as best overall response. Serious treatment-related adverse events (TRAEs) occurred in 2 (4%) pts. TRAEs led to discontinuation in 2 (4%) pts. More pts with baseline AFp < 400 μg/L had SD (57%) and a higher DCR (68%) vs those with AFP ≥ 400 μg/L. Comparison data for pts with CP-A aHCC, and additional data by etiology, HBV/HCV viral kinetics, and extended follow-up for pts with CP-B aHCC will be presented.
Conclusion: In pts with CP-B aHCC, NIVO demonstrated promising efficacy and manageable safety, with no new safety signals. Hepatic AEs were manageable and did not lead to high discontinuation rates. Results support further investigation of NIVO as an option for pts with CP-B aHCC.

FRI-500

Sorafenib for recurrent hepatocellular carcinoma after liver transplantation: Intrinsic resistance or not?

Francesco Tovoli[1], Vito Sansone[1], Giovan Giuseppe Di Costanzo[2], Giulia Magini[3], Rodolfo Sacco[4], Tiziana Pressiani[5], Franco Trevisani[1], Raffaella Tortora[2], Laura Bucci[1], Maria Grazia Lucà[3], Luigi Bolondi[1]. *[1]University of Bologna, Department of Medical and Surgical Sciences, Bologna, Italy; [2]Cardarelli Hospital, Department of Transplantation-Liver Unit, Napoli, Italy; [3]Papa Giovanni XXIII Hospital, Gastroenterology and Transplant Hepatology, Bergamo, Italy; [4]Azienda Ospedaliero-Universitaria Pisana, Pisa, Italy; [5]Humanitas Clinical and Research Center, Medical Oncology and Hematology Unit, Rozzano (Milano), Italy*
Email: vito.sansone@studio.unibo.it

Background and aims: the use of sorafenib in patients with hepatocellular carcinoma (HCC) recurring after orthotopic liver transplantation (OLT) may be challenging. Increased toxicity from interaction with immunosuppressants are a common issue. Also, poor outcomes have been reported. However, it has not been investigated whether these outcomes derive from a dire clinical presentation or from a resistance to sorafenib. We aimed to compare the overall survival (OS) of sorafenib-treated post-OLT HCC with that other sorafenib-treated HCCs.
Method: We analyzed a large retrospective-prospective database gathering the clinical data of 487 patients from 6 Italian centres, who were prescribed with sorafenib between 2008 and 2017. Eighteen patients with HCC recurring after OLT were identified. A propensity score analysis comparing their clinical and tumor characteristics with those of 90 matched controls (sorafenib in patients without OLT) was performed. Propensity score included performance status, alfa-fetoprotein > 400 ng/ml, macrovascular invasion, extrahepatic spread.
Results: Characteristics of the OLT patients and matched controls are reported in the Table. Immunosuppressant in OLT patients included: everolimus (n = 10), tacrolimus (n = 4), sirolimus (n = 2), cyclosporine (n = 2). Toxicities were similar in the two groups. The median treatment duration [4.5 months (95%CI 3.0-6.1) vs 5.9 months (95% CI 4.0-7.9), p = 0.344] was comparable as well as the rate of radiologic disease control (44.4 vs 52.5%, p = 0.323). Finally, the OS was also similar [11.5 months (95%CI 9.2-13.8) vs 13.5 months (95%CI 9.7-17.3), p = 0.725] in OLT and non-OLT groups, respectively.

	OLT patients (n = 18)	Sorafenib controls (n = 90)	P
Males	16 (88.9%)	80 (88.9%)	1.000
Age	59 (56–67)	65 (62–74)	0.101
Performance status			
-ECOG-PS 0	14 (77.8%)	71 (78.9%)	1.000
-ECOG-PS 1	4 (22.2%)	19 (21.1%)	
BCLC stage			
-Intermediate	4 (22.2%)	21 (22.2%)	1.000
-Advanced	14 (77.8%)	69 (73.8%)	
Macrovascular invasion	2 (11.1%)	16 (17.8%)	1.000
Extrahepatic spread	13 (72.2%)	65 (72.2%)	1.000
Alfa-fetoprotein > 400 ng/ml	4 (22.2%)	19 (21.1%)	1.000

Conclusion: Extrahepatic spread was common in patients with HCC recurring after OLT, possibly reflecting the negative effects of immunomodulation. However, once sorafenib was started, treatment duration, radiological response and OS were comparable with those of controls. The prognosis of these patients seems to be more influenced by their clinical presentation rather than by a reduced efficacy of sorafenib.

FRI-501

Survival among patients with advanced hepatocellular carcinoma in the pre-TKI versus TKI eras

Miyuki Sensui[1], Sadahisa Ogasawara[1], Yoshihiko Ooka[1], Kazufumi Kobayashi[1], Susumu Maruta[1], Hiroaki Kanzaki[1], Kengo Kanayama[1], Takahiro Maeda[1], Yuko Kusakabe[1], Soichiro Kiyono[1], Masato Nakamura[1], Tomoko Saito[1], Eiichiro Suzuki[1], Shingo Nakamoto[1], Shin Yasui[1], Akinobu Tawada[1], Tetsuhiro Chiba[1], Makoto Arai[1], Tatsuo Kanda[1], Hitoshi Maruyama[1], Naoya Kato[1]. [1]*Chiba University, Graduate School of Medicine, Department of Gastroenterology, Chiba, Japan*
Email: ahta4598@chiba-u.jp

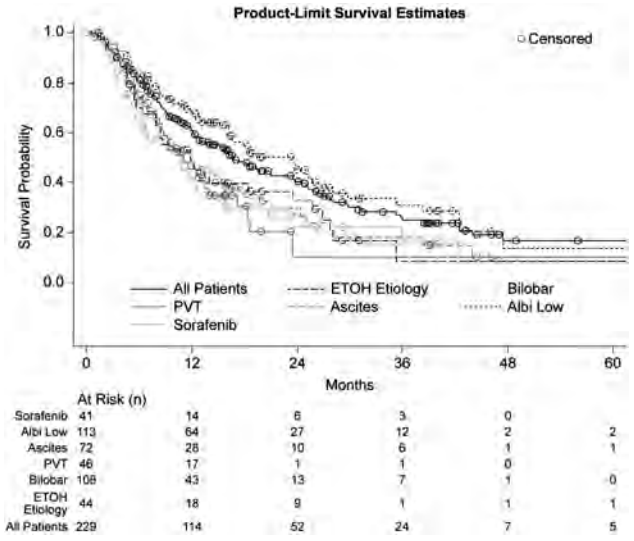
Background and aims: The first multityrosine kinase inhibitor (TKI)—sorafenib—was approved as the standard of care to prolong overall survival (OS) in patients with advanced hepatocellular carcinoma (HCC) in 2009. Until date, several TKIs have been used in field practices. However, it remains unclear how these pharmaceutical innovations affect survival in the real-world setting. Here, we examined the changes in survival between the pre-TKI therapy and TKI therapy periods in advanced HCC patients.
Method: We identified advanced-stage HCC patients from the database of our institution between 2003 and 2016 and divided them into 3 groups: pre-TKI group (2003-2008), first-term TKI group (2009-2012), and second-term TKI group (2013-2016). OS was defined as the time from being diagnosed with advanced-stage HCC to either death from any cause or the date of last follow-up.
Results: A total of 547 patients who were initially diagnosed with advanced HCC were included in this study (pre-TKI group: 121 patients, first-term TKI group: 185 patients, second-term TKI group: 241 patients). Their median age was 69 years (range: 34-87 years), 50% had HCV infection, 19% had HBV infection, and 30% had non-viral infection. The rates of HCV infection decreased and those of non-viral infection increased over time (HCV infection rates: 64.5% [pre-TKI group], 54.1% [first-term TKI group], and 41.5% [second-term TKI group], non-viral infection rates: 16.5% [pre-TKI group], 25.9% [first-term TKI group], and 39.8% [second-term TKI group].
The receiving rates of TKI with pre-, first-, and second-term groups were 3.3, 52.4, and 50.6%, respectively. The OS of the second-term group was significantly longer than that of the other two groups (pre-TKI group: 9.1 months [95%CI 7.2-11.0], first-term TKI group: 8.7 months [95%CI 7.3-10.1], second-term TKI group: 13.3 months [95% CI 9.7-16.9]; p = 0.017). Of the 451 Child-Pugh ≤ 7 patients, who had indication of TKI in field practice generally, the OS of the second-term group was significantly longer than that of the other two groups (pre-TKI group: 9.6 months [95%CI 7.1-12.1], first-term TKI group: 9.8 months [95%CI 7.8-11.8], and second-term TKI group: 14.9 months [95%CI 10.9-18.9]).
Conclusion: Patients diagnosed with advanced HCC during the second-term TKI showed better survival outcomes than those diagnosed during the pre-TKI and first-term TKI. As sorafenib may not be manageable, the first-term TKI group did not show improved OS when compared with the pre-TKI group. Therefore, skillful use of TKI may improve the prognosis of advanced HCC patients.

FRI-502

Factors impacting survival in a large cohort of patients with unresectable hepatocellular carcinoma treated with Y-90 resin microspheres at a single centre

Rucha Shah[1], Sarah Sheikh[1], Jimmy Shah[1], Alejandro Mejia[1], Islam Shahin[1], Parvez Mantry[1]. [1]*The Liver Institute, Methodist Dallas Medical Center, Interventional Radiology, Dallas, United States*
Email: ruchashah@mhd.com

Background and aims: Locoregional treatment of unresectable hepatocellular carcinoma (HCC) with selective internal radiation therapy with Y-90 resin microspheres (Y-90 SIRT) has yielded median overall survivals (OS) of 8.0 to 14.4 months in prospective and retrospective studies of > 100 patients. In a previous study of patients treated at our centre from 2004 to 2013 (n = 111), OS was 13.1 months (Mantry et al. 2017), and we identified several factors associated with longer OS. We have extended this retrospective study to include patients treated through March 2017 in order to examine survival and predictive factors in a larger cohort.
Method: Demographics, disease aetiology and presentation, Y-90 treatment parameters, previous treatments, and OS were abstracted from the charts of patients with unresectable HCC treated with Y-90 SIRT at our facility from April 2004 through March 2017. Patients with incomplete data (< 20% of parameters available) were excluded. OS (from the first Y-90 SIRT treatment to death or last follow-up) was assessed with the Kaplan-Meier method and univariate Cox proportional hazards models.
Results: We analysed data from 229 patients with HCC who underwent 313 SIRT procedures. Most were male (76%) and white (59%); hepatitis C (61%) and alcohol (19%) were the most common aetiologies. Most patients (71%) had a single SIRT procedure, 24% had 2 procedures, and 5% had > 2 procedures; bilobar SIRT was sequential and considered 2 treatments.
Median OS was 16.6 months (95% CI 13.1, –). In a univariate analysis, alcohol aetiology (hazard ratio [HR] 1.5, 95% CI 1.0-2.3); the presence at baseline of bilobar disease (HR 1.9, 95% CI 1.3-2.6), portal vein thrombosis (HR 1.8, 95% CI 1.2-2.8), ascites (HR 1.6, 95% CI 1.1-2.3), and ALBI score (HR 1.5, 95% CI 1.1-2.0); and prior treatment with sorafenib (HR 1.8, 95% CI 1.2-2.7) were among the factors significantly associated with shorter OS (all $p < .04$).
Age, aetiology other than alcohol, and prior treatment other than sorafenib did not significantly affect OS.



Conclusion: In this large, single-centre study, OS after Y-90 SIRT was longer than that reported in many previous studies. Our long duration of experience and high volume of procedures support Y-

90 SIRT as an option for early therapy. Several factors, such as the presence of ascites or bilobar disease at baseline and alcohol as an aetiology, may predict shorter survival. Future analyses will include multi-variable models of predictive factors.

FRI-503

Sorafenib starting dose impacts on survival in the elderly population with hepatocellular cancer

Saur Hajiev[1], David J Pinato[1], Ramya Ramaswami[1], James M Black[1], t arizumi[2], Mario Pirisi[3], m kudo[2], rohini sharma[1]. *[1]imperial college london, london, United Kingdom; [2]Kinki University School of Medicine, Osaka, Japan; [3]Università degli Studi del Piemonte Orientale "A. Avogadro," Novara, Italy*
Email: r.sharma@imperial.ac.uk

Background and aims: There is no consensus on the effect of sorafenib dosing on efficacy and toxicity among elderly patients (> 75years) with Hepatocellular Cancer (HCC). Advancing age is a significant risk factor for HCC, and the effect of sorafenib dosing on the elderly population has not been investigated in large, international studies. We aimed to compare a starting dose of 400 mg/day or less (low dose) with 800 mg/day (full dose) on toxicity and overall survival (OS) in an international multi-center study.
Method: 430 consecutive patients from 5 different international institutions who were treated with sorafenib were included in the study. Baseline demographic data, sorafenib dosing data including toxicities and response to treatment was collected.
Results: Median overall survival (OS) of the entire study population was 7.6months (95% CI: 6.71-8.56). When considering the elderly (n = 145), median OS was significantly lower (7.5 months vs 8.7, log rank p = 0.03). Starting dose had a significant impact on OS such that in patients over 75years receiving 800 mg (n = 103) had a median OS of 7.9months compared to 10.8months in those receiving low dose (n = 42), log rank p = 0.02 (Figure 1). Toxicity was similar between both groups.

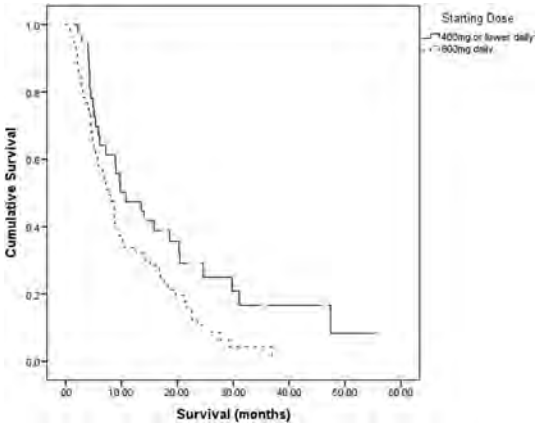


Figure 1: Overall survival in patients over the age of 75 receiving a starting dose of sorafenib of either high dose (800 mg daily) or low dose (400 mg or less), log rank test p = 0.02

Conclusion: Starting dose of sorafenib has a significant impact on OS in patients over the age of 75. Full dose should be used with caution.

FRI-504

Sorafenib use in patients with HCC on a background of non-alcoholic fatty liver disease

Amit Samani[1], David J Pinato[1], Dominik Bettinger[2], David E Kaplan[3], Rohini sharma[1]. *[1]Imperial College, London, United Kingdom; [2]Klinik für Innere Medizin II, Frieburg, Germany; [3]University of Pennsylvania, Philadelphia, United States*
Email: r.sharma@imperial.ac.uk

Background and aims: Fuelled by a rise in obesity and related risk factors, the incidence of non-alcoholic steatohepatitis-related hepatocellular carcinoma (NASH-HCC) is rising. Data pertaining to the utility of sorafenib in this setting is needed, but lacking. We examined the efficacy of sorafenib in a multicentre cohort of patients with NASH-HCC and compared this with currently available data of sorafenib efficacy in other settings.
Method: An international data-set from centres in Europe and USA was prospectively collected on patients with NASH-HCC who had been treated with sorafenib. Kaplan Meier method was used to estimate progression-free and overall survival. Univariate and multivariate analyses by Cox regression were used to identify prognostic factors.
Results: 136 patients were identified across the three centres. The median progression-free survival was 5.03 months (95% CI: 3.78-6.21) and median overall survival (OS) was 7.99 months (95% CI: 6.08-9.91). In a subset with Child-Turcot-Pugh A and Barcelona Clinic Liver Disease B/C disease, the median OS was 8.00 months (95% CI: 5.15-10.84). Univariate analysis identified several significant factors however only CTP and BCLC scores remained significant in multivariate Cox regression.
Conclusion: The median OS of comparable patients with NASH-HCC treated with sorafenib in our study appears lower than historical data from both clinical trial and real-world data sets. In addition, these results suggest that patients with CTP-B/C and BCLC C disease likely derive little benefit from treatment. Prospective data is needed confirm this. As the burden of NASH-HCC continues to increase rapidly, these results will be important for treatment stratification and patient prognostication.

FRI-505

Early response and safety of lenvatinib for patients with advanced hepatocellular carcinoma in a real-world setting

Takuya Sho[1], Goki Suda[1], Koji Ogawa[1], Masato Nakai[1], Kenichi Morikawa[1], Naoya Sakamoto[1]. *[1]Hokkaido University, Sapporo, Japan*
Email: shotaku0128@yahoo.co.jp

Background and aims: Lenvatinib has been recently approved as a first-line systematic therapy for patients with advanced hepatocellular carcinoma (HCC) based on the results of the phase 3 clinical trial REFLECT. However, this trial excluded patients with a history of systemic chemotherapy, bile duct invasion, and low platelet counts. This study aimed to investigate the efficacy and safety of lenvatinib for these patients and in the real-world setting.
Method: Patients who were administered lenvatinib for advanced HCC between April and October 2018 were enrolled. They were followed for more than 2 months, and the treatment response and safety were evaluated via dynamic computed tomography at baseline and 2 months after treatment initiation. Further analysis by stratifying patients according to compliance and non-compliance with the REFLECT inclusion criteria was conducted.
Results: A total of 41 patients were included. More than 50% (23/41) did not meet the REFLECT inclusion criteria. In total, 5 (12.2%), 20 (48.8%), 12 (29.3%), and 4 (9.3%) showed complete response, partial response, stable disease, and progressive disease, respectively. The objective response rate was 61.2%. The objective response rate (p = 0.8293) and disease control rate (p = 0.7965) was similar between patients who did and did not meet the REFLECT inclusion criteria. Moreover, the safety profile was also similar between the patients.
Conclusion: Lenvatinib showed high early response rate and tolerability for patients with advanced HCC. Favorable outcomes were similarly observed even in patients who did not meet the REFLECT inclusion criteria.

Email: tsuchiyakaoru5@gmail.com

Background and aims: Lenvatinib (LEN) has been approved as a single agent for patients with unresectable hepatocellular carcinoma (u-HCC) since Mar 2018 in Japan. We performed a retrospective nationwide multicenter study in Japan, especially focused on the antitumor effect and adverse events in real world practice.
Method: A total of 131 u-HCC patients received LEN from March 2018 at 15 sites in Japan were registered. Tumour assessments in accordance with RECICT ver1.1 and modified RECIST were done using dynamic CT or MRI within 4-8 weeks and every 6-8 weeks thereafter. Adverse events (AEs) were graded according to the CTCAE ver4.0.
Results: Median age was 73 (46-91)years, 102 (77.9%) patients were male, and median body weight (BW) was 60 (30-94) kg. The baseline liver function was Child-Pugh class A in 109 (83.2%) patients. Eighty-two (62.6%) patients were BCLC stage C. As the 2nd-line therapy (after sorafenib), 33 (25.2%) patients received LEN and 19 (14.5%) patients did as the 3rd-line (after regorafenib). Median observation time was 3.0 months and 8 patients died from HCC progression. The imaging findings of 66 (50.3%) patients were evaluated at 4-8weeks. Based on mRECIST, CR was shown in 5 (7.6%), PR in 22 (33.3%), SD in 28 (42.4%), and PD in 11 (16.7%). Overall response rate (ORR)ORR and disease control rate (DCR)DCR of tyrosine kinase inhibitor (TKI) naïve patients (n = 37) were 40.4% and 83.7%, while those of TKI experienced (n = 29) were 41.3% and 82.7%. Fifty-two patients started at 12 mg/day and dose reduction was necessary in 87.0% of the patients. The common any-grade AEs were hypertension (52.2%), diarrhoea (30.9%), decreased appetite (57.4.%), fatigue (51.6%) and proteinuria (41.0%). Hand-food skin reaction (HFSR) was observed in 28.9% of patients. The incidence of decreased appetite and fatigue were higher in the patients with lower BW (< 60 kg), even though the initial dose was based on actual BW.
Conclusion: The efficacy of LEN therapy in real world practice in Japan was equivalent to the phase 3 clinical trial. The response rate in TKI experienced patients was similar to TKI naïve patients. The incidence of HFSR during LEN in real world practice was lower than that of the sorafenib group in the phase 3 trial of LEN. AE profile was different from sorafenib and decreased appetite must be carefully monitored and managed.

FRI-507

Hepatocyte-specific role of c-Jun N-terminal kinase 2 for disease progression and therapy in chronic liver disease

Marius Woitok[1], Miguel Eugenio Zoubek[1], Dennis Doleschel[2], Fabian Kiessling[2], Wiltrud Lederle[2], Christian Trautwein[1], Francisco Javier Cubero[1,3,4]. *[1]Department of Internal Medicine III, University Hospital RWTH Aachen, Aachen, Germany; [2]Institute for Experimental and Molecular Imaging, University Hospital RWTH Aachen, Aachen, Germany; [3]Department of Immunology, Ophthalmology and ORL, Complutense University School of Medicine, Madrid, Spain; [4]12 de Octubre Health Research Institute (imas12), Madrid, Spain*
Email: mawoitok@ukaachen.de

Background and aims: The c-Jun N-terminal kinases (JNKs) play a crucial role in liver physiology and disease pathogenesis by modulating cell death and inflammation. Here, we tested the hypothesis that *Jnk2* specifically in hepatocytes prevents chronic liver disease (CLD) progression and define the potential use of MAPK9 as a new therapeutic target. Therefore, we compared conventional hepatocyte-specific *JNK2* knockdown with disease stage-specific *JNK2* deletion using RNAi in an experimental model of CLD, the $NEMO^{\Delta hepa}$ mice.
Method: Double knock-out mice with hepatocyte-specific deletion of JNK2 and NEMO/IKKγ ($NEMO^{\Delta hepa}JNK2^{\Delta hepa}$, DKO) were generated and CLD progression was examined. *Jnk2* inhibition specifically in hepatocytes using siRNA (*siJnk2*) was first validated *in vitro* and then *in vivo* in wild-type (WT) and in $NEMO^{\Delta hepa}$ mice. *siJnk2* was administered at different CLD stages. Disease activity was analyzed using imaging analysis of fluorescence molecular and microcomputed tomography (FMT, μCT), protein expression, IHC, IF and histopathology.
Results: Twelve-week-old DKO animals showed significantly elevated serum transaminases and deteriorated liver parenchyma, together with immune cell infiltration compared to $NEMO^{\Delta hepa}$ mice and controls. Further, DKO mice display significant increased hepatic stellate cell (HSC) activation markers including αSMA and Col1A1 mRNA expression levels, which was confirmed by Sirius red staining. In contrast, *Jnk2* deletion in aged $NEMO^{\Delta hepa}$ mice caused a significant improvement of HCC development, as observed by reduction of total numbers of tumors. Concomitantly, analysis of specific HCC markers such as TNF-α, AFP, VEGF-B and c-MYC demonstrated significantly improved mRNA expression levels. RNAi for JNK2 specifically in hepatocytes impaired liver function at an early phase of CLD in $NEMO^{\Delta hepa}$ mice. *siJnk2* caused increased liver transaminases, hepatocellular apoptosis and compensatory proliferation. In addition, elevated HSC activation deteriorated hepatic fibrogenesis progression. In contrast, *siJnk2* in aged $NEMO^{\Delta hepa}$ mice (44-52 weeks) resulted in improved liver parenchyma and diminished serum values. In addition, FMT/μCT analysis revealed reduced hepatocellular apoptosis. Moreover, chronic *siJnk2* treatment dramatically reduced HCC formation in 52 weeks old $NEMO^{\Delta hepa}$ mice. This correlated with a reduced presence of premalignant and malignant liver tumors corresponding to dysplastic nodules and differentiated adenomas, respectively.
Conclusion: Progression of liver diseases is associated with different stages of phase transition. Our findings demonstrate a dependent role of JNK2 during CLD progression in $NEMO^{\Delta hepa}$ mice. Notably, formulated *siJnk2* delivery to hepatocytes in the late phase of CLD ameliorated NASH and HCC progression and thus might be an attractive therapeutic option for precision medicine in CLD.

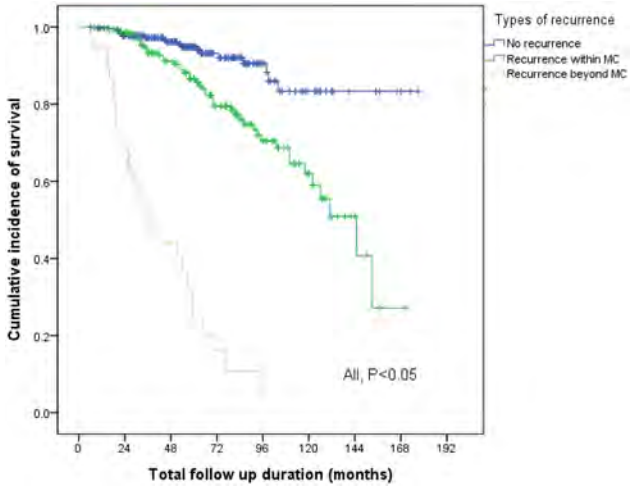
FRI-508

How reliable is initial liver resection before salvage liver transplantation and what are the predictors of dropout?

Soon Ho Um[1], Chung Gyo Seo[1], Sun Young Yim[1,1], Yoo Jin Lee[2], Young Dong Yu[3], Dong Sik Kim[3], Tae Hyung Kim[1], Hyung Joon Yim[1], Ji Hoon Kim[1], Yeon Seok Seo[1]. *[1]Korea University Hospital, Internal Medicine, Division of Gastroenterology and Hepatology, Seoul, Korea, Rep. of South; [2]Korea University Hospital, Pathology, Seoul, Korea, Rep. of South; [3]Korea University Hospital, Hepatobiliary Surgery, Seoul, Korea, Rep. of South*
Email: eug203@naver.com

Background and aims: In the era of liver donor shortage, there is a controversy whether to undergo liver resection or liver transplantation (LT) at early stage HCC. Thus, we aimed to find the rate of HCC recurrence beyond Milan criteria (MC) after liver resection and factors that reliably predict recurrence beyond MC which lead to dropout of salvage LT.

Method: This study included patients diagnosed with HCC within MC at baseline and had liver resection as initial treatment from year 2002 to 2016. In total, 480 patients were enrolled.



Results: Among 480 HCC resected patients, 32.7% patients were in BCLC stage 0, 42.3% of resected HCC showed high Edmonson's grade (III-IV), 22.9% with lymphovascular invasion and 76.9% had liver cirrhosis. All patients were followed up for a median duration of 59 months (range, 6-177). During follow-up, a total of 214 recurrence occurred with 176 (37%) patients recurring within MC and 38 (8%) patients recurring beyond MC. Baseline PIVKA-II level were significantly higher for those who showed recurrence beyond MC 113 mAU/ml (range, 17-13, 622) than those who recur within MC 34 mAU/ml (range, 5-1, 562) ($p < 0.001$). Majority of HCC recurrence beyond MC developed within 2 years with cumulative incidence of 29%, 79% and 95% compared to 21%, 56%, and 88% for those who recur within MC at year 1, 2 and 5 (log rank, $P < 0.01$). Predictors for those who will recur beyond MC that hamper salvage LT were analyzed. In univariate analysis, multiple tumor number (2, 3 vs 1), BCLC stage (A vs 0), high Edmonson grade, lymphovascular invasion, gross finding (multinodular confluent, infiltrative vs. expanding nodular, expending nodular with perinodular expanding type) and high PIVKA level (> 100 mAU/ml) were associated with recurrence beyond MC. In multivariate analysis, high Edmonson grade, lymphovasular invasion, tumor gross findings and high PIVKA level were independent predictive factors of recurrence beyond MC. When scoring was made using the independent factors (score 0: none of the factors, score 1: at least 1 factor and score 2: at least 3 factors), patients with the highest score showed highest cumulative incidence of recurrence beyond MC followed by score 2 and 3 (log rank $P < 0.05$). Survival rate was significantly the lowest in patients that recurred beyond MC followed by within MC and no recurrence group (figure).

Conclusion: Our study involving large number of HCC resected patients showed that early HCC within MC that had low rate of lymphovascular invasion and high Edmonson grade at baseline showed relatively low rate of HCC recurrence beyond MC (8%) which imply that liver resection as first treatment before salvage LT could be more realistic than performing LT as first line in the era of organ shortage. However, those with high risk of recurring beyond MC as mentioned above should undergo salvage LT after liver resection before the development of recurrence.

Validity of urinary bio markers and cardiac echo in diagnosis of acute kidney injury in patients with liver cirrhosis

Ayman El Shayeb[1], Akram Deghady[2], Eman El Sharkawy[3], Marwa Ibrahim[1], Amany Abbasy[1]. [1]*Alexandria, Tropical Medicine, Alexandria, Egypt;* [2]*Alexandria, Clinical and chemical pathology, Alexandria, Egypt;* [3]*Alexandria, Cardiology and Angiology, Alexandria, Egypt*
Email: aymanelshayeb65@gmail.com

Background and aims: Acute kidney injury in liver cirrhosis patients in specific acute tubular necrosis and hepatorenal syndrome carry bad prognosis and hence early recognition of the two entities is crucial. This study was done to test urinary Neutrophil Gelatinase Associated Lipocalin and Trefoil Factor 3 as well as cardiac echo as markers differentiating acute kidney injury aetiologies in patients with liver cirrhosis.

Method: It was conducted in Alexandria University Hospital from September 2017 till June 2018 enrolling 80 patients with liver cirrhosis diagnosed based on clinical, laboratory and ultrasonography divided into four groups. Group I, 20 patients with hepatorenal syndrome, group II, 20 patients with prerenal azotaemia and group III, 20 patients with acute tubular necrosis diagnosed based on the revised consensus recommendations of the International Club of Ascites 2015. Group IV, 20 patients with liver cirrhosis without renal impairment and an additional group V with 20 healthy individuals as controls. Urinary Neutrophil Gelatinase associated Lipocalin and Trefoil Factor 3 were measured by Quantikine® Enzyme Linked Immunosorbent Assay from RandD Systems Minneapolis, MN, USA.

Results: Urinary Neutrophil Gelatinase Associated Lipocalin was significantly higher in patients with acute tubular necrosis, followed by patients with hepatorenal syndrome and prerenal azotaemia followed by patients without renal impairment while urinary Trefoil Factor 3 was significantly highest in patients with acute tubular necrosis without significant difference between the other groups ($p < 0.001$). Cut off values of $\geq$ 14.40 ng/dl and > 28.76 ng/dl were found to differentiate acute tubular necrosis from hepatorenal syndrome with 85% and 90% sensitivity and 70% and 95% specificity for each marker respectively. Moreover, number of patients with diastolic dysfunction was significantly higher in patients with hepatorenal syndrome than acute tubular necrosis ($p < 0.001$). Also, uTFF3 was significantly lower in patients with diastolic dysfunction than those without ($p < 0.001$).

Conclusion: Urinary Neutrophil Gelatinase Associated Lipocalin and Trefoil Factor 3 are potential markers for diagnosing acute tubular necrosis from hepatorenal syndrome. Diastolic dysfunction in patients with liver cirrhosis and acute kidney injury favours diagnosis of hepatorenal syndrome. Lower uTFF3 values could predict development of diastolic dysfunction in patients with liver cirrhosis.

Lusutrombopag is a safe treatment option for thrombocytopenia in patients with chronic liver disease undergoing an invasive procedure: Pooled safety analysis from 3 studies

Nezam Afdhal[1], Robert Brown[2], Namiki Izumi[3], Takeshi Kano[4], Toshimitsu Ochiai[5], Masayuki Kurosaki[3], Francesco Violi[6], Pomy Shrestha[7]. [1]*Beth Israel Deaconess Medical Center, Liver Center, Boston, MA, United States;* [2]*Weill Cornell Medical College, Division of Gastroenterology and Hepatology, New York, NY, United States;* [3]*Musashino Red Cross Hospital, Department of Gastroenterology and Hepatology, Tokyo, Japan;* [4]*Shionogi and Co., Ltd., Global Project Management Department, Osaka, Japan;* [5]*Shionogi and Co., Ltd., Biostatistics Center, Osaka, Japan;* [6]*Sapienza Universita di Roma, Dipartimento di Medicina Interna e Specialità Mediche, Rome, Italy;* [7]*Shionogi Inc., Product Safety and Pharmacovigilance, Florham Park, NJ, United States*
Email: nafdhal@bidmc.harvard.edu

Background and aims: Lusutrombopag (LUSU) is a thrombopoietin receptor agonist (TPO-RA) approved in Japan (2015) and the US (2018) for the treatment of thrombocytopenia (TCP) in patients (pts) with chronic liver disease (CLD) who are scheduled to undergo an invasive procedure. In a pooled analysis of 2 Phase 3 studies, LUSU reduced the need for platelet transfusions (PT) compared to placebo. Treatment with TPO-RAs has been associated with an increased risk of thrombotic events in pts with CLD. Thus, a thorough safety assessment of new agents is critical. A pooled retrospective analysis of 3 clinical studies was performed to assess safety of LUSU.

Method: Safety data from 3 double-blind, randomized, placebo-controlled studies in pts with CLD and TCP undergoing an elective invasive procedure (Phase 2b: M0626, Phase 3: L-PLUS 1 and L-PLUS 2) were pooled. Adult subjects with platelet counts (PC; $x10^9$/L) < 50 at baseline received LUSU 3 mg or placebo (PBO) for up to 7 days before a procedure scheduled 9-14 days after randomization. PT was mandated if the PC remained < 50 immediately prior to procedure. Adverse event (AE) data were collected from signing of informed consent through completion of posttreatment period or early termination.

Category, n (%)	Lusutrombopag 3 mg	Placebo
≥1 AE	112 (65.5)	115 (67.6)
≥1 AE leading to death	3 (1.8)	0
≥1 Serious AE	9 (5.3)	12 (7.1)
≥1 AE leading to withdrawal of study drug	0	1 (0.6)
≥1 treatment-related AE	13 (7.6)	14 (8.2)
≥1 treatment-related serious AE	2 (1.2)	1 (0.6)

AE, adverse event

Results: The pooled safety population included 341 pts (n = 171, LUSU; n = 170 PBO). Approximately 65% of pts in the LUSU and PBO groups experienced an AE (Table). Thrombotic and thromboembolic AEs occurred in 1.8% (3/171) of LUSU pts (cardiac ventricular thrombosis, n = 1 [pt had prior history of cardiac ventricular thrombosis]; portal vein thrombosis, n = 2) and 2.4% (4/170) of PBO pts (mesenteric vein thrombosis, n = 2; portal vein thrombosis, n = 2). Overall, bleeding-related AEs occurred in significantly less LUSU vs

ELSEVIER

PBO pts (15 [8.8%] vs 27 [15.9%]), respectively. The 3 AEs leading to death were not considered treatment-related but due to the progression of underlying or concomitant disease.
Conclusion: In this pooled safety analysis, LUSU was safe and well-tolerated in pts with TCP and CLD undergoing invasive procedures. Approximately 50% fewer bleeding-related AEs were observed in pts treated with LUSU vs PBO.

SAT-003
Real-world data demonstrate safety and effectiveness of lusutrombopag in chronic liver disease patients with thrombocytopenia undergoing planned invasive procedures: Interim analysis

Nezam Afdhal[1], Chikako Shiino[2], Ritsue Sasaki[3], Roy Bentley[4], Bin Cai[5].
[1]Beth Israel Deaconess Medical Center, Liver Center, Boston, MA, United States; [2]Shionogi Pharmacovigilance Center Co., Ltd., Postmarketing Surveillance and Pharmacoepidemiology, Osaka, Japan; [3]Shionogi and Co., Ltd., Pharmacovigilance, Osaka, Japan; [4]Shionogi Inc., Global Market Access, Florham Park, NJ, United States; [5]Shionogi Inc., Global Observational Research, Epidemiology and Health Outcomes, Florham Park, NJ, United States
Email: nafdhal@bidmc.harvard.edu

Background and aims: Lusutrombopag (LUSU) is a thrombopoietin receptor agonist, developed by Shionogi and Co., Ltd. and approved in Japan (2015) and US (2018) for treatment (tx) of thrombocytopenia (TCP) in adult patients (pts) with chronic liver disease (CLD) scheduled to undergo planned invasive procedure. Ongoing post-marketing surveillance (PMS; Oct 2016-May 2021) collects safety and effectiveness data in Japanese clinics. As of Sept 2018, data from 338 pts, including 21 re–tx pts, were analysed for this interim report.
Method: PMS plans to enrol 1, 000 pts and follow them for 2 months (mo) after initial LUSU dose. Pts receiving ≥ 1 re-tx within 6 mo of initial tx are observed for 2 mo from start of each re-tx. This study captures data on adverse events (AEs) occurring during and after tx. Primary efficacy outcome is proportion of pts who do not require pre-operative platelet transfusion (PT).
Results: 334 pts were evaluable for safety (4 excluded: registration violations [n = 2]; overlapping pts [n = 2]) and 318 for efficacy (16 excluded: off-label use [n = 1]; off-indicated dosage/administration [n = 1]; use in unapproved population [Child-Pugh C; n = 14]). Most pts had liver cirrhosis (n = 315, 94%). Mean baseline platelet count (PC)±SD was 46 ± 14×10^9/L (range: 15-110; n = 315). There were 380 procedures in 334 pts, including 110 (28.9%) radiofrequency ablation, 59 (15.5%) transarterial chemoembolisation, and 49 (12.9%) endoscopic injection sclerotherapy. 14 adverse drug reactions (ADRs), including portal vein thrombosis (PVT; n = 4), increased ALT (n = 2), and increased AST (n = 2), were reported in 11 pts (3.3%). 41 serious AEs occurred in 29 pts (8.7%), including hepatic failure (n = 3; 0.9%), hepatic encephalopathy (n = 2; 0.6%), ascites (n = 2; 0.6%), and thrombosis (n = 1 splenic vein, 0.3%; n = 6 PVT, 1.8%); 7 were considered tx-related. Mean time to procedure after starting LUSU was 12.4 days. 282 (93%) of 303 pts without PT refractoriness underwent procedure without PT. After LUSU, mean maximum PC was 89 ± 35×10^9/L (range: 25-352; n = 288); mean maximum change from baseline PC was 42 ± 31×10^9/L (range: –6 to 276; n = 288). In 21 re-tx pts, no ADRs were reported during the observational period; PT avoidance rate was 100%.
Conclusion: Use of LUSU in real-world clinical practice demonstrates the product is safe and effective for CLD TCP pts undergoing planned invasive procedures (consistent with previously reported clinical trial data).

Email: chtriantos@hotmail.com

Background and aims: Bacterial translocation has been associated with increased bacterial infection risk in patients with liver cirrhosis. Endotoxaemia has been considered a critical trigger for variceal bleeding. The aim of the study was to investigate the presence of bacterial translocation in cirrhotic patients with variceal bleeding at admission.
Method: Blood samples were collected before any diagnostic/therapeutic intervention. Lipopolysaccharide (LPS), IgM and IgG antibodies against endotoxin, soluble CD14 and lipopolysaccharide binding protein (LBP) were measured by ELISA for the assessment of bacterial translocation and the Fatty acid-binding protein (I-FABP) for the evaluation of intestinal permeability. Bacterial DNA determination was performed by PCR, using universal 16SrRNA primers.
Results: Forty-one cirrhotics with variceal bleeding [median age: 58 years (range 47.5-66.5), M/F: 33/8, cirrhosis etiology: alcohol/HBV ±HDV/HCV/NASH/other: 24 (58.5%)/4 (9.8%)/7 (17.1%)/4 (9.8%)/2 (4.8%), CP stage A/B/C: 8/26/7)] and 43 stable cirrhotics [median age: 61 (54-65) years, M/F: 30/13, cirrhosis etiology: alcohol/HBV ±HDV/HCV/AH/other: 19 (44.2%)/15 (34.8%)/3 (7%)/3 (7%)/1 (2.2%)/3 (7%), CP stage A/B/C: 22/12/9)] were included. Three patients had overt infection (1 had detectable bacterial DNA) at admission. No statistical difference was observed in the bacterial translocation or intestinal permeability markers between the examined groups of any stage (table 1).

Table 1:

	Variceal bleeders	Stable cirrhotics
CP_A	**Median (IQR)**	
CD14 (pg/ml)	1946.1 (1531-4451)	2255.5 (1443-3120)
LPS (EU/ml)	1.9 (1-3)	2.4 (1-4)
IgM (MU)	33.6 (26-93)	48.2 (28-53)
IgG (MU)	185.1 (161-347)	200.5 (136-287)
LBP (μg/ml)	8.3 (0-13)	4.3 (3-5)
I-FABP (pg/ml)	2795.2 (1364-5250)	1379.5 (1060-1699)
CP_B		
CD14 (pg/ml)	3198.9 (1766-3412)	3121.6 (2008-3892)
LPS (EU/ml)	3.7 (2-19)	2.8 (2-4)
IgM (MU)	38.6 (21-54)	34.9 (31-83)
IgG (MU)	232.4 (175-350)	244.8 (115-563)
LBP (μg/ml)	5.4 (4-9)	4.5 (4-18)
I-FABP (pg/ml)	2247.2 (1771-5128)	1665.1 (665-3996)
CP_C		
CD14 (pg/ml)	3312.3 (2236-3674)	2725.8 (1980-3872)
LPS (EU/ml)	17.6 (2-33)	14.6 (3-35)
IgM (MU)	38.3 (20, 53)	116.2 (96, 129)
IgG (MU)	237.8 (194-603)	318.6 (284-375)
LBP (μg/ml)	1.8 (0-7)	7.8 (5-28)
I-FABP (pg/ml)	2484.8 (1229-4299)	3808.6 (1145-6199)

Conclusion: This study does not support a greater degree of intestinal barrier disintegration, endotoxemia or bacterial translocation in cirrhotics with variceal bleeding compared to stable cirrhotics.

SAT-005

Prognostic factors associated with mortality of acute variceal hemorrhage in cirrhotic patients : Multi-center results

Kuntapon Akkarachinores[1], Sakkarin Chirapongsathorn[2], Pawinee Saybungkla[3]. [1]*Phramongkutklao Hospital, Department of medicine, Bangkok, Thailand;* [2]*Phramongkutklao Hospital, Division of Gastroenterology and Hepatology, Bangkok, Thailand;* [3]*College of Medicine and Phramongkutklao Hospital, Office Research Development, Bangkok, Thailand*
Email: akkarachinores@hotmail.com

Background and aims: Acute variceal hemorrhage is a serious complication in liver cirrhosis associated with high mortality. Thus it is important to determine the risk factors associated with this high mortality.To investigate the risk factors for 5-day and 6-week mortality and rebleeding in acute variceal hemorrhage in cirrhotic patients treated by early vasoactive drugs with endoscopic management

Method: Retrospective study of acute variceal hemorrhage patients who underwent early vasoactive drugs with endoscopic treatment was collected since 1 October 2012 to 30 September 2018 in Phramongkutklao hospital and Maharat Nakhon Sri Thummarat hospital. Demographic information, medical histories, physical examination findings, and laboratory test results were collected. Survival analysis was estimated using the Kaplan-Meier method and compared using the log-rank test. The multivariate analysis was performed using the Cox proportional hazard model to identify independent risk factors for mortality and rebleeding at 5-day and 6-week

Results: Since 1 October 2012 to 30 September 2018 Phramongkutklao hospital 2654 cases of UGIB was EV bleeding 385 cases (14.5%) and Maharat Nakhon Sri Thummarat hospital 3753 cases of UGIB was EV bleeding 760 cases (20.25%) 5-day mortality was 110 (9.6%) and 6-week mortality was 141 (12.33%) out of total 1144 cases which associated risk factors through multivariate analysis composed of MAP < 50 (HR = 2.01, 95%CI:1.18-3.44, *P = 0.011*), and high risk stigmata EV on endoscopic finding (HR = 4.01, 95%CI:2.50-6.44, *P < 0.001*). And one additional risk factor that found only in 6-week mortality was Glasgow Blatchford score ≥ 6 (HR = 34.66, 95%CI:13.88-86.52, *P < 0.001*). Whereas GU and/or DU on endoscopic finding appeared to be protective factors of mortality. 5-day rebleeding was 155 cases (13.6%) and 6-week rebleeding was 244 cases (21.3%) which associated with risk factors through multivariate analysis composed of MELD score ≥ 18 (HR = 2.46, 95% CI:1.76-3.45, *P < 0.001*), Glasgow Blatchford Score ≥ 6 (HR = 2.20, 95% CI:1.19-4.05, *P = 0.012*), high risk stigmata EV on endoscopic finding (HR = 2.02, 95%CI:1.39-2.93, *P < 0.001*), weekend visit (H = 1.33, 95% CI:1.00-1.75, *P = 0.048*), duration of cirrhosis ≥ 2 years (HR1.59, 95% CI:1.06-2.39, *P = 0.025*), antiplatelet (HR = 1.83, 95%CI:1.06-3.17, *P = 0.031*) and NSAIDS use. (HR = 3.39, 95%CI:2.06-5.60, *P < 0.001*).

Conclusion: In this study, strong risk factors associated with 5-day and 6-week mortality in acute variceal hemorrhage were high risk stigmata on endoscopic finding, MAP < 50, and high MELD score accordingly. Additional risk factor in 6-week mortality was Glasgow Blatchford Score ≥ 6. 5-day and 6-week rebleeding risk factors also similar with mortality risk factors which included Glasgow Blatchford Score ≥ 6, antiplatelet and NSAIDS use, duration of cirrhosis and weekend visit.

SAT-006

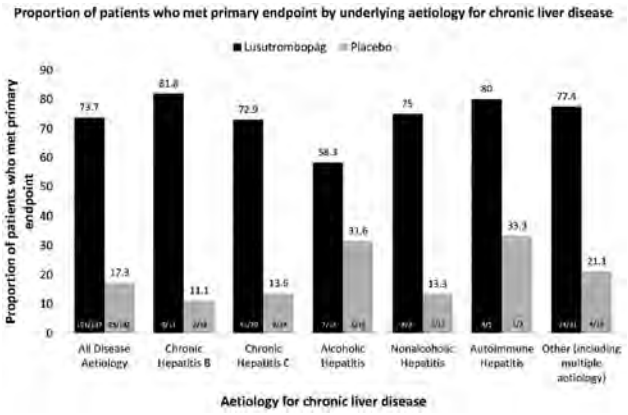
Efficacy of oral thrombopoietin receptor agonist lusutrombopag in chronic liver disease by underlying disease aetiology

Naim Alkhouri[1], Michio Imawari[2], Namiki Izumi[3], Yukio Osaki[4], Toshimitsu Ochiai[5], Roy Bentley[6], Takeshi Kano[7]. [1]*Texas Liver Institute, Department of Metabolic Center, San Antonio, TX, United States;* [2]*Shin-Yurigaoka General Hospital, Institute for Gastrointestinal and Liver Disease, Kawasaki, Japan;* [3]*Musashino Red Cross Hospital, Department of Gastroenterology and Hepatology, Tokyo, Japan;* [4]*Meiwa Hospital, Nishinomiya, Japan;* [5]*Shionogi and Co., Ltd., Biostatistics Center, Osaka, Japan;* [6]*Shionogi Inc., US Global Market Access, Florham Park, NJ, United States;* [7]*Shionogi and Co., Ltd., Global Project Management Department, Osaka, Japan*
Email: alkhouri@txliver.com

Background and aims: Lusutrombopag (LUSU) is an oral thrombopoietin (TPO) receptor agonist that has been approved in Japan (2015) and the US (2018) for treatment of thrombocytopenia (TCP) in patients (pts) with chronic liver disease (CLD) prior to invasive procedures. Certain aetiologies for CLD, such as alcohol abuse, may cause bone marrow suppression and low TPO production. The aim of this pooled analysis was to evaluate the efficacy of LUSU in pts with CLD by underlying disease aetiology.

Method: L-PLUS 1 (Japan) and L-PLUS 2 (global) were similarly designed, Phase 3, multicentre, randomized, double-blind, placebo-controlled studies. Pts with CLD and platelet count (PC) < 50×10^9/L scheduled for an invasive procedure were randomized 1:1 to LUSU 3 mg or placebo (PBO) and dosed orally once daily for up to 7 days. For this analysis, the per-protocol (PP) pt population (defined as all randomized pts with no major protocol violations) was pooled by underlying CLD disease aetiology. The primary efficacy end point was the proportion of pts who required no platelet transfusion (PT) prior to the invasive procedure and no rescue therapy for bleeding from randomization through 7 days post-invasive procedure.

Results: Of the 312 pts randomized, 270 pts were in the PP population (LUSU group: n = 137; PBO group: n = 133). Underlying aetiology for CLD in the PP population was: chronic hepatitis B, 10.7% (29/270); chronic hepatitis C, 47.8% (129/270); alcoholic hepatitis, 11.5% (31/270); non-alcoholic hepatitis, 8.5% (23/270); autoimmune hepatitis, 3.0% (8/270); and other hepatitis or mixed disease aetiology, 18.5% (50/270). The underlying aetiologies for CLD were generally similar between the 2 treatment arms. Overall, 73.7% (101/137) of pts in the LUSU group met the primary end point vs 17.3% (23/133) in the PBO group (difference of proportion, 55.8 [95% CI: 46.6, 65.0]; p < 0.0001). A greater proportion of pts met the primary end point in the LUSU arm vs PBO arm in each disease aetiology group (Figure). The proportion of pts experiencing ≥ 1 adverse event was 61.9% in the LUSU group and 64.5% in PBO group; 6.5% and 9.0% events, respectively, were deemed treatment-related.



Conclusion: Compared to PBO, LUSU was efficacious in avoiding the need for PT in pts with CLD-TCP scheduled to undergo invasive procedures, regardless of underlying disease aetiology.

SAT-007

Survival and risk factors of mortality after emergency transjugular intrahepatic portosystemic shunt for uncontrolled acute variceal bleeding caused by cirrhosis-related portal hypertension

Manon Allaire[1], Aurélie Walter[1], Isabelle Ollivier-Hourmand[1], Cléa Rouillon[1], Olivier Sutter[2], Olivier Seror[3], Roland Amathieu[4], Nathalie Ganne[4], Jean Charles Nault[4], Thong Dao[1]. *[1]CHU Côte de Nacre, Service d'hépato-gastroentérologie et de nutrition, CAEN, France; [2]CHU de jean Verdier, Service de radiologie, Bondy, France; [3]CHU de jean Verdier, Service de réanimation, Bondy, France; [4]CHU de jean Verdier, Service d'hépatologie, BONDY, France*
Email: aurelie.wal@gmail.com

Background and aims: Few data are available regarding the prognosis of covered emergency transjugular intrahepatic portosystemic shunt (TIPS) for refractory variceal bleeding caused by portal hypertension in the era of Baveno V/VI consensus. The aims of this study were to assess survival and identify risk factors of death in these patients.
Method: All patients treated with emergency TIPS for refractory variceal bleeding due to cirrhosis related portal hypertension in two French tertiary centers between 2007 and 2017 were included. 45-days mortality was correlated with clinico-biological data at admission and with dispensed treatments using Kaplan-meier curves with the log-rank test as well uni and multivariate analysis using a Cox Model.
Results: 73 patients were included (80% of men, median age of 56 years old, 94.5% of alcoholic cirrhosis, median MELD at 22 and 43% of ACLF grade 3). All patients were managed according to the Baveno consensus, 73% of patients required vasopressors, 62% oral tracheal intubation and 23% renal replacement therapies. TIPS could not be performed in 1 patient and 8% of patients experienced acute pulmonary edema after TIPS. Rate of TIPS failure (including death or non-control of hemorrhage) at 5 days was 26%. The 45-day mortality was 49% (76% for ACLF grade 3, 91% for lactates > 5mmol/L and 93% for MELD > 30). No patient with an MELD > 30 was alive at 2 months. The causes of death at 45 days were multi-visceral failure (67%), refractory bleeding (22%) and sepsis (8%). In multivariate analysis, the MELD score (OR = 1.09, 95% CI [1.05-1.13], p < 0.001) and renal replacement therapies (OR = 4.5, 95% CI [2.00-10.11], p < 0.001) were independently associated with 45-day mortality. Despite initial antibiotic prophylaxis, 42% of patients developed an in-hospital infection, including 23% of multi-drug resistant bacteria and 18% of yeast. Overall survival was 40% at 2 years. 19% of patients had bleeding recurrence due to portal hypertension and 54% hepatic encephalopathy Type 2 diabetes was associated with the occurrence of hepatic encephalopathy.
Conclusion: After emergency TIPS for refractory acute variceal bleeding, 45-days mortality was 49% and could be predicted by the MELD-score. Early diagnosis and treatment of acute kidney injury and of infections will be useful to improve the prognosis of these patients. Due to the occurrence of rebleeding, implementation of standardized endoscopic and ultrasonographic surveillance should be discussed.

SAT-008

Quality of medical care measurement in hepatic cirrhosis outpatients: Is there room for improvement?

Alberto Amador[1], Silvia Salord[1], Xavier Xiol[1], Valeria Perez-Campuzano[1], Alba Cachero[1], Carme Baliellas[1], José Castellote[1]. *[1]University Hospital of Bellvitge, Gastroenterology and Hepatology department, Hospitalet de Llobregat, Barcelona, Spain*
Email: aamadornavarrete@gmail.com

Background and aims: Sets of indicators have been reported to measure cirrhosis related quality-of-care, and fulfilment of those are important in clinical practice. Adherence to those quality indicators in the few reported studies differs between 40 and 80%. The aims of our study were to assess adherence to cirrhosis-related quality-of-care measurements in outpatients' follow-up and to compare it depending on attendant physician's experience (junior vs senior doctor).
Method: Observational unicentric study. Clinical records of all cirrhotic patients visited during the second semester of 2017 as outpatients have been reviewed. General data, attendant physician's experience and 13 indicators of 5 great domains (cirrhosis aetiology, severity of the disease, hepatocellular carcinoma screening, variceal haemorrhage prophylaxis and vaccinations) have been collected.
Results: Of 591 patients' clinical records reviewed, 324 were included (123 excluded due to absence of cirrhosis, 39 due to liver transplantation, 47 treated from a hepatocellular carcinoma, and 58 not visited at the hospital). Cirrhosis aetiology was reported in 92% of cases, and severity and liver transplant indication in 75% and 78% respectively. Current alcohol consumption was reported in 79%. Updated ultrasonography was performed in 90% of the patients (9% requested but not scheduled, 1% not requested), but only 67% had all biannual ultrasonographies done. Initial upper endoscopy for variceal screening was performed in 97% of the cases, and follow-up endoscopies in 84%. Variceal bleeding prophylaxis was begun in 98% of patients in which was indicated. Beta-blockers dose was reported in 53% of cases, and it was not possible to assess its adequacy in 56%. Regarding vaccination policy, 71%, 49% and 42.9% received HAV, HBV and pneumococcus, respectively. There were significant differences between junior and senior doctors: in patients visited by junior doctors, aetiology, disease severity and beta-blockers dose were reports more frequently. Nevertheless, senior doctors had a better rate of current ultrasonography performed.
Conclusion: Our results could be considered excellent in variceal bleeding prophylaxis, good in hepatocellular carcinoma screening and worse in vaccinations. There were differences according medical experience, with a good quality of care in clinical records done by junior doctors. It is important to know the adherence to quality indicators in order to implement an improvement plan.

SAT-009

Pharmacokinetics of ertapenem in plasma and ascitic fluid in cirrhotic patients with spontaneous bacterial peritonitis

Alberto Amador[1], Sara Cobo[2], Ariadna Padulles[2], Raul Rigo[3], Inmaculada Grau[4], Fe Tubau[5], Albert García-Sumalla[1], Núria Padullés Zamora[2], José Castellote[1]. *[1]University Hospital of Bellvitge, Gastroenterology and Hepatology department, Hospitalet de Llobregat, Barcelona, Spain; [2]University Hospital of Bellvitge, Pharmacy deparment, Hospitalet de Llobregat, Barcelona, Spain; [3]University Hospital of Bellvitge, Clinical LAB department, Hospitalet de Llobregat, Barcelona, Spain; [4]University Hospital of Bellvitge, Infectious disease department, Hospitalet de Llobregat, Barcelona, Spain; [5]University Hospital of Bellvitge, Microbiology department, Hospitalet de Llobregat, Barcelona, Spain*
Email: aamadornavarrete@gmail.com

Background and aims: Spontaneous bacterial peritonitis caused by multidrugs resistant bacteria is a therapeutic challenge and can decrease survival in cirrhotic patients. The exposure of ertapenem in plasma or ascitic fluid in cirrhotic patients is unknown. The aim of our study was to investigate if ertapenem concentrations in plasma or ascitic fluid were above the minimum inhibitory concentrations (MIC) of the main bacteria involved.
Method: Prospective unicentric study of patients with hepatic cirrhosis and nosocomial or health-care related spontaneous bacterial peritonitis. Demographic data and the episode features were recorded. Ascitic fluid and plasma concentrations of ertapenem were

analysed in day 1, 2 and 5 of treatment. Dose of ertapenem used was 1 gr daily. C50 was defined as the concentration above the MIC reached during at least 50% of time of the administration interval (a therapeutic goal in carbapenemics treatment), considering a maximum MIC of 1 mg/L (EUCAST).

Results: Between April 2017 and October 2018, 74 episodes of spontaneous bacterial peritonitis were admitted, and finally 20 episodes met the inclusion criteria. Most of the patients had moderate liver dysfunction measured by MELD and Child Pugh score. In 81% of the episodes infection were resolved at the fifth day of treatment, without therapeutics failures. In-hospital mortality was 11%. In 55% of the episodes ascitic fluid culture were positive, with a mean MIC of 0.1 mg/L [0.01-0.25] to ertapenem. Finally, 70 determinations (45 in plasma and 25 in ascitic fluid) were analysed. Ertapenem concentrations in ascitic fluid reached C50 in 48% of the samples, although this goal was reached in plasma in 86% of the samples. Diffusion ratio of ertapenem (concentration in ascitic fluid/ concentration in plasma) was 76.9% [21.1-161.5%]. In 63.6% of patients, concentration of ertapenem in ascitic fluid was below 1 mg/L during the first 36 hours of treatment.

Conclusion: Plasma concentrations of ertapenem were good, although the diffusion rate was low compared to the diffusion rate observed in studies in non-cirrhotic patients. In more than 50% of times and up to 63.6% of times in the first 36 hours of treatment, ertapenem concentrations in ascitic fluid did not achieve values above the maximum MIC during at least 50% of time of the administration interval, but was above of MIC of isolated bacteria in all cases. Our data suggest that concentrations of ertapenem used at a 1 gr dose may not be enough for carbapenem-sensitive bacteria with high MIC.

SAT-010

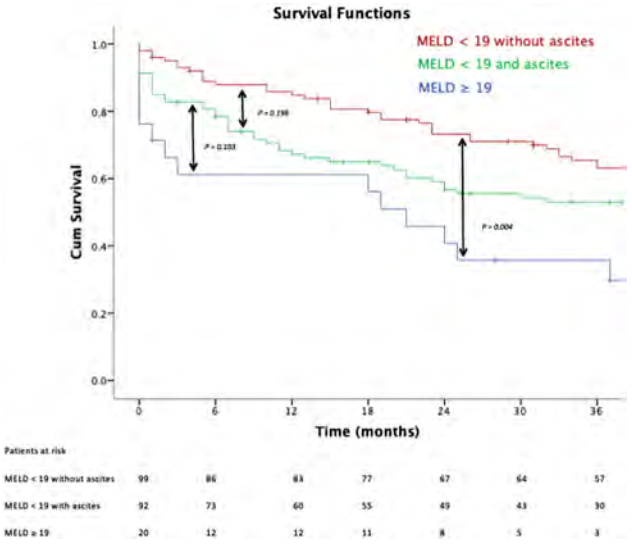
Predictors of mortality in Child B cirrhotic patients with acute variceal bleeding

Alberto Amador[1], Gerard Surís[1], Alba Cachero[1], Silvia Salord[1], Rosa Rota[1], Carme Baliellas[1], José Castellote[1]. [1]*University Hospital of Bellvitge, Gastroenterology and Hepatology department, Hospitalet de Llobregat, Barcelona, Spain*
Email: aamadornavarrete@gmail.com

Background and aims: The prognostic factors of mortality in the subgroup of cirrhotic patients Child B with variceal bleeding are not well understood and differs between the previous published studies. These factors are important to consider the placement of preemptive TIPS. The aim of our study is to identify the predictors of mortality at 6 weeks and 12 months in patients with hepatic cirrhosis and moderate hepatic dysfunction (Child B) with variceal bleeding.

Method: observational study including patients with liver cirrhosis and moderate dysfunction (Child B) with variceal bleeding and without exclusion criteria for preemptive TIPS consecutively admitted at university hospital between January 2006 and December 2017. Patients were treated according to current clinical guidelines. A univariate and multivariate analysis of the predictors of mortality at 6 weeks and an actuarial survival analysis were performed.

Results: In 11 years, 283 Child B patients with variceal bleeding were admitted, and 69 patients were excluded for met exclusion criteria for preemptive TIPS. Of the 214 patients included, 106 (49.5%) had ascites at admission, in 63 (29.4%) active bleeding was observed in the initial endoscopy and 21 patients (10%) had MELD ≥ 19. Active bleeding was not a prognostic factor of mortality neither in 6 weeks (14.3% vs 9%, $p = 0.334$) nor 12 months (34% vs 22%, $p = 0.310$). The 6-week mortality of the entire cohort was 10.7%. 11 patients needed a rescue TIPS due to treatment failure. The univariate analysis showed that the presence of hepatic encephalopathy, ascites on admission, MELD ≥ 19 and treatment failure were predictors of mortality at 6 weeks. In the multivariate analysis, had MELD score ≥ 19 (OR 4.74 [1.59-14.1]), the presence of ascites (OR 3.18 [1.28-8.78]) and treatment failure (OR 3.15 [1.1-9.8]) were independent predictors of mortality. We have defined three groups with significant differences in mortality at 6 weeks: 21 patients (10% of all cohort) with MELD ≥ 19 with a mortality of 33.3%, 93 patients (43.5%) with a MELD score below 19 points and with ascites that presented a mortality of 14%, and a low risk group of 100 patients (46.7%) with MELD below 19 points and without ascites with a mortality of 3% at 6 weeks. Actuarial survival at 12 months, calculated using Kaplan-Meier method, was 58% of patients with MELD ≥ 19, 67.3% of patients with MELD below 19 points and ascites, and 84.8% of the low-risk group (MELD below 19 and without ascites).



Conclusion: The presence of MELD equal or above 19 points defines a group with high mortality at 6 weeks. Patients with MELD below 19 points and without ascites have an excellent prognosis at 6 weeks and at 12 months. Active bleeding at the index endoscopy should not be considered as a poor prognostic factor.

SAT-011

Cirrhotic patients:Is there any role to malnutrition in predicting mortality?

Cátia Arieira[1,2,3], Francisca Dias de Castro[1,2,3], Joana Teixeira Magalhães[1,2,3], Carla Maria Moura Marinho[1,2,3], José Cotter[1,2,3]. [1]*Hospital da Senhora da Oliveira, Gastroenterology Department, Guimarães, Portugal;* [2]*Life and Health Sciences Research Institute, School of Medicine, University of Minho, Braga/Guimarães, Portugal;* [3]*ICVS/3B's, PT Government Associate Laboratory, Braga/ Guimarães, Portugal*
Email: catia_arieira@hotmail.com

Background and aims: Protein-caloric malnutrition and sarcopenia are common conditions in liver cirrhosis and are associated with poor prognosis and decreased survival. However, it remains to be enlightened whether deficient nutritional status predicts mortality in liver cirrhosis.

The aim of the study was to assess if the incorporation of sarcopenia into the Meld score (Meld-Psoas) may improve the prediction of mortality in liver cirrhosis when compared to Meld and Meld-Na scores

Method: retrospective study, included cirrhotic patients with computed abdominal tomography study between 2007 and 2017. Analytical parameters (creatinine, total bilirubin, INR and sodium) were analyzed and the transverse diameter of the right psoas muscle (TPMT) was determined at the cross-sectional level of L3-L4. The analytical parameters were collected within±7 days of the abdominal tomography.

The Meld-Psoas score: ([0.2xMELD]-[0.08xTPMT/height] +2), MELD and MELD-Na were calculated. A descriptive analysis and a ROC curve was performed to compare the predictive capability of each score to predict mortality at 6 weeks, 3, 6 and 12 months.

Results: 78 patients were included, 76.2% male gender with mean age of 56.5 ± 11.6 years. 89.7% of the patients presented alcoholic cirrhosis. 46 patients (59%) presented ascites and 10 (12.8%) hepatic encephalopathy. Patients presented a median creatinine of 0.89 (0.4-3.89)mg/dl, a bilirubin of 1.6 (0.25-18.61) mg/dl, INR of 1.4 (0.9-3.3) and sodium of 138.0 (123-145) meq/l. Regarding the scores, they presented a median Meld of 13.0 (6-43), a Meld-Na of 14.0 (6-42) and Meld-Psoas of 3.1 (1.32-9.4).

Meld-Psoas presented an AUROC of 0.90 (0.81-0.95, CI95%), 0.87 (0.77 -0.93) and 0.86 (0.77- 0.93) and 0.87 (0.78-0.94) predicting mortality at 6 weeks, 3, 6 and 12 months respectively.

Meld presented an AUROC of 0.88 (0.79-0.94), 0.83 (0.73-0.91), 0.83 (0.73- 0.91) and 0.84 (0.74-0.91) predicting mortality at 6 weeks, 3, 6 and 12 months respectively.

Meld-Na presented an AUROC of 0.87 (0.78-0.94), 0.82 (0.72-0.90), 0.82 (0.72-0.90), 0.84 (0.74-0.91) predicting mortality at 6 weeks, 3, 6 and 12 months respectively.

Meld-Psoas of 0.71 predicts 6 week mortality with a sensitivity of 100% and a specificity of 71%.

Conclusion: The incorporation of sarcopenia in Meld score (Meld-Psoas) presented an excellent accuracy in predicting mortality of cirrhotic patients, in particular 6 week mortality, superior than the observed in previous scores (Meld, Meld-Na).

SAT-012

Alterations in skin microbiota, serum bile acids and autotaxin modulate itching intensity in patients with cirrhosis

Jasmohan S Bajaj[1], Andrew Fagan[1], Masoumeh Sikaroodi[2], Genta Kakiyama[1], William Pandak[1], Hajime Takei[3], Edith Gavis[1], Phillip Hylemon[1], Douglas Heuman[1], Hiroshi Nittono[3], Patrick Gillevet[2]. *[1]Virginia Commonwealth University and McGuire VAMC, GI Hepatology and Nutrition, Richmond, United States; [2]George Mason University, Microbiome Analysis Center, Manassas, United States; [3]Junshin Clinic Bile Acid Institute, Junshin Clinic Bile Acid Institute, Tokyo, Japan*

Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Cirrhotics often complain of itching and have gut dysbiosis. Itching in non-cirrhotic cholestasis has been linked to autotaxin. Altered skin microbiota are associated with pruritic skin diseases but their impact on cirrhosis is unclear. Aim: To determine the effect of serum bile acids (BA), autotaxin, and skin microbiota on itching in cirrhosis.

Method: Cirrhotic outpts without PBC/PSC [with/without decompensation (decomp)] and controls underwent skin swabs for microbiota (16srRNA, 7 sites), serum BA analysis (LC/MS total, conjugated, primary BAs) and autotaxin, and 5D-itch scale (0-10, 10 = max intensity). Systemic inflammation (IL-6) and gut barrier (LPS binding protein LBP) were also tested. Skin sites tested were sebaceous (neck, forehead), dry (shin, forearm) and moist (umbilicus, lower abdomen, armpit). Data were compared between groups (cirrhosis/controls, decomp/not and 5D-scale ≥ 5/not). Linear discriminant analysis was used to compare microbiota. Correlation networks between serum BAs, skin microbiota were compared between cirrhotics with/without 5D ≥ 5.

Results: 70 subjects (20 controls, 59 years and 50 cirrhotics, 61 years, MELD 12, 20 decomp) were included. MELD score was higher in decomp (16 vs 9, $p < 0.001$) Itching: was worse in cirrhosis with greater proportion 5D score ≥ 5 compared to controls (Table). However, 5D scores between compensated and decomp pts were similar. Serum BA and autotaxin: All BA moieties and autotaxin were higher in cirrhosis (Table). Serum BAs were highest in those with 5D score ≥ 5 ($p < 0.05$-$p < 0.001$). Il-6 and LBP were also higher in cirrhotics and decomp pts. Skin microbiota: Composition was altered at all skin sites between controls and cirrhotics, compensated/decomp cirrhotics and those with/without significant itching. Gammaproteobacteria, Streptococcaceae and Staphylococcaceae were higher in cirrhosis, especially in 5D score ≥ 5 and were positively linked with serum autotaxin ($p < 0.03$-$p < 0.001$). IL-6, LBP or MELD score were not associated with itching intensity. On correlation networks, there was a significantly more complex interaction at every skin site between microbiota and serum BAs in pts with itching compared to those without itching.

*p<0.05 between groups	Controls vs Cirrhosis		Compensated vs Decompensated	
	Control (n=20)	Cirrhosis (n=50)	Comp (n=30)	Decomp (n=20)
Age	59.6±9.1	52.5±7.8	52.9±8.0	53.2±6.6
Gender (men)	16 (80%)	43 (86%)	26 (87%)	17 (85%)
Serum LBP (ng/ml)	2413±909	3120±1654*	2474±1338	3593±1725*
IL-6 (pg/ml)	1.9±1.4	14.2±8.5*	6.9±7.2	15.9±16.9*
Serum autotaxin(ng/ml)	189.3±58.4	440.0±221.0*	341±154	574±231*
Itching intensity (0-10)	0 (1)	3.0 (5.0)*	2 (5)	4.5 (4.75)
Itching intensity 5D≥5%	1 (5%)	18 (36%)*	8 (27%)	10 (50%)
Total serum BA	3.3 (4.1)	14.8 (48.5)*	9.8 (21.4)	60.5 (90.2)
Total Primary BA	1.5 (2.2)	8.0 (47.3)*	5.9 (15.3)	59.1 (86.4)*
Total Conjugated BA	1.5 (3.0)	10.0 (46.9)*	5.3 (11.8)	57.8 (90.5)*
Linear Discriminant Microbiota Changes	*Higher in controls*	*Higher in Cirrhosis*	*Higher in compensated*	*Higher in decompensated*
Neck	Chloroplast	Staphylococcaceae Clostridiales	—	Gammaproteobacteria, Fusobacteria, Streptococcaceae,
Forehead	Synergestetes, Deinococcus	—	—	Gammaproteobacteria, Alphaproteobacteria,
Shin	Actinobacteria	Gammaproteobacteria	—	Gammaproteobacteria, Alphaproteobacteria, Streptococcaceae
Forearm	Clostridiaceae, Fusobacteria	Staphylococcaceae Flavobacteriaceae	—	Gammaproteobacteria, Streptococcaceae
Umbilicus	Verrucomicrobiaceae Nitrosomonadaceae	Porphyromondaceae Leptotrichaceae	Actinobacteria	Gammaproteobacteria, Alphaproteobacteria, Streptococcaceae,
Lower Abdomen	Tenericutes, Rhizobiales	Gammaproteobacteria	Lactobacillaceae, Cyanobacteria	Gammaproteobacteria, Betaproteobacteria, Streptococcaceae,
Armpit	Clostridiaceae, Acidaminococcaceae	Staphylococcaceae	Peptostrepto coccaceae	Gammaproteobacteria, Alphaproteobacteria

Conclusion: Cirrhotics have higher serum BAs, itching intensity, serum autotaxin and altered skin microbiota compared to controls. The skin microbiota of patients with significant itching demonstrates higher potentially pathogenic Gammaproteobacteria and Streptococcaceae, which have strong correlations with serum BAs and autotaxin but not with cirrhosis severity, systemic inflammation or LBP. Skin microbiota could be a novel target for addressing pruritus in cirrhosis.

SAT-013

Potentially Preventable readmissions and complications in hospitalized patients with hepatic encephalopathy in a large multi-center cohort

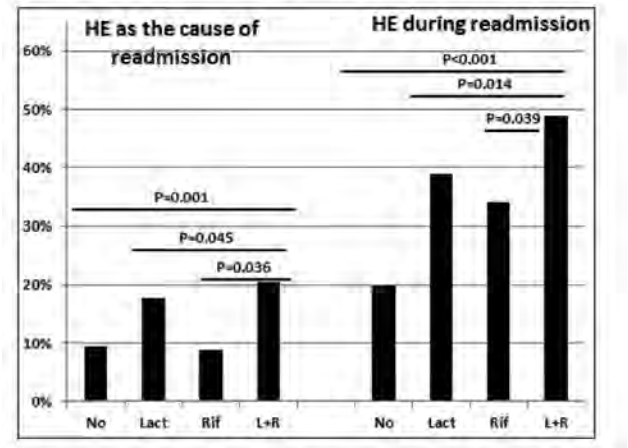
Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Hepatic encephalopathy (HE) is the major cause of readmissions and expenditure in cirrhotic pts in North America and quality improvement (QI) is needed.

Aim: Determine the rates/causes of potentially preventable readmissions and complications in hospitalized pts with HE using the North American Consortium for the Study of End-stage Liver Disease (NACSELD) cohort.

Methods: NACSELD prospectively enrolled admitted cirrhotics in 14 hepatology centers and followed them for 90 days post-discharge. QI analysis of HE was performed focusing (a) medication-related HE precipitants (b) aspiration in HE pts (c) initiation of HE Rx on discharge and (d) HE readmissions vis-a-vis lactulose/rifaximin use.
Results: Index HE episode: 2810 pts were studied, of whom 1677 (59%) were on HE Rx at admission (665 lactulose only, 153 rifaximin only, 859 both) and 930 patients were admitted for HE. The major precipitants were medication-related (32%) followed by acute kidney injury (18%), infections (17%), hyponatremia (16%) and others (17%). Medication-related precipitants were lactulose non-adherence 20%, lactulose overuse 1%, rifaximin underuse in 3%, opioids 4%, sleep aids 1% and psychoactive drugs 5%.
Index Hospital Course: *Grade3/4 HE*: 217 pts were admitted in grade 3/4 HE, of which 34 (16%) developed HE-related aspiration without ICU monitoring. *Rx change*: In all HE pts, rifaximin was initiated in 28%, with lactulose oral/enema in the rest. *On discharge*: The percent on HE Rx increased from 59% on admission to 66% at discharge (n = 1847 of 2810, n = 710 lactulose only, 151 rifaximin only and 918 both). 90-day outcomes: 421 pts died/were transplanted and were excluded. Remaining were 2447 (136 on rifaximin only, 639 on lactulose only, 855 on both and 790 without HE) pts, of whom 41% (n = 991) were readmitted. Readmission rate and discharge MELD was lowest in pts without HE compared to the rest (34%, 16 ± 6, p = 0.001) but were similar across all HE Rx pts[lactulose only (43%, 17.7 ± 7), rifaximin only (42%, 18.6 ± 6) and both (44%, 19.4 ± 6, p = 0.4). Major reasons for readmission were HE (16%), infection (10%) and GI bleeding (8%). Also, 36% of readmitted pts developed HE during the readmission. Within readmitted pts, HE-related readmission was lowest in those without prior HE. Of those on HE Rx, rate of HE readmissions or HE development during readmissions was significantly lower in pts only on rifaximin compared to the rest (Figure). A binary logistic ANCOVA model studying HE Rx and discharge MELD showed that the HE Rx was still significant (p = 0.009).

Figure: Percentage of Patients Discharged on HE-medications and 90-day readmissions



No: no prior HE, Lact: on lactulose alone, Rif: on rifaximin alone, L+R: on lactulose and rifaximin

Conclusions: HE is a common reason for readmission and several remediable steps in HE management that could adversely affect prognosis were identified in a large, multi-center inpatient cohort. These were related to medication-precipitated HE, need for monitoring to prevent aspiration and optimization of HE Rx at discharge, which should serve to reinforce better outpatient and inpatient management.

SAT-014

Efficacy of rifaximin soluble solid dispersion in patients with early decompensated cirrhosis and a Conn score of 0: A post hoc analysis of a randomized, double-blind, placebo-controlled trial

Jasmohan S Bajaj[1], Zeev Heimanson[2], Robert Israel[2], Arun Sanyal[3].
[1]*Virginia Commonwealth University and McGuire VA Medical Center, Richmond, United States;* [2]*Salix Pharmaceuticals, Bridgewater, United States;* [3]*Virginia Commonwealth University, Richmond, United States*
Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Treatments to prevent early decompensation of cirrhosis are needed. Rifaximin soluble solid dispersion (SSD) increases gastrointestinal luminal water solubility of rifaximin molecule, while minimizing systemic exposure. Rifaximin SSD is being studied as immediate-release (IR) or sustained extended-release (SER) tablet. This post hoc analysis evaluated rifaximin SSD in preventing all-cause hospitalization or mortality in adults with less advanced cirrhosis and without covert/overt hepatic encephalopathy (HE; Conn/West Haven score of 0).
Method: In a phase 2, randomized, double-blind study, adults with cirrhosis and well-controlled ascites (grade 1), with no history of esophageal variceal bleeding or spontaneous bacterial peritonitis and Conn score of < 2, were randomized to 1 of 5 rifaximin SSD groups (IR 40 mg, IR 80 mg, SER 40 mg, SER 80 mg, IR 80 mg + SER 80 mg) or placebo (PBO) once nightly (qhs) for 24 wks. Patients with baseline Conn score of 0 who received ≥ 1 dose of treatment were included.
Results: Of 516 patients in the original study, 317 had Conn score of 0 (rifaximin SSD, n = 260; PBO, n = 57) and were included in post hoc analysis. In Conn score 0 group, a significantly lower rate of all-cause hospitalizations or mortality was observed with rifaximin SSD (5 groups pooled) vs PBO (26.9% vs 38.6%; p = 0.04) and the individual treatment group rifaximin SSD IR 40 mg vs PBO (18.8% vs 38.6%; p = 0.02; Table). Also, rifaximin SSD IR 40 mg significantly reduced all-cause hospitalization or mortality for subgroups of female sex, age < 65 y, white race, and MELDNa score of 11-18 (Table). Significant differences vs PBO not observed for the other 4 rifaximin groups (except rifaximin SSD IR 80 mg qhs for MELDNa ≤ 10 subgroup [p = 0.03] and SER 40 mg qhs for female sex subgroup [p = 0.04]). Rifaximin SSD was well tolerated.

Table: All-cause hospitalization or mortality

Subgroup	Rifaximin SSD IR 40 mg qhs (n = 48), n/n (%)	PBO (n = 57), n/n	p value vs PBO*	5 Rifaximin groups pooled (n = 260), n/n (%)	p value vs PBO*

B	8/39 (20.5)	17/45 (37.8)	0.08	54/200 (27.0)	0.11
C	1/1 (100.0)	2/3 (66.7)	0.26	10/16 (62.5)	0.16

*Log-rank test stratified by country.

Conclusion: Once-daily rifaximin SSD IR 40 mg reduced all-cause hospitalization/mortality due to cirrhosis complications in patients with ascites, without HE.

SAT-015

Sarcopenia is associated with a worst prognosis in cirrhotic patients in the context of liver transplantation

Nguyen Mimosa[1,2], Tremblay Mélanie[2], Huard Geneviève[3], An Tang[4], Christopher F Rose[2,5], Chantal Bemeur[1,2]. [1]*Université de Montréal, Nutrition, Montreal, Canada;* [2]*CRCHUM, Hepato-Neuro Lab, Montreal, Canada;* [3]*CHUM, Liver Unit, Montreal, Canada;* [4]*Université de Montréal, Radiology, Montreal, Canada;* [5]*Université de Montréal, Medicine, Montreal, Canada*
Email: chantal.bemeur@umontreal.ca

Background and aims: Muscle wasting (sarcopenia) affects 30 to 70% of cirrhotic patients. The presence of sarcopenia may be associated with a worst prognosis in cirrhotic patients awaiting and after liver transplantation (LT). To this day, few studies have evaluated and followed muscle mass (in terms of quantity and quality) after LT. The goal of this study was to assess the association between the evolution of sarcopenia and the prognosis of cirrhotic patients before and after LT.
Method: In total, 94 cirrhotic patients who underwent LT at the Montreal University Hospital Center-Liver Unit were included. Sarcopenia was assessed at the third lumbar level vertebrae using a computed tomography scan (CT-scan). The diagnostic of sarcopenia was based on previously established sex-specific cut-off values of skeletal muscle index. Patients were classified into two groups: (1) persistent or newly developed sarcopenia after LT (Sarc+); (2) resolved sarcopenia or absence of sarcopenia before and after LT (Sarc-). Muscle quality (myosteatosis) was assessed by calculating intramuscular adipose tissue content. The prognostic factors were collected 6 months before and during 1 year after LT through medical records and included the number of complications, the episodes of infections, the length of stay, and the frequency of readmissions.
Results: Sarcopenia persisted or was newly developed (Sarc+) in 62% of the patients (n = 58). It remained absence or was resolved after LT in 38% of the patients (n = 35). Muscle quality was significantly decreased post-LT ($p = 0.034$). The group Sarc+ experienced more complications pre-LT ($p = 0.012$) and post-LT ($p < 0.001$), infections post-LT ($p = 0.006$) and readmissions ($p = 0.048$) compared to the group Sarc-. The length of stay was longer for the group Sarc+ as opposed to the group Sarc- ($p < 0.001$).
Conclusion: Persistent and newly developed sarcopenia after LT appear to have negative outcomes on the prognosis of patients. Interventional strategies to optimize, increase or preserve muscle mass could help to improve post-operative recovery as well as the quality of life in patients who have undergone LT.

SAT-016

Impact of sarcopenia in patients undergoing transjugular intrahepatic portosystemic shunt insertion for refractory ascites

Amine Benmassaoud[1], Davide Roccarina[1], Dominic Yu[2], Felix Cheng[1], Becky Yu[1], David Patch[1], Emmanuel Tsochatzis[1]. [1]*The Royal Free Sheila Sherlock Liver Centre, Royal Free Hospital, Royal Free London NHS Trust, London, United Kingdom;* [2]*Department of Radiology, Royal Free Hospital, Royal Free London NHS Trust, London, United Kingdom*
Email: amine.benmassaoud@mail.mcgill.ca

Background and aims: Sarcopenia is associated with worse outcome in patients with cirrhosis, however its impact in patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) insertion for refractory ascites is unknown. We therefore assessed the association of pre-TIPS sarcopenia on post-TIPS clinical outcomes and the impact of TIPS insertion on sarcopenia.
Method: We retrospectively evaluated all adult patients who underwent TIPS insertion for diuretic refractory ascites at the Royal Free Hospital, London, UK between January 2010 and April 2018. Sarcopenia was assessed using the total psoas muscle area index at the third lumbar vertebrae (L3-PMI, mm^2/m^2) based on cross-sectional imaging. Sarcopenia was defined as the lowest quartile of L3-PMI separately for male and female patients.
Results: 117 patients were included: median age was 55.7years, and 60% were male. The most common cause of liver disease was alcohol in 66% of patients. 31 patients were considered sarcopenic, (L3-PMI 244 vs 435, $p < 0.001$). On univariate analysis, body mass index (BMI), platelets, and MELD score were associated with the presence of sarcopenia. On multivariate (MV) analysis, only a high BMI was inversely associated with sarcopenia (aOR = 0.82, $p = 0.006$). During follow-up, 37 patients died, and 18 received a liver transplant. Median survival of the entire cohort was 48.9months. On MV cox regression, mortality was independently associated with increasing age (aHR = 1.04, $p = 0.03$), lower platelets (aHR = 0.99, $p = 0.03$) and higher MELD score (aHR = 1.10, $p = 0.03$). Hepatic encephalopathy (HE) occurred in 27 (25%) patients. On MV cox regression analysis, MELD was the only predictor of HE (aHR = 1.13, $p = 0.01$). Ascites control improved in 73 (66%) patients. On MV cox regression analysis, high bilirubin ($p = 0.003$) and absence of TIPS revision ($p = 0.001$) predicted improved ascites control. Sarcopenia or L3-PMI as a quantitative value did not have an impact on mortality, HE, or ascites control.
In patients with follow-up CT (n = 51), L3-PMI improved compared to baseline (L3 PMI 427 vs 489, $p < 0.001$), and the presence of sarcopenia decreased from 23.5% to 17.6% ($p = 0.37$). On MV cox regression, high bilirubin (aHR = 1.03, $p = 0.02$) and low albumin (aHR = 0.92, $p = 0.01$) were associated with improved L3-PMI. Baseline sarcopenia did not predict lack of improvement in L3-PMI.
Conclusion: Our results suggest that sarcopenia should not be considered as a contra-indication to TIPS insertion. TIPS might improve patients' nutritional status and sarcopenia and therefore long-term outcomes.

SAT-017

Anticoagulant effect of edoxaban in patients with cirrhosis: The POET study

Sarah Bos[1], Tim Schreuder[1], Hans Blokzijl[1], Jelle Adelmeijer[2], Ton Lisman[2], Pieter Willem Kamphuisen[3]. [1]*University Medical Center Groningen, Gastroenterology and hepatology, Groningen, Netherlands;* [2]*University Medical Center Groningen, Department of Surgery, Groningen, Netherlands;* [3]*Tergooi Hospital Hilversum, Internal Medicine, Hilversum, Netherlands*
Email: s.bos01@umcg.nl

Background and aims: Cirrhosis is a prothrombotic condition characterized by complications such as portal vein thrombosis and venous thromboembolism. Anticoagulant treatment for prevention or treatment of these thrombotic complications is indicated. However, the optimal anticoagulant approach is uncertain. Direct oral anticoagulant drugs (DOACs) have potential advantages over traditional anticoagulant drugs. However, in vitro experiments have suggested altered anticoagulant potency of DOACs in patients with cirrhosis due to their altered hemostatic profile. In addition, as DOACs are metabolized by the liver and kidney, a concern for accumulation exists.
Method: 14 patients with Child-Pugh A and 1 patient with Child-Pugh B cirrhosis and 15 healthy controls received 60 mg edoxaban once daily orally for 7 days. Blood samples were taken at baseline and 2 hours after drug ingestion at day 1, 3, and 7. Thrombin generation (TG) tests were performed to assess the anticoagulant effect, and edoxaban plasma levels were calculated by edoxaban-calibrated anti-Xa assays.
Results: At baseline, TG was substantially elevated in cirrhotic patients compared to controls (endogenous thrombin potential 733 nM*min vs 417 nM*min, $p = 0.053$). Administration of edoxaban reduced TG in patients to 143, 162, 180, at day 1, 3, and 7, respectively. In controls, TG was reduced to 69, 80, 69, at day 1, 3, and 7, which was significantly lower than TG in patients ($p < 0.01, < 0.01, < 0.01$). The

relative reduction in TG compared to baseline was 75%, 72%, 72% in patients and 83%, 81%, 82% in controls at day 1, 3, and 7, respectively, which was significantly different between the groups. Edoxaban plasma levels were similar in patients and controls throughout the study with 196, 182 and 229 ng/ml in patients 182, 211 and 220 ng/ml in controls on day 1, 3 and 7, respectively.

Conclusion: We have shown that one week of edoxaban at a therapeutic dose of 60 mg results in comparable plasma levels in patients with cirrhosis compared to healthy controls. However, TG remained higher in edoxaban-treated patients, combined with a reduced relative reduction in TG. These results support the safety profile of DOAC treatment in this difficult-to-treat population, but question the optimal dosing of a DOAC in cirrhotic patients to adequately treat thrombosis.

SAT-018

Relation of CT determined sarcopenia and anthropometry to serum C-reactive protein levels in patients with chronic liver disease

Sarah Brown[1], anne langan[2], pauline kane[3], Nigel Heaton[1], Kosh Agarwal[1], William Bernal[4]. [1]*Institute of Liver Studies, King's College Hospital, London, United Kingdom;* [2]*Dietetic Department, King's College Hospital, London, United Kingdom;* [3]*Radiology Department, King's College Hospital, London, United Kingdom;* [4]*Liver Intensive Care, King's College Hospital, London, United Kingdom*
Email: sarahbrown21@nhs.net

Background and aims: Sarcopenia, the progressive and generalised loss of skeletal muscle mass and strength, is recognised as common and prognostically important in patients with chronic liver disease (CLD), and associated with impaired survival. Its pathophysiology in CLD is not well understood. In other chronic illness sarcopenia is linked with chronic systemic inflammation and elevated serum pro-inflammatory markers, including C-reactive protein (CRP). We assessed patients with CLD undergoing liver transplant (LT) assessment for the presence of sarcopenia and its association with CRP levels.

Method: 88 patients with cirrhotic CLD, with no evidence of active infection or concurrent antibiotic usage, undergoing LT assessment were studied. Abdominal CT imaging was analysed using Sliceomatic software to determine L3 muscle area. L3 skeletal muscle index (L3SMI) was calculated with predefined cut-offs for CT-defined sarcopenia. Assessment of muscle strength was determined by hand grip strength (HGS) using dynamometry, performed by trained dietetic staff. Serum CRP was measured using an immunoturbidimetric method with the Siemans Advia 2400 analyser.

Results: Median age of patients was 53 (IQR 45-61) years, and MELD 13 (10-18), 36% were female and 29% had alcoholic liver disease. Median CRP levels were 7.6 (2.2-20.9) mg/L and 59% of patients had CRP elevated above the normal range. L3SMI was 38.5 (31.3-46.3) cm/M^2 with 74% of patients fulfilling CT criteria for sarcopenia. Median HGS was 32.7 (26.1-37.1) Kg and 44% of cases had < 85% predicted values.

There was no significant difference in CRP levels between patients with CT-defined sarcopenia and those without (7.7 (2.0-18.6) mg/L vs. 7.5 (3.2-28.5) mg/L (p = 0.43)), but CRP levels were elevated in patients with reduced HGS compared to those with normal HGS (11.1 (4.4-31.48) mg/L vs. 4.2 (1.9-15.2) mg/L (p = 0.009)). There was positive correlation with MELD and UKELD score (r = 0.258, p = 0.015 and r = 0.262, p = 0.014 respectively). CRP levels inversely correlated with HGS (r = -0.358, p = 0.002) but not with L3SMI (r = -0.100, p = 0.352).

Conclusion: We report for the first time the association between CRP and muscle strength in patients with CLD, suggesting systemic inflammation may have a role in its pathogenesis. The lack of association between CT-determined sarcopenia and CRP levels may reflect a greater role for chronic inflammation in loss of muscle strength than reduced muscle mass.

SAT-019

Minimal hepatic encephalopathy: Which test should we use in clinical practice?

Benjamin Buchard[1], Armand Abergel[1], Camille Teilhet[1], Leon Muti[1], Géraldine Lamblin[1], Didier Deffond[2]. [1]*CHU Estaing, Service de médecine digestive, Clermont-Ferrand, France;* [2]*CHU Gabriel Montpied, Service de neurologie, Clermont-Ferrand, France*
Email: bbuchard@chu-clermontferrand.fr

Background and aims: Minimal hepatic encephalopathy (MHE) in cirrhosis is a latent and asymptomatic neurological disorder. MHE has a prognostic value, especially before liver transplant or transjugular intrahepatic portosystemic stent shunt. Its presence greatly affects quality of life. A large choice of diagnostic tests is available. The best test seems to be the Psychometric Hepatic Encephalopathy Score (PHES) but is difficult to use in every day practice.

Method: Four non-invasive tests to diagnose MHE were performed in two centers in patients with cirrhosis without clinical evidence of hepatic encephalopathy (< grade I according to West-Haven criteria): PHES, *Critical Flicker Frequency* (CFF) with two pathological cutoffs set at 38 and 39Hz, *Simplified Animal Naming Test* (S-ANT) with cut-off set at 15 and venous ammonia. PHES was chosen as gold standard. Due to lack of normative data in France, were used normal values from Spain and Italy. Cohen's kappa coefficients were calculated. Area under curve was used to determine the value with the best sensitivity and specificity. We also performed an analysis to evaluate the risk of OHE at 6 months. Exclusion criteria were HE ≥ grade I, neuropsychiatric disorders, ophthalmological diseases, active bleeding or infection and treatments to reduce hyperammonia.

Results: 48 patients were included. 25 patients (50%) were Child-Pugh A, 19 (40%) Child B and 5 (10%) Child C. Median MELD was 12. MHE was diagnosed with PHES in 42% and 44%. Agreement between PHES and other tests was poor (k < 0.4), except between PHES and S-ANT (k = 0.41 and k = 0.4). Agreement between Spanish and Italian PHES was excellent (k = 0.87). Predictive values of these tests were moderate with positive likelihood-ratio between 2 and 5, and negative likelihood-ratio between 0.2 and 0.5. According to Younden index, best cutoff for CFF was 37Hz, close to values we use in practice. For S-ANT, best cutoff was 15, which is the value highlighted in a previous study. Benzodiazepines were associated with abnormal PHES (OR = 4; p = 0.04). Severity of liver disease, estimated by Child-Pugh and MELD, increases the risk of MHE but not significantly, mainly because of lack of power. On a univariate analysis, abnormal PHES using Spanish (p = 0.017) and Italian normative data (p = 0.023), S-ANT < 15 (p = 0, 049) were significantly associated with occurrence of OHE at 6 months during follow-up.

	CFF 38Hz	CFF 39Hz	S-ANT	NH3
PHES (SPA)	0, 33	0, 27	0, 45	−0, 44
PHES (ITA)	0, 3	0, 23	0, 41	−0, 29

Conclusion: Lack of agreement between PHES and CFF or S-ANT is not surprising as they evaluate different neurological functions. Venous ammonia appears to be of little interest in detecting MHE. Despite excellent agreement between Spanish and Italian data, it is essential to find normative data for PHES in France to generalize its use in practice. Abnormal PHES or S-ANT was significantly associated with occurrence of OHE at 6 months.

SAT-020

Transjugular intrahepatic portosystemic shunt implantation improves renal function in patients with ascites

Theresa Bucsics[1,2], Maria Schoder[3], Mattias Mandorfer[1,2], Philipp Schwabl[1,2], Nicolas Göschl[1,2], Sophie Hoffmann[1,2], Johanna Grünberger[1,2], Franz Karnel[4], Josef Karner[5], Markus Peck-Radosavljevic[6], Thomas Reiberger[2]. Gastroenterology and Hepatology, Vienna, Austria; [2]Medical University of Vienna, Vienna Hepatic Hemodynamic Laboratory, Vienna, Austria; [3]Medical University of Vienna, Department of Biomedical Imaging and Image-Guided Therapy, Division of Cardiovascular and Interventional Radiology, Vienna, Austria; [4]Sozialmedizinisches Zentrum Sued-Kaiser-Franz-Josef-Spital, Radiology, Vienna, Austria; [5]Sozialmedizinisches Zentrum Sued-Kaiser-Franz-Josef-Spital, Surgery, Vienna, Austria; [6]Klinikum Klagenfurt am Woerthersee, Department of Internal Medicine (IMuG) and Gastroenterology, and Hepatology, Endocrinology, Rheumatology, and Nephrology with Centralized Emergency Service (ZAE), Klagenfurt, Austria
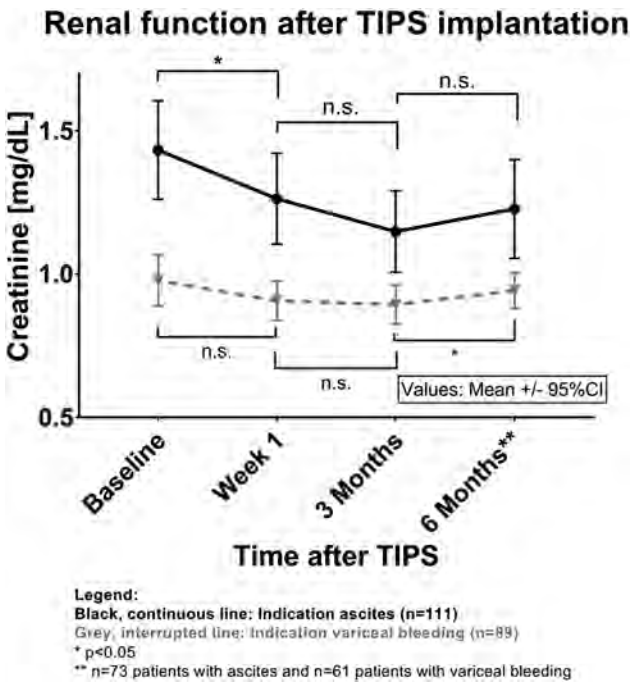
Email: theresa.bucsics@meduniwien.ac.at

Background and aims: The implantation of a transjugular intrahepatic portosystemic shunt (TIPS) is used to treat complications of portal hypertension. Limited data is available on the course of renal function after TIPS.
Methods: In this single-center registry study, we retrospectively assessed serum creatinine (sCr) as a marker for renal function at baseline (prior to TIPS), and at 1 week (W1), 3 months (M3), and 6 months (M6) after TIPS implantation in patients with cirrhosis.
Results: 200 patients were included: etiology: 71.5% alcoholic liver disease; 76.0% male; mean age: 55.6 (SD±10) years; MELD: 12.9 ± 3.8; indication: 40% variceal bleeding (VB), 55.5% ascites, 4.5% bleeding +ascites. Patients with refractory ascites were older than those with VB (57.4 ± 8.8 vs 53.4 ± 10.8years; p = 0.002), but hepatic function was comparable (MELD 12.8 ± 3.7 vs 13.3 ± 3.9; p = 0.506). Median baseline sCr was 1.06 (range:0.38-5.88)mg/dL. sCr values were higher in patients with ascites than in those with VB [baseline: 1.29 (0.38-5.88)mg/dL vs 0.90 (0.39-2.65)mg/dL; p < 0.001]. sCr significantly decreased in patients with ascites already at W1 after TIPS implantation (median −13.4% (range:-64%-+212.9%), p < 0.0001). Afterwards, sCr mostly remained stable [rel. changes W1-M3: ascites: −1.44% (−73.5%-+335.3%), p = 0.4979; bleeding: +1.23% (−83.9%-+142.4%), p = 0.653], but slightly increased again between M3 and M6 in patients with VB [median:+7.3% (−28.4%-+169.8%), p = 0.013], but not in patients with ascites [median:+0.9% (−32.2%-+350%), p = 0.465].



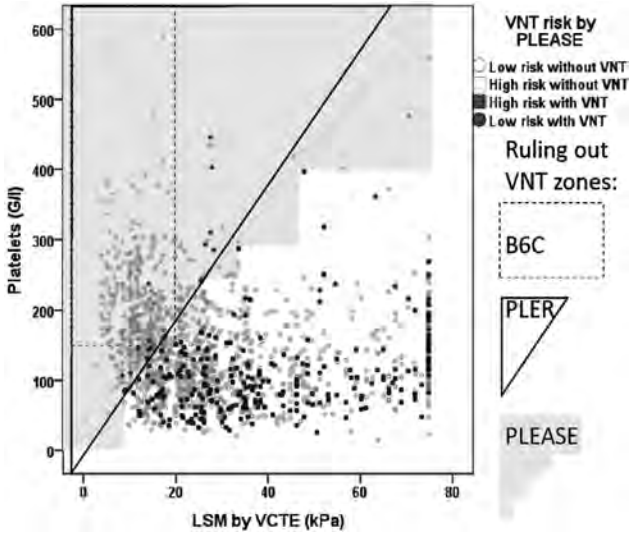
Conclusions: TIPS appears to permanently improve renal function as early as W1 after implantation in patients with ascites. Although the retrospective design limits the significance of our findings, patients with VB didn't show improvements in sCr. Further prospective studies are warranted to confirm the impact of TIPS on renal function.

SAT-021

How to use platelets and liver stiffness to rule out esophageal varices needing treatment?

Arthur Berger[1], Federico Ravaioli[2], Oana Farcau[3], Davide Festi[2], Horia Stefanescu[3], Bureau christophe[4], Nathalie Ganne-Carrié[5], Annalisa Berzigotti[6], Victor De Ledinghen[7], Paul Cales[1]. *[1]University hospital, Hepatology, Angers, France; [2]University of Bologna, Department of Medical and Surgical Sciences, Bologna, Italy; [3]Regional Institute of Gastroenterology and Hepatology, Liver Unit, Cluj-Napoca, Romania; [4]Hôpital Purpan CHU Toulouse, Hepato-Gastroenterology, Toulouse, France; [5]APHP Jean Verdier Hospital, Hepato-Gastroenterology, Bondy, France; [6]Universitätsklinik für Viszerale Chirurgie und Medizin (UVCM), Inselspital, University of Bern, Hepatology, Swiss Liver Center, Bern, Switzerland; [7]Haut-Lévêque Hospital, Hepatology, Bordeaux, France*
Email: paul.cales@univ-angers.fr

Background and aims: Original Baveno VI criteria (B6C), expanded B6C (EB6C) and ANTICIPATE score, based on platelets (PLT) and liver stiffness measurement (LSM by Fibroscan), allow to rule out varices needing treatment (VNT). Our objective was to evaluate and improve these tests.
Method: 1866 patients (1563 in derivation population and 303 in validation population) with chronic liver disease of various etiologies were included in a multicentric retro-prospective study (15 centers in 5 European countries). Three published tests (B6C, EB6C, ANTICIPATE score) were compared to three new tests: PLER (PLT/LSM ratio), PLES (logit score including PLT and LSM) and PLEASE (where the spared endoscopy rate was optimized via multiple cut-off pairs for PLT and LSM: figure).



Results: Patient characteristics (derivation population): male: 63.7%, age: 58.6 ± 11.1 years, VNT: 17.3%, BMI: 26.6 ± 4.6 kg/m², etiologies: virus: 62.1%, alcohol: 28.6%, others: 9.3%, LSM ≥ 10kPa: 93.5%. The tests are listed according to increasing spared endoscopy rate (%) with missed VNT rate (%, denominator: VNT) in brackets in the derivation population: B6C: 20.3% (p < 0.001 vs other tests) (missed VNT: 1.1%),

PLER: 27.6% (4.8%), ANTICIPATE: 29.2 (4.8%), PLES: 29.4 (4.4%), PLEASE: 33.3% ($p < 0.001$ vs previous tests) (4.8%) and EB6C: 37.1% ($p < 0.001$ vs others) (8.1%). In the validation population, results were: B6C: 23.4% ($p < 0.001$ vs others) (0%), PLER: 34.0% (5.4%), ANTICIPATE: 36.3 (2.7%), PLES: 37.3 (2.7%), PLEASE: 42.6% ($p < 0.001$ vs previous tests) (5.4%) and EB6C: 44.2% ($p < 0.001$ vs other tests except for PLEASE: $p = 0.522$) (8.1%). Results were evaluated according to etiology and MELD score due to their significant interaction in the prediction of spared endoscopy rate. Most tests were robust for sparing effect and missed VNT as a function of etiology and/or MELD score but the sparing effect was modest in MELD scores > 10. The cut-off of PLER for missed VNT rate at 5% was PLT/LSM ratio close to 10 whatever etiology.
Conclusion: B6C are very robust and EB6C are disqualified due to a high missed VNT rate. PLT and LSM can be used in two ways to screen VNT: the simple PLER usable everywhere in which VNT are ruled out when PLT (G/l) are ≥ 10 folds LSM (kPa); the PLEASE algorithm, usable via a free e-calculator, is the most performant test. Thus, the spared endoscopy rate can be safely (i.e. with acceptable missed VNT rate ≤ 5%) increased from 20-23% (in B6C) to 28-34% (PLER) and even doubled to 33-43% (PLEASE).

SAT-022

Transjugular intrahepatic portosystemic shunts is still an effective treatment for refractory variceal haemorrhage in patients with high MELD/Child Pugh scores

Rigers Cama[1], Vedat Barut[2], David Fidler[3], Amine Benmassaoud[3], Hannah Fenn[3], Mukur Ghosh[4], Raj Mookerjee[3], Dominic Yu[4], Jennifer Ryan[4], Neil Davies[4], David Patch[4], Rachel Westbrook[4]. *[1]Shiela Sherlock Liver Centre, Royal Free Hospital London, London, United Kingdom; [2]Shiela Sherlock Liver Centre, Royal Free Hospital London, London, United Kingdom; [3]Shiela Sherlock Liver Centre, Royal Free Hospital London, London, United Kingdom; [4]Shiela Sherlock Liver Centre, Royal Free Hospital London, London, United Kingdom*
Email: r.cama@nhs.net

Background and aims: The Baveno VI recommends that TIPS must be considered in patients who have failed endoscopic therapy or are at high risk of treatment failure (Child Pugh Class (CP) C < 14 or B with active bleeding) after endoscopic therapy. The benefit of TIPS to patients with advanced liver disease remains controversial with some studies suggesting poor outcome.
Method: We undertook a retrospective review of all TIPS (24 hour service) for acute severe VH since Baveno V in 2010 at our centre.
Results: 121 patients (31% Female) with median age 52-years were included. Aetiology of cirrhosis was alcohol in 71%. Median time to TIPSS was 1-day (IQR 2) with 95% done within 5-days; 89% of patients were transferred into our tertiary centre for their VH. Median ITU/hospital stay was 2/9 days (IQR 7/8). Median MELD was 15 (IQR 8) with 30-patients having a MELD ≥ 19 at presentation. Overall survival at 1, 3 and 12 months was 88%, 84% and 80%, respectively. Reduced survival at 3 months was associated with a higher pre-TIPS MELD score ($p < 0.001$) and CP score ($p < 0.001$); consolidation on CXR ($p < 0.01$) and Sengstaken tube placement ($p < 0.01$) but not peripheral blood WCC ($p = 0.1$), age ($p = 0.6$), post tips pressure gradient ($p = 0.1$) or days to index bleed ($p = 0.9$). In patients with a MELD ≥ 19 survival was 70%, 63% and 60% at 1, 3 and 12-months respectively and significantly worse than those with MELD < 19 ($p < 0.01$, all groups). In MELD ≥ 22 (n = 20) 1, 3 and 12-month survival was 64%, 59% and 53% respectively. Patients with a CPS ≥ 12, 1 and 3-month survival was 44% and 33% respectively, and significantly lower than those with a CPS < 12 ($p = 0.001$). Only 1 patient with a CPS ≥ 14 underwent a TIPS and survived. The only predictor of poor outcome in those with MELD ≥ 19 or CPS ≥ 12 was sengstaken tube placement ($p = 0.01$). Overall pre-procedure MELD/CPS score did not influence diameter of TIPS choice, nor concurrent variceal embolization. The requirement for a TIPSS reduction/occlusion for HE (4%) was not more common in MELD ≥ 19; nor was a return to radiology for uncontrolled bleeding (TIPSS dilatation±embolization (10%)).
Conclusion: In patients with refractory VH and high MELD/CP score, TIPS placement is not futile and potentially allows a 'window' for hepatic recompensation or liver transplantation. Moreover in contrast to recent published data we show timely and tertiary access to TIPS is possible and not restricted to those with less severe cirrhosis.

SAT-023

The lack of benefit of prophylactic transfusions of patients with cirrhosis and esophageal varices undergoing endoscopic variceal ligation

Anabel Blasi[1], Geovanny Hernández Cely[2], Raquel Risco[1], Karina Chavez[1], Adria Juanola[1], Andres Cardenas[3]. *[1]Hospital Clínic, Barcelona, Spain; [2]Fundacion Cardio Infantil Instituto De Cardiologia, Bogotá, Colombia; [3]Hospital Clínic, GI/Liver Unit, Barcelona, Spain*
Email: acardena@clinic.cat

Background: Endoscopic variceal ligation (EVL) of esophageal varices is commonly performed in patients with cirrhosis. Prophylactic administration of platelets and fresh frozen plasma (FFP) is recommended in subjects with low platelets/prolonged INR. In this analysis we evaluated post-EBL bleeding event in patients undergoing outpatient EBL and the use of prophylactic administration of blood products in this setting.
Methods: Retrospective analysis of consecutive EBL procedures in patients with cirrhosis from 01/2010-12/2016. Fresh frozen plasma (FFP) and platelet transfusion were administered at the discretion of the clinician if INR was > 1.5 and/or platelet count < 50×10^9/L. Patient demographics, endoscopic findings, bleeding events after EBL and the use of prophylactic FFP or platelets were recorded.
Results: 467 patients underwent 1174 EBL procedures: (70% male), etiology: HCV and alcohol (77%), median MELD 11, Child A/B/C (62/31/7%). EBL procedures were performed for primary (51%) and secondary (49%) prophylaxis. Median procedure per patient was 2 (1-4). The prophylactic transfusion protocol was only followed in 15% and 21% of patients that met criteria for an elevated INR and/or low platelets respectively. FFP and/or platelets were administered in 26 patients (5.6%) and in 63 procedures (5.4%). Bleeding occurred in 13 patients (2.8%) and in 21 procedures (1.8%). Bleeding was due to post-EBL ulcer in 11 patients and due to varices in 2. In 2 patients, bleeding occurred within 24 hrs and in the remaining it occurred within 2 weeks after EBL. In those that bled, 3 met criteria for transfusion; 1 received FFP and 2 with low platelets did not receive transfusion; the remaining 10 patients did not meet criteria for transfusion. Patients that bled had higher MELD scores and most underwent secondary EBL compared to those that did not bleed ($p = 0.01$).
Conclusion: The incidence of post EBL bleeding is low and correlates with advanced liver disease. There is no clear relationship between post-EBL bleeding, INR/platelet count, and prophylactic transfusion. Established cutoffs do not seem to predict bleeding in these patients. Prophylactic transfusion in the setting of outpatient EBL needs to be further evaluated.

SAT-024

Effect of acute kidney injury on long-term outcomes of spontaneous bacterial peritonitis in cirrhotics using ICA-AKI criteria

Sohn Won[1], Jung Hee Kim[2], Ju-Yeon Cho[3]. *[1]Wonkwang University Sanbon Hospital, Gunpo, Korea, Rep. of South; [2]Hallym University Hangang Sacred Heart Hospital, Seoul, Korea, Rep. of South; [3]Chosun University Hospital, Gwang-Ju, Korea, Rep. of South*
Email: hand0827@naver.com

Background and aims: Spontaneous bacterial peritonitis (SBP), a crucial complication of liver cirrhosis, is associated with high

mortality. Acute kidney injury (AKI) is an important risk factor for the prognosis in cirrhosis. Recently, a new AKI criteria (International Club of Ascites, ICA-AKI) has been introduced in patients with cirrhosis. This study aimed to investigate the effect of AKI on long-term mortality of SBP in cirrhosis using ICA-AKI criteria.

Method: A total of 157 cirrhotic patients with a first episode of SBP between January 2007 and December 2016 from three medical centers in Korea were analyzed. We investigated the long-term mortality with related risk factors of SBP in cirrhosis including the ICA-AKI criteria. The ICA-AKI stage at SBP diagnosis is as follows: stage 0, no increase of serum creatinine (SCr) or increase of SCr < 0.3 mg/dl; stage 1, increase of SCr ≥ 0.3 mg/dl or SCr ≥ 1.5-2 times from baseline; stage 2, increase of SCr ≥ 2-3 times from baseline; stage 3, increase of SCr ≥ 3 times from baseline, or SCr ≥ 4.0 mg/dl with an acute increase of ≥ 0.3 mg/dl, or initiation of renal replacement therapy. Stage progression was defined as a progression of AKI to a higher stage.

Results: The mean age was 58.6 years. The etiology of liver cirrhosis was alcohol (n = 73), hepatitis B virus (n = 70), hepatitis C virus (n = 9), and others (n = 5). At the diagnosis of SBP, 106 patients were Child-Pugh class C (67%), the mean level of MELD score was 20.6, and the mean SCr level was 1.7 mg/dl. The ICA-AKI stage was stage 0 in 91 (58%), stage 1 in 33 (21%), stage 2 in 19 (12%), and stage 3 in 14 patients (9%). Stage progression within 48 hours after SBP diagnosis was noted in 18 patients (12%). Of 157 patients, a total of 71 patients died (45.2%). The median time of overall survival was 6.7 months. Overall survival rates at 6, 12, 36, and 60 months were 50.2%, 45.2%, 43.7%, and 39.8%, respectively. Multivariable analysis showed that the risk factors for overall survival were Age ≥ 60 years (hazard ratio (HR) 1.74, $p = 0.029$), serum sodium level ≤ 130 mmol/L (HR 1.3, $p = 0.017$), ICA-AKI stage 1 (HR 2.51, $p = 0.003$), ICA-AKI stage 2 or 3 (HR 3.36, $p < 0.001$), and stage progression at 48 hours after SBP diagnosis (HR 2.57, $p = 0.004$).

Conclusion: AKI and its progression are significant risk factors for mortality in cirrhotic patients with SBP. The new ICA-AKI criteria may be a useful tool to evaluate the prognosis of cirrhotic patients with SBP.

SAT-026

Mid-arm circumference and triceps skinfold thickness independently predicts mortality in hospitalized patients with decompensated cirrhosis

Camila Saueressig[1], Pâmela Kremer Ferreira[1], Joana Hoch Glasenapp[2], Thais Ortiz Hammes[3], Vivian Cristine Luft[4], Valesca Dall'alba[1].
[1]Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, Brazil., Postgraduate Program: Sciences in Gastroenterology and Hepatology., Porto Alegre, Brazil; [2]Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, Brazil., Course of Nutrition, Medical School of UFRGS, Porto Alegre, Brazil., Porto Alegre, Brazil; [3]Hospital de Clínicas de Porto Alegre (HCPA)., Nutrition Division, HCPA, Porto Alegre, Brazil., Porto Alegre, Brazil; [4]Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, Brazil., Postgraduate Program of Epidemiology, UFRGS, Porto Alegre, Brazil., Porto Alegre, Brazil
Email: camilasaueressig@hotmail.com

Background and aims: Malnutrition is common in patients with advanced liver disease. However, even with a high prevalence, malnutrition is often not diagnosed at admission to hospital. Hydric changes by the presence of edema and ascites are factors that lead to misdiagnosis, reinforcing the importance of using appropriate assessment tools. The aim of the study was to evaluate the nutritional status of hospitalized patients with decompensated cirrhosis by different tools and the predictive capacity of the nutritional assessment tools in predicting survival.

Method: this was a prospective cohort study performed with patients > 19 years of age with decompensated cirrhosis (ascites and/or hepatic encephalopathy, variceal bleed, spontaneous bacterial peritonitis, hepatorenal syndrome or Child-Pugh B or C) who were hospitalized by the Gastroenterology and Hepatology Division at Hospital de Clínicas de Porto Alegre, Brazil. Data were collected within 72 hours of admission, from April 2017 to April 2018. The severity of liver impairment was assessed by Child-Pugh criteria. Nutritional assessment comprised: mid-arm circumference (MAC), triceps skinfold thickness (TSF), mid-arm muscle circumference (MAMC), phase angle (PhA) and Subjective Global Assessment (SGA). Multivariate analysis according to Cox's model assessed the predictive power of nutritional parameters on survival.

Results: One hundred patients were assessed and the median time of follow-up of 6.9 (range, 1-10.9) months. By multivariate Cox analysis, in a model adjusted for Child-Pugh, malnutrition according to MAC (HR = 2.63, 1.4-4.9) and TSF (HR = 2.04, 1.1-3.9) is associated with an increased in-hospital mortality. The increment in 1 degree in PA was associated with protection against mortality (HR = 0.65, 0.47-0.89).

Table 1: Clinical and nutritional status according to the occurrence of death.

Mortality	Yes (n = 41)	No (n = 59)	p value
Age	61, 8 ± 10, 4	59 ± 10, 3	0, 196
Male	25%	38%	0, 889
Female	16%	21%	
Child-Pugh			
A	2%	7%	**0, 012**
B	20%	41%	
C	19%	11%	
MAC	26, 5 ± 3, 7	28, 9 ± 4, 3	**0, 003**
TST	15 (9-20, 1)	20 (11, 6-25)	0, 085
MAMC	21, 9 ± 2, 4	23, 3 ± 2, 6	0, 013
PhA	4, 8 ± 1, 1	5, 5 ± 0, 9	**0, 001**
SGA			
A	7%	24%	**0, 028**
B	24%	21%	
C	10%	14%	

Conclusion: Malnutrition, evaluated by classic anthropometric measures, is an independent predictor of mortality. Phase angle seems to be a good indicator for mortality. Our results suggest that these tools are not affected by hydric changes and may be useful and reliable bedside tool to evaluate nutritional status.

SAT-027

Effects of propranolol on liver- and spleen-stiffness measured by MR-Elastography in patients with cirrhosis

Karen Vagner Danielsen[1], Jens Hove[2], Søren Møller[3], Flemming Bendtsen[1]. *[1]Hvidovre Hospital, Centre of Gastroenterology, Hvidovre, Denmark; [2]Hvidovre Hospital, Dept. Cardiology, Hvidovre, Denmark; [3]Hvidovre Hospital, Centre of Functional and Diagnostic Imaging and Research, Hvidovre, Denmark*
Email: kvdanielsen@gmail.com

Background and aims: MR-elastography (MRE) is a non-invasive diagnostic method and analyses shear wave movement through tissue to determine stiffness. The technique is often uses for detection and characterization of liver fibrosis and cirrhosis.

It is well-known that liver-stiffness increases postprandial due to increased portal blood inflow. To avoid false elevated values of the liver stiffness, fasting 4 hours prior to MRE or ultrasound elastography is recommended. However, evidence regarding non-selective beta-blockers (NSBBs) effect on the liver- and spleen stiffness is lacking. NSBB reduces portal pressure in responders owing partly to a reduced portal inflow, but unfortunately only 50% of the patients respond to the treatment. We therefore hypothesized that NSBBs reduces the liver- and spleen-stiffness due to a decrease in blood flow into the portal system.

The purposes of this study were to evaluate whether NSBB influences the liver- and spleen-stiffness in patients with cirrhosis and if MRE can predict the individual NSBB response.
Method: Twenty-one patients (7 women and 14 men) with cirrhosis and clinical indication for NSBB treatment underwent MRE, liver vein catheterisation (LVC), and registration of clinical and biochemical characteristics. The responders to NSBB were defined as a reduction in the hepatic venous pressure gradient (HVPG) ≥ 10%, or to HVPG < 12mmHg after intravenous propranolol administration (0.15 mg/kg bodyweight) during a LVC.
Results: Among the patients 52% were responders to the NSBB treatment. In these patients NSBB treatment reduced the mean liver-stiffness by 43.5 Pa (4.3%) and the mean spleen-stiffness by 95.7 Pa (7.5%). In patients with non-response to NSBB the mean reductions were 9.7 Pa (0.08%) in liver-stiffness and 39.2 Pa (3.3%) in spleen-stiffness after NSBB administration.
The reduction in HVPG after NSBB administration was not significantly associated with a reduction in spleen-stiffness or liver-stiffness after NSBB (NS).
Conclusion: Treatment with NSBB reduces liver and spleen-stiffness in NSBB-responders. However, the reduction in stiffness is unrelated to the reduction in HVPG.
Our results emphasize the importance of considering betablocker treatment when interpreting MRE results but MRE cannot be used to predict responsiveness to NSBB-treatment.

SAT-028

Diabetes is associated with TIPS failure in cirrhotic patients with refractory ascites

Stella De Nicola[1], Aldo Airoldi[1], Giovanni Perricone[1], Marcello Vangeli[1], Raffaella Viganò[1], Marco Solcia[2], Fabiane Barbosa[2], Ruggero Vercelli[2], Carmelo Migliorisi[2], Antonio Rampoldi[2], Luca Saverio Belli[1]. *[1]ASST GOM Niguarda, Epatologia e Gastroenterologia, Milan, Italy; [2]ASST GOM Niguarda, Radiologia interventistica, Milan, Italy*
Email: stella.denicola@gmail.com

Background and aims: Ascites is the most frequent clinical sign associated to portal hypertension in cirrhosis. When ascites becomes refractory (10% of patients with ascites), TIPS placement is a good therapeutic option which (effective in approximately 2/3of the cases). The aim of our study was to explore for possible predictors of TIPS failure in refractory ascites.
Method: 105 consecutive patients underwent TIPS placement from Feb 2014 to Dec 2017 at Niguarda Hospital, Milan; 38 patients received TIPS for refractory ascites. A covered stent with a nominal diameter of 10 mm was used in all cases. Response to TIPS was defined as complete (off diuretics) or partial (low dose diuretics required).
Results: Overall, median age was 58, the majority were male (71%), median time from the diagnosis of refractory ascites to TIPS placement was 24 weeks (range 12-44). Median MELD score was 11 (range 7-26). Child-Pugh score was B in 36 and C in 2. Three patients died from liver related events during the first six weeks (8%) and 6 within the first 6 months (16%). One patient underwent LT. The rate of hepatic encephalopathy after intervention was of 29% (11/38). Sixteen patients (16/25, 64%) had a complete response, 9 (9/25, 36%) a partial response and 7 (7/38, 18%) TIPS failure. No statistically significant differences were observed in responders *vs* non-responders in terms of median age at baseline, MELD score, Child Pugh classes, time-interval from diagnosis to TIPS insertion, diastolic disfunction (expressed as E/A), porto-systemic gradient pre and post TIPS and median dilatation of covered stent at insertion (see table). The only baseline feature associated with failure was the presence of diabetes at baseline: 71% (5/7) vs 24% (6/25), p = 0, 0318.

Table:

Variables	Responders (25)	Non-responders (7)
Age, years, median (range)	57, 5 (42-77)	58 (54-71)
MELD score, median (range)	9 (6-17)	10 (8-15)
Child-Pugh class B, % (n)	96% (24/25)	86% (6/7)
Time from diagnosis, median (range)	24 (12-44)	28 (12-48)
E/A, median (range)	0, 86 (0, 48-1, 36)	0, 95 (0, 64-1, 4)
Stent dilatation mm, median (range)	6 (5-8)	6 (6-10)
Portal pressure Gradient, mmHg, median (range)		
-Pre TIPS	21 (10-27)	18 (11-25)
-Post TIPS	11.9 (5-21)	11.8 (9-15)
Diabetes mellitus, % (number)	24% (6)	71% (5)

Conclusions: In our cohort the presence of diabetes is statistically associated with inefficacy. Larger studies are needed to confirm this preliminary results and to understand the underlying mechanisms of failure.

SAT-029

Prediction of hepatic hydrothorax in cirrhosis patients with ascites

Thomas Deleuran[1], Hugh Watson[2], Hendrik Vilstrup[1], Peter Jepsen[1,3]. *[1]Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus N, Denmark; [2]Evotec ID, Marcy l'Etoile, France; [3]Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus N, Denmark*
Email: thomas.deleuran@clin.au.dk

Background and aims: Hydrothorax is a common complication of ascites. It requires hospitalization and may cause respiratory failure, but its risk factors are unknown.
Method: To develop a model that predicts the cumulative risk of hepatic hydrothorax, we used data from three randomized trials on satavaptan treatment of ascites in 1, 198 patients with cirrhosis followed for 1 year. We excluded trial participants with heart failure, renal failure, cancer, or myxedema. The candidate predictors were clinical observations: age, gender, diuretic refractory ascites (yes/no), mean arterial blood pressure; serum biochemistry: creatinine, bilirubin, International Normalized Ratio, albumin, sodium and, platelet count; pharmacological treatments: non-selective beta-blockers, antidiabetics (insulin, metformin, or other oral antidiabetics), proton pump inhibitors, furosemide, and spironolactone; and presence of diabetes (yes/no) recorded at randomization. Predictors were included in a Fine and Gray regression model that considers death as a competing risk. We chose our predictors with backward selection and the Akaike Information Criterion as stopping rule, and reported sub-distribution hazard ratios (sHR). We evaluated discrimination with Wolbers C-index, and adjusted this measure for optimism bias with 1, 000 bootstrap simulations.
Results: We developed our prediction model on 942 patients, of whom 41 developed hydrothorax and 65 died. Serum bilirubin (sHR: 1.02, 95% CI: 1.01-1.03), treatment with non-selective beta-blockers (sHR: 0.43, 95% CI: 0.21-0.85), and antidiabetic treatment (sHR: 3.88, 95% CI: 2.02-7.46) predicted the cumulative risk of hydrothorax (Figure). We found a Wolbers C-index 1 year post randomization of 0.74 (95% CI: 0.65-0.84) after adjustment for optimism bias.
Conclusion: The cumulative risk for hydrothorax increased with serum bilirubin and antidiabetic treatment, whereas treatment with non-selective beta-blockers decreased it.

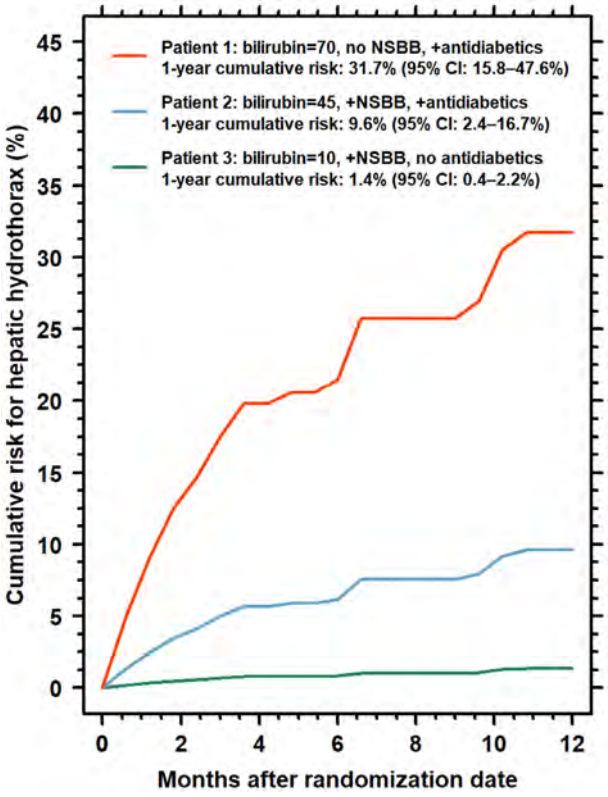


Figure: Illustration of the estimated cumulative risk for hepatic hydrothorax based on our prediction model for patients with 'high' (Patient 1), 'intermediate' (Patient 2), and 'low' (Patient 3) risk for hepatic hydrothorax. The values of each predictor are shown. NSBB = non-selective beta-blockers.

SAT-030

Annual contrast-enhanced MRI is highly effective in the surveillance of hepatocellular carcinoma in cirrhotic patients

Coskun Ozer Demirtas[1], feyza gunduz[1], Davut Tuney[2], Feyyaz Baltacioglu[2], Yesim Alahdab[1], Osman Cavit Ozdogan[1].
[1]Marmara University, School of Medicine, Gastroenterology, Istanbul, Turkey; [2]Marmara University Research And Education Hospital, Radiology, Istanbul, Turkey
Email: coskun_demirtas10@hotmail.com

Background and aims: Current guidelines recommend patients with cirrhosis to undergo surveillance for hepatocellular carcinoma (HCC) with biannual ultrasonography (USG). However, the sensivity of USG to detect early stage HCC is suboptimal. We aimed to investigate the effectiveness of surveillance with annual contrast-enhanced magnetic resonance imaging (MRI) to detect HCC in earlier stages.

Method: We reviewed the prospectively collected data of 1261 cirrhosis patients, who were followed in our hospital between 2008 and 2018, to determine the patients with appropriate annual MRI surveillance. Patients were determined as low, intermediate and high risk HCC patients according to Toronto Risk Score. We recorded surveillance-related benefits, defined as early tumor detection and curative treatment, and surveillance-related physical harms, defined as computed tomography or magnetic resonance imaging scans, biopsies, or other procedures performed for false-positive or indeterminate surveillance results.

Results: A total of 294 (23.3%) patients underwent 989 MRI screenings in 10 years period. Thirty-five (11.9%) patients developed HCC, of whom 25 (72.7%) were detected at earlier stages (BCLC A or B) and 29 (84.8%) fulfilled Milan criteria. Twenty-nine (82.9%) were high risk HCC patients at the entry, while 4 (11.4%) were intermediate risk and 2 (5.7%) were low risk at the entry. Surveillance with annual MRI had a sensivity rate of 97.1% and specifity rate of 95.3% with an area under the receiver operating characteristic curve (AUC) of 0.96 (%95 confidence interval; 0.92-0.99) for the detection of HCC. Combination of annual MRI and AFP didn't add any value to MRI alone in detecting HCC (sensivity : 97.1%, specifity : 93.4%, AUC : 0.95). Surveillance-related benefits were observed in 28 (9.5%) patients, while only 16 (5.4%) experienced surveillance-related physical harms.

Table 1: General characteristics of patients who underwent surveillance with annual MRI for the detection of HCC

Age	60.24 (29-86)
Gender (M/F)	148 (50.3%)/146 (49.7)
Etiology of cirrhosis	
HBV	122 (41.5%)
HCV	58 (19.7%)
NASH	25 (8.5%)
ASH	21 (7.1%)
Others	68 (23.1%)
BMI	29.09 (17.72-47.75) kg/m^2
Child-Pugh Score	
A	229 (77.9%)
B	58 (19.7%)
C	7 (2.4%)
MELD	9 (6-16)
Toronto risk score	
< 120 (low risk)	27 (9.2%)
120-240 (intermediate risk)	139 (47.3%)
> 240 (high risk)	128 (43.5%)
AFP	4.57 (0.1-18) ng/ml
Tumor size	24.55 (8-70) mm
Number of tumors	
1	28 (72.5%)
2	5 (15%)
3	2 (7.5%)
HCC stage	
A (very early)	14 (42.4%)
B (early)	11 (30.3%)
C (intermediate)	10 (27.3%)
D (advanced)	0
Initial treatment	
Transplantation	6 (18.2%)
Rf ablation	19 (18%)
TACE	9 (24.2%)
BSC	1 (3%)

Conclusion: HCC surveillance with annual contrast-enhanced MRI alone has a high sensivity and specifity to detect HCCs in earlier stages in patients with cirrhosis with negligible surveillance-related physical harms in clinical practice.

SAT-031

Bleeding risk-scores for prediction of acute variceal bleeding outcome

Marwa Elfayoumy[1], Mohamed Eltabbakh[1], Prof. Dr. Gamal Badra[1], Eman Rewisha[1], Imam Waked[1]. *[1]National Liver Institute, Menoufia University, Hepatology and Gastroenterology Department, Menoufia, Egypt*
Email: elfayomymarwa@gmail.com

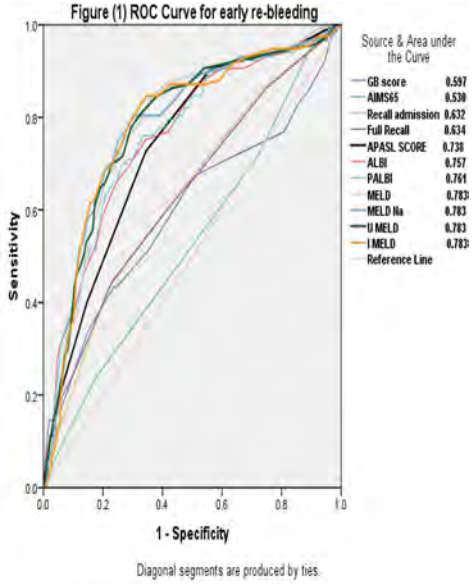
Background and aims: Variceal bleeding is a devastating complication of portal hypertension. The six-week mortality in patients with liver cirrhosis is 17%-28% and the risk of re-bleeding after acute variceal hemorrhage (AVH) is highest within the first six weeks with a peak in the first 5 days. This study is to evaluate bleeding risk-scores for predicting bleeding control, re-bleeding and six-week mortality in patients with acute variceal bleeding.

Method: Patients presenting with acute variceal bleeding were prospectively evaluated. Patients were resuscitated, were given intravenous antibiotics, and received blood and vaso-active drugs as needed. Endoscopy was performed as early as feasible within the first six hours of admission.

The following scores were calculated on admission and/or after urgent endoscopy: AIMS65, Glasgow Blatchford, Rockall and full Rockall score, the platelet-albumin-bilirubin (P-ALBI), ALBI, MELD, IMELD, MELD-Na, UMELD and the APASL severity score. Scores were correlated to control of acute bleeding, re-bleeding, in-hospital mortality, and 6 weeks mortality.

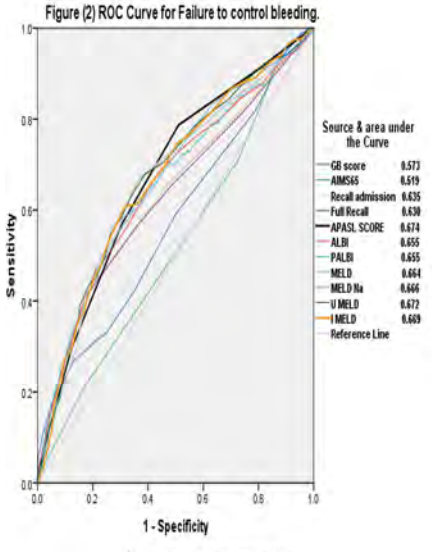
Results: Esophageal and/or gastric varices was the cause of acute bleeding in 703 cirrhotic patients (71.4% males, mean age 58.1 ± 10.3 years, 43.1% presenting with first attack of hematemesis, 38.3% had HCC, 21.5% had portal vein thrombosis, 18.2% with blood spurting from esophageal and/or gastric varices on endoscopy, 14.1% Child-Turcotte-Pugh (CTP) A, 47.2% CTP B, 38.7% CTP C). Bleeding was controlled in 422 patients (59.9%) and 210 patients died (29.8%), 122 patients (20.5%) during hospitalization, 69 patients died from cause not related to the acute hemorrhage (9.8%), 281 patients (39.9%) had re-bleeding after the first week. The area under the ROC curve (AUROC) for failure to control bleeding, mortality in hospitalization and at 6 weeks for each score are shown in the figures, with the IMELD score of > 31.5 offering the best prediction of bleeding control and mortality during hospitalization and at 6 weeks.

Figure (1) ROC Curve for early re-bleeding



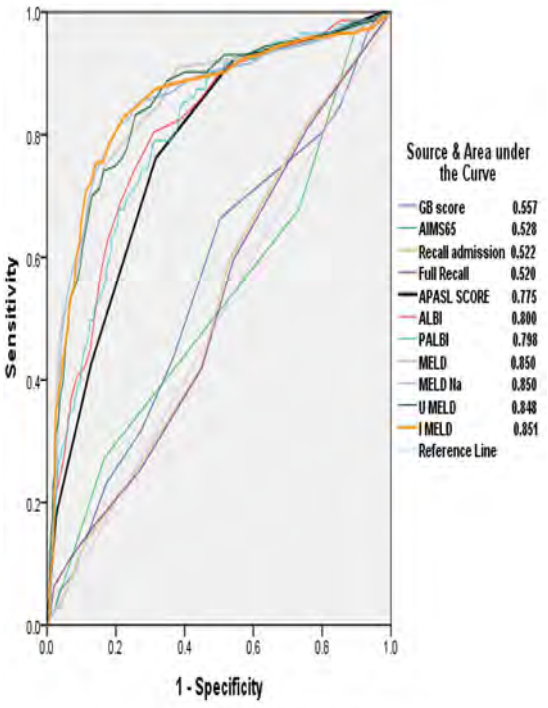
Diagonal segments are produced by ties.

Figure (2) ROC Curve for Failure to control bleeding.



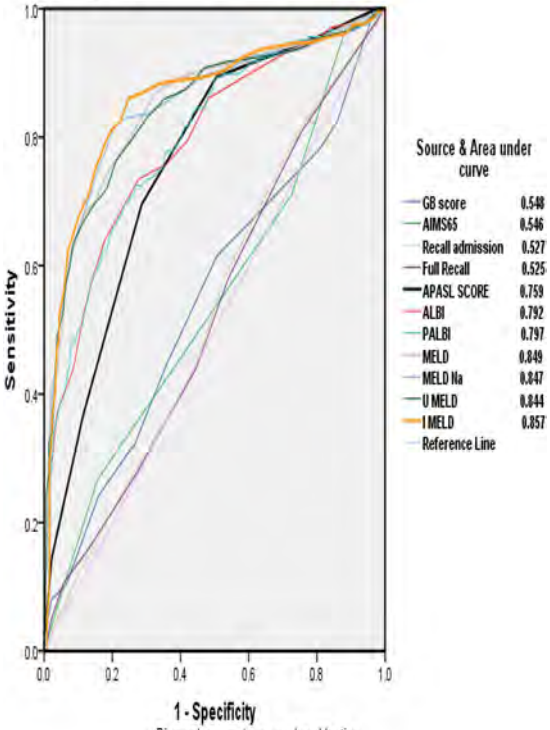
Diagonal segments are produced by ties.

Figure (3) Roc Curve for in hospital mortality



Diagonal segments are produced by ties.

Figure (4) ROC Curve for 6 weeks mortality.



Diagonal segments are produced by ties.

Conclusion: IMELD predicts re-bleeding, mortality during hospitalization and at 6 weeks following acute variceal bleeding better than other bleeding severity scores.

SAT-032

Spleen to liver stiffness ratio significantly differs between ALD and HCV and predicts disease specific complications

Omar Elshaarawy[1], Johannes Mueller[1], Indra Neil Guha[2], Jane Chalmers[2], Rebecca Harris[3], Maja Thiele[4], Bjørn Stæhr Madsen[4], Aleksander Krag[4], Horia Stefanescu[5], Oana Stancu[6], Andreea Ardelean[6], Sebastian Mueller[1]. *[1]University of Heidelberg, Department of Medicine Salem Medical Center and Center for Alcohol Research, Heidelberg, Germany; [2]Nottingham University Hospitals NHS, Nottingham Digestive Diseases Centre, Nottingham, United Kingdom; [3]Nottingham University Hospitals NHS, Nottingham Digestive Diseases Centre, Nottingham, United Kingdom; [4]Odense University Hospital, Department of Gastroenterology and Hepatology and Odense Patient data Exploratory Network, Odense, Denmark; [5]Regional Institute of Gastroenterology and Hepatology, Department of Hepatology and Liver Research Club, Cluj-Napoca, Romania; [6]University of Medicine and Pharmacy Cluj-Napoca, Department of Internal Medicine, 3rd Medical Clinic and Liver Research Club, Cluj-Napoca, Romania*
Email: sebastian.mueller@urz.uni-heidelberg.de

Background and aims: Both liver stiffness (LS) and spleen stiffness (SS) are widely used to non-invasively assess liver fibrosis and portal hypertension, respectively. However, the impact of portal and lobular inflammation (HCV vs ALD) on SS/LS remains unclear so far.

Methods: LS and SS were prospectively assessed in 411 patients with ALD and HCV using Fibroscan (Echosens, Paris) including the effects of treatment interventions (alcohol withdrawal, HCV therapy). LS and spleen size were further analysed in a retrospective cohort of 449 patients with data on to in related to with liver-related decompensation and death.

Results: Both, SS and spleen size were significantly higher in HCV as compared to ALD (42.0 vs 32.6 kPa, $P < 0.0001$, 15.6 vs 11.9 cm, $P < 0.0001$) despite a lower mean LS in HCV (14.9 vs 28.5 kPa). Consequently, the SS/LS and spleen size/LS ratio were significantly higher in HCV (3.8 vs 1.72, $P < 0.0001$ and 1.46 vs 0.86, $P < 0.0001$) and it remained higher in HCV through all fibrosis stages. After treatment, LS significantly decreased in both diseases while SS only significantly declined in HCV. No significant changes of SS/LS were observed during treatment. In the prognostic cohort, ALD patients had higher LS values (30.5 vs 21.3 kPa), predominantly presented for jaundice (65.2%) which was also the major cause of death ($p < 0.01$). In contrast, in HCV, spleens were larger (17.6 vs 12.1 cm), the primary sign of decompensation (73.2%) and major cause of death ($p < 0.001$) was variceal bleeding.

Table showing a comparison between matched cohorts for LS

Parameter	ALD	HCV	P
Age	52.6 ± 10.8	54.8 ± 10.5	0.163
BMI	26.2 ± 4.0	25.5 ± 4.5	0.288
Sex	69%	67%	0.747
LS (kPa)	19.0 ± 11.7	19.8 ± 9.3	0.629
SS (kPa)	27.8 ± 17.6	47.7 ± 13.0	<0.001
Spleen size (cm)	11.8 ± 2.1	15.3 ± 2.8	<0.001
AST	73 ± 88	58 ± 44	0.0569
Albumin	4.0 ± 0.5	4.1 ± 0.5	0.040
Bili	1.6 ± 1.5	0.9 ± 0.5	<0.001
Platelets	174 ± 93	117 ± 51	<0.001
INR	1.4 ± 0.5	1.0 ± 0.2	<0.001

Conclusion: Both the SS/LS and the spleen size/LS ratio are significantly higher in patients with portal disease such as HCV as compared to lobular disease (ALD) and it predicts disease-specific complications and survival such as liver failure in ALD and variceal bleeding in HCV. In conclusion, combined LS and SS measurements provide additional information about disease aetiology and potential risk of decompensation.

SAT-033

Body fat composition determines outcomes before and after liver transplantation in cirrhosis

Cornelius Engelmann[1,2], Stefan Schob[3], Ines Nonnenmacher[2], Luise Werlich[3], Jane Macnaughtan[1], Alexander Hung[1], Niklas Aehling[2], Adam Herber[2], Alexey Surov[3], Thorsten Kaiser[4], Rajiv Jalan[1], Daniel Seehofer[5], Michael Moche[3], Thomas Berg[2]. *[1]Liver failure group-ILDH, University College London, London, United Kingdom; [2]University Hospital Leipzig, Section Hepatology, Leipzig, Germany; [3]University Hospital Leipzig, Department of Diagnostic and Interventional Radiology, Leipzig, Germany; [4]University Hospital Leipzig, Institute of Laboratory Medicine, Clinical Chemistry and Molecular Diagnostics, Leipzig, Germany; [5]University Hospital Leipzig, Department of Visceral, Vascular, Thoracic and Transplant Surgery, Leipzig, Germany*
Email: cornelius.engelmann@medizin.uni-leipzig.de

Background and aims: A low body fat content in cirrhosis has been recently shown to be associated with poor outcome before liver transplantation. We conducted a study comparing different CT derived fat parameters regarding its prognostic impact on the development of complications and death on the waiting list and after liver transplantation.

Method: 612 patients with liver cirrhosis and no HCC listed for transplantation between 2001 and 2014 met the inclusion and exclusion criteria; including an abdominal CT scan (± 200 days to listing). 109 non-cirrhotic patients CT scan after polytrauma acted as controls. The paraspinal muscle fat index (PSFI), the subcutaneous fat index (SCFI) and the visceral fat index (VFI) were assessed at L3/L4 level, normalized to the height (cm^2/m^2). Parameters' cut offs were calculated according to the upper or lower tertile, as appropriate.

Results: Of 612 patients with liver cirrhosis, 63.6% had alcoholic liver disease, and 66.7% were male. The PSFI ($p = 0.002$), the SCFI ($p = 0.002$) and the VFI ($p < 0.001$) were lower in cirrhosis compared to controls. At baseline a low SCFI was associated with a higher rate of ascites ($p < 0.001$) and higher CRP levels ($p < 0.001$). Patients with high PSFI and VFI had higher creatinine values ($p < 0.001$), WBC levels ($p = 0.023$; $p = 0.007$) and more often metabolic complications such as diabetes ($p < 0.001$), arterial hypertension ($p < 0.001$) and increased BMI ($p < 0.001$) whereas the liver function (MELD score, Child-Pugh score) was not different between groups. After multivariate Cox regression analysis adjusting for age, BMI and MELD an increasing SCFI was associated with reduced risk of cirrhosis related complications (any complication HR 0.984 ($p = 0.001$), bacterial infection HR 0.984 ($p = 0.001$), SBP HR 0.97 ($p < 0.001$) and death (HR 0.985 ($p = 0.023$) on the transplant waiting list in both genders whereas a increased PSFI (HR 1.343 (1.133-1.592), $p = 0.001$) and VFI (HR 1.021 (1.006-1.036) were predictive for death within 1-year after transplantation only in men (fig 1).

Conclusion: The distribution of body fat is a major determinant for complications in cirrhosis before and after liver transplantation and results highlight the gender as a confounding factor. Further research on whether CT derived fat parameter should be implemented in patient prioritisation on the waiting list and surveillance strategies before and after liver transplantation is necessary.

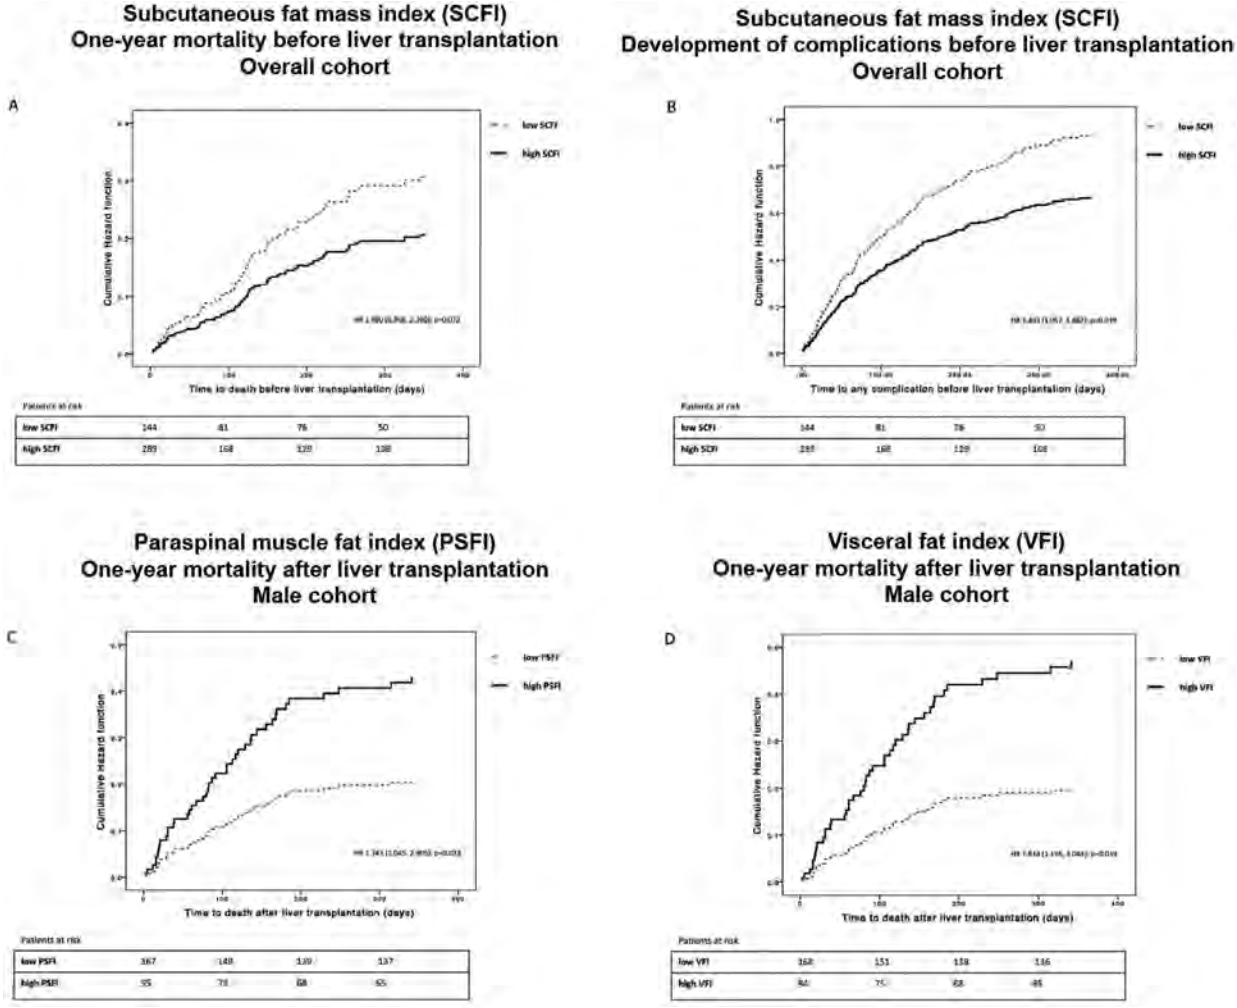


Figure: (abstract: SAT-033): Risk of death and complications in patients with low SCFI (A, B) or high PSFI (C) and VFI (D)

SAT-034

The psychomotor vigilance task: Role in the diagnosis of hepatic encephalopathy and relationship with driving ability

Chiara Formentin[1], Michele De Rui[1], Mirko Zoncapè[1], Silvia Ceccato[1], Lisa Zarantonello[1], Marco Senzolo[2], Patrizia Burra[2], Paolo Angeli[1], Piero Amodio[1], Sara Montagnese[1]. [1]*University of Padova, Department of Medicine, Padova, Italy;* [2]*University of Padova, Department of Surgery, Oncology and Gastroenterology, Padova, Italy*
Email: chiara.formentin@hotmail.it

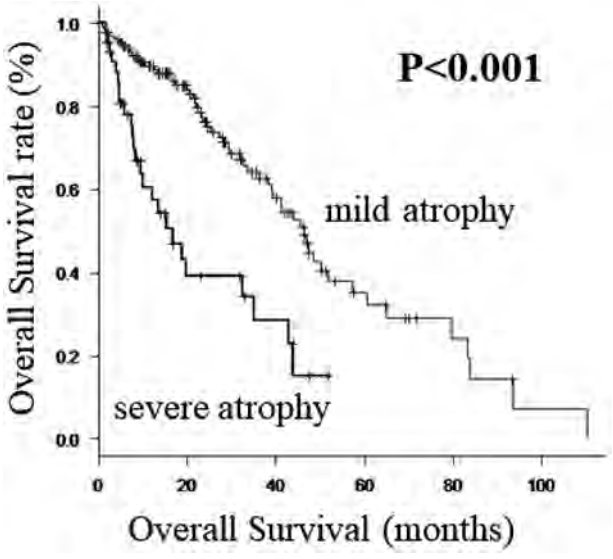
Background and aims: Hepatic Encephalopathy (HE) can be interpreted as a syndrome of decreased vigilance, and has been associated with impaired driving ability. The aim of the present study was to evaluate the Psychomotor Vigilance Task (PVT), which is used to assess both vigilance and driving ability, in a group of patients with cirrhosis and varying degree of neuropsychiatric impairment.
Method: 145 patients (120 males, 59 ± 10 years, MELD 13 ± 5) underwent the PVT; a subgroup of 117 also completed a driving questionnaire; a subgroup of 106 also underwent the Psychometric Hepatic Encephalopathy Score (PHES) and the electroencephalogram (EEG), based on which, plus a clinical evaluation, they were classed as unimpaired (n = 51), as having minimal (n = 35) or overt HE (n = 20). All were followed up for an average of 13 ± 5 months in relation to the occurrence of accidents/traffic offences, HE-related hospitalizations and death. Sixty-six healthy volunteers evenly distributed by sex, age and education served as reference for the PVT.
Results: Patients as a group showed worse PVT performance compared to healthy volunteers, and PVT indices significantly correlated with MELD, ammonia levels, PHES and the EEG. Significant associations were observed between neuropsychiatric performance (unimpaired/minimal/overt) and license/driving status; PVT indices were also significantly different between classes of license/driving status. PVT, PHES and the EEG all predicted HE-related hospitalizations and death over the follow-up period; none predicted accidents/traffic offences. However, individuals with the slowest reaction times/most lapses on PVT were often not driving albeit in possession of a license. When patients whose own insecurity/doctor/family had stopped them driving because of HE-related reasons (n = 6 out of the 14 not driving despite having a license) were modeled as having an accident/fine over the subsequent 6 or 12 months (assumed accident/fine dates: 3 and 6 months, respectively), the PVT parameter lapses was a predictor of accidents/traffic offences, also after correction for MELD and age.
Conclusion: the PVT is worthy of further study in patients with cirrhosis, for purposes of both HE quantification and the assessment of driving ability.

SAT-035

The negative impact of skeletal muscle volume loss during transarterial chemoembolization for hepatocellular carcinoma

Masashi Fujita[1], Atsushi Takahashi[1], Hiromasa Ohira[1]. [1]*Fukushima Medical University School of Medicine, Gastroenterology, Fukushima, Japan*
Email: mfujita@fmu.ac.jp

Background and aims: Sarcopenia has a negative impact on the prognosis of patients with hepatocellular carcinoma (HCC). We investigated the significance of skeletal muscle volume and its changes in HCC patients receiving transarterial chemoembolization (TACE).
Method: We retrospectively analyzed 179 HCC patients receiving TACE from 2006 to 2017. Skeletal mass index was calculated as the left-right sum of the major × minor axis of the psoas muscle at the third lumbar vertebra, divided by height squared (psoas muscle index [PMI]). Patients were classified into two groups (low and normal PMI) depending on an index < 6.0 and < 3.4 cm2/m2 for men and women, respectively. We assessed overall survival (OS) and TACE period (between the first TACE (pre) and the time of TACE refractoriness (post)). Changes in PMI per month during TACE period (CPMI; (PMI [pre]-PMI [post])/TACE periods) were calculated as an index of progressive muscle atrophy. Patients were classified into two groups (severe and mild muscle atrophy) depending on CPMI above the upper quartile.
Results: There were no significant differences in OS between groups with low and normal PMI at pre. Multivariate analysis showed that CPMI was significantly associated with poor OS (hazard ratio, 1.884; p = 0.001). Patients with severe muscle atrophy had a significantly lower OS than those with mild muscle atrophy (p < 0.001). Compared with patients with mild muscle atrophy, patients with severe muscle atrophy had a significant loss of liver function reserves at post.



Conclusion: Progressive loss of skeletal muscle volume is an important predictor of poor prognosis in patients with HCC treated by TACE. Preventing skeletal muscle volume loss is essential for good prognosis in patients with HCC.

SAT-036

Prognostic implications of encephalopathy to adequately define differentiated stages of decompensated cirrhosis

Marta García Guix[1], Edilmar Alvarado[1], Alba Ardevol[1], rosa montañés[1], Berta Cuyas[1], bea de riba[1], carlos gonzalez[1], ana brujats[1], Maria Poca[1], Xavier Torras[1], Carlos Guarner[1], German Soriano[1], Candid Villanueva[1]. [1]*Hospital de Sant Pau i la Sant Creu, Barcelona, Spain*
Email: martagguix89@gmail.com

Background and aims: In decompensated cirrhosis, ascites and variceal bleeding are the main decompensating events, and are well characterized. Hepatic encephalopathy (HE) usually occurs in top of these complications and worsens prognosis. This study aimed to clarify whether the development of encephalopathy has particular prognostic implications and hemodynamic features, which may define a differentiated stage in decompensated cirrhosis.
Method: We consecutively included patients admitted due to variceal bleeding (VB), differentiating those with bleeding-alone from those who also had ascites, and patients with ascites and varices without previous bleeding referred for primary prophylaxis. Patients with present (or previous) encephalopathy were identified to investigate the role in the prognosis of each stage of decompensated cirrhosis. Portal pressure was measured in all patients before starting therapy with β-blockers. Risk of outcomes was estimated in a competing risks framework considering death and liver transplant as competing events.
Results: 267 patients with VB (177 of them with ascites) and 131 with ascites without VB were included. Of these, 55 patients (33%) with VB-plus-ascites and 20 (15%) with ascites-alone had present HE. Patients with HE had significantly worse liver function than those without encephalopathy in each subgroup. The HVPG progressively worsen from patients with VB-alone to those with ascites-alone (17.9 ± 4 vs 19.4 ± 5 mmHg, P = 0.02) and to those with VB-plus-ascites (21.1 ± 4mmHg, P = 0.01). Among patients with ascites-alone, those with-HE had similar HVPG than those without-HE, while among patients with VB-plus-ascites those with-HE had higher HVPG than those without-HE (22.2 ± 5 vs 20.3 ± 5 mmHg, P = 0.05). The probability of survival without liver transplant (OLT) was better in patients with VB-alone than in those with ascites-alone (83%vs69% at 3 y, P = 0.01) and was better in these than in those with VB-plus-ascites (69%vs 49% at3y, P < 0.001). Among patients with ascites-alone, the probability of survival without OLT was worse in patients with-HE than in those without-HE (35%vs72% at 3 y, P = 0.03). Among patients with VB-plus-ascites, the probability of survival without OLT was worse in patients with-HE than in those without-HE (36% vs 55% at 3 y, P = 0.005). Overall, encephalopathy was an independent predictor of death or OLT (HR = 1.57, 95%CI = 1.04-2.38) after adjusting for relevant baseline factors including MELD, etiology of cirrhosis, HCC and age.
Conclusion: In each stage of decompensated cirrhosis, either ascites alone or VB plus ascites, HE is associated with worse liver function and a trend toward higher HVPG, and is also independently associated with greater risk of death or OLT. This suggests that in all stages of decompensated cirrhosis encephalopathy identify a sub-stage with worse prognosis.

Email: alexgeo@hua.gr

Background and aims: Malnutrition is common among cirrhotic patients and affects their quality of life and survival. An algorithm for nutritional screening and assessment in cirrhotic patients has been included in 2018 EASL guidelines on nutrition in chronic liver disease. The aim of our study was to apply this algorithm in a sample of cirrhotic patients and examine the association of malnutrition diagnosis with 1-year survival.
Method: 171 cirrhotic patients (57.3% male, mean age 59.5 ± 10.6 years) of any etiology and stage (50.9% compensated) were enrolled. Child-Pugh score (CP), dry weight in case of fluid retention and body mass index (BMI) were estimated. Nutritional screening was performed using the Royal Free Hospital Nutritional Prioritizing Tool and nutritional assessment using Subjective Global Assessment. Dietary intake (DI) was estimated utilizing three 24h recalls and considered adequate if it exceeded 75% of estimated needs. Appendicular Skeletal Muscle Index (ASMI) resulting from DEXA was used as an indicator of sarcopenia. Physical performance was assessed with Short Physical Performance Battery (SPPB). Data on one-year survival was available in a subgroup of 74 patients.
Results: According to CP, 119 (69.6%) patients were categorized as class A, 41 (24%) as B and 11 (6.4%) as C. Based on BMI, 2 (1.2%) patients were underweight, 51 (29.8%) had normal weight, 50 (29.2%) were overweight and 68 (39.8%) were obese. In the total sample, 11.7% of patients were at moderate and 31.6% at high risk for malnutrition. According to the proposed EASL algorithm 28.7% were malnourished, 7% sarcopenic and 0.6% sarcopenic obese. Malnutrition and sarcopenia were more prevalent in underweight/normal weight compared to overweight/obese (both $p < 0.001$), in alcoholic etiology disease ($p = 0.006$ and $p = 0.014$) and in CP classes B-C (both $p < 0.001$). Sarcopenia prevalence was also higher in men (12.2% vs 1.4% in women, $p = 0.008$). Malnutrition was inversely associated with 1-year survival (OR = 0.13, 95%CI 0.03-0.63, $p = 0.01$) after adjustment for age, decompensation and ASMI and so was sarcopenia (OR = 0.11, 95%CI 0.02-0.81, $p = 0.03$) after adjustment for age, decompensation and low DI.
Conclusion: According to EASL algorithm, the total prevalence of malnutrition was 28.7%, while 7.6% were classified as having sarcopenia. Furthermore, malnutrition and sarcopenia were inversely associated with 1-y mortality in cirrhotic patients.

SAT-038

Lusutrombopag for treatment of thrombocytopenia in patients with chronic liver disease who are undergoing planned invasive procedures: pooled safety analysis of bleeding-related adverse events

Edoardo Giovanni Giannini[1], Takeshi Kano[2], Toshimitsu Ochiai[3], Roy Bentley[4], Pomy Shrestha[5]. *[1]Universita Degli Study Di Genova, Dipartimineto di Medicina Interna e Specialita Mediche, Genova, Italy; [2]Shionogi and Co., Ltd., Global Project Management Department, Osaka, Japan; [3]Shionogi and Co., Ltd., Biostatistics Center, Osaka, Japan; [4]Shionogi Inc., US Global Market Access, Florham Park, NJ, United States; [5]Shionogi Inc., Product Safety and Pharmacovigilance, Florham Park, NJ, United States*
Email: egiannini@unige.it

Background and aims: Thrombocytopenia (TCP) is a common complication in patients (pts) with chronic liver disease (CLD). Lusutrombopag (LUSU) is a thrombopoietin receptor agonist approved in Japan (2015) and US (2018) for pts with TCP-CLD undergoing an invasive procedure. A pooled safety analysis was performed to assess differences in bleeding events (BE) following LUSU treatment, with or without platelet transfusion (PT).
Method: Safety data were pooled from 3 double-blind, placebo-controlled studies, in pts with TCP-CLD undergoing planned invasive procedure (Phase 2b: M0626; Phase 3: L-PLUS 1, L-PLUS 2). Pts enrolled in these studies were randomised to LUSU 3 mg or placebo (PBO) for up to 7 days prior to procedure. PT was administered if platelet count was $< 50\times10^9$/L prior to procedure. Pts were classified into 1 of 4 subgroups: LUSU with or without PT or PBO with or without PT. BE were summarized pre-, during, and post-procedure.
Results: Lower BE rates, regardless of severity and timing of onset, were observed for LUSU alone vs PBO+PT (Table). Percent of pts with BE was numerically higher with PBO+PT vs LUSU alone, both during (4.8% vs 3.2%) and post-procedure (7.1% vs 4.0%). Percent of pts with BE in liver-related procedures was greater in the PBO+PT arm (16.1%) vs LUSU alone (11.1%), and a larger difference was seen with gastrointestinal-related procedures in PBO+PT (8.9%) vs LUSU alone (2.0%).

Table: Bleeding Events by Severity and Timing of Onset (Pooled Safety Data)

Patients (%) [BE]	Pre-Procedure[a]	Procedure[b]	Post-Procedure[c]
Placebo with PT (n = 126)			
Severe	0	0	1 (0.8) [1]
Moderate	0	2 (1.6) [2]	0
Mild	12 (9.5) [14]	4 (3.2) [4]	8 (6.3) [13]
Total	12 (9.5) [14]	6 (4.8) [6]	9 (7.1) [14]
LUSU 3 mg without PT (n = 124)			
Severe	0	0	0
Moderate	0	0	1 (0.8) [1]
Mild	4 (3.2) [5]	4 (3.2) [4]	4 (3.2) [4]
Total	4 (3.2) [5]	4 (3.2) [4]	5 (4.0) [5]

Represented as: # of pts (% pts with BE) [# of events]
Pts could be counted >1x in same time period if they experienced 2 BE with different severities, but only 1x if severity was the same
The same patient could be counted > 1x if they experienced BE in different time periods
[a]Pre-procedure: BE prior to procedure. Includes BE in pts who did not undergo invasive procedure
[b]Procedure: BE on day of procedure (day 1)
[c]Post-procedure: BE after day of procedure (after day 1) regardless of procedural haemorrhage

Conclusion: In this post-hoc analysis, a trend toward lower BE rates was observed with LUSU alone vs PBO+PT, regardless of type of invasive procedure.

SAT-039

The assessment of sarcopenia by quadriceps muscle ultrasound in patients with liver cirrhosis

Stefania Gioia[1], Barbara Lattanzi[1], Stefano Ginanni Corradini[1], Daria D'ambrosio[1], Nicoletta Fabrini[1], Angelo Bruni[1], Alessandra Pigliacelli[1], Adriano De Santis[1], Manuela Merli[1]. *[1]Sapienza, Università di Roma, Department of Clinical Medicine, Rome, Italy*
Email: stensgioia@hotmail.com

Background and aims: Sarcopenia is a frequent complication in cirrhotic patients associated with worse prognosis. To date, Computed Tomography (CT) is considered the gold standard to quantify muscle mass in cirrhotic patients but it is not usable only for muscle assessment due to the cost, radiation exposure and logistics difficulties. Quadriceps muscle thickness detection by ultrasound has been recently proposed as an easier bedside tool to assess sarcopenia. The aim of our study was to evaluate the role of quadriceps thickness pressure index (TPI) in the detection of sarcopenia in comparison to CT assessed skeletal muscle index (SMI) in cirrhotic patients.

Method: Consecutive cirrhotic patients, who performed a CT scan between +8/-8 weeks from outpatient visit were included. Sarcopenia was evaluated by L3 SMI using the following cut-offs: < 39 cm^2/m^2 for females and < 50 cm^2/m^2 for males. The TPI was performed in the middle point on the line connecting the patella with the upper anterior iliac spine. Three measurements with pressure to collapse the muscle as much as possible were taken. TPI was obtained by the average of these measures normalized for the height².
Results: Eighty-three patients were enrolled in the study and the 58% of them were sarcopenic, according to CT scan. Sarcopenic patients were older (64 ± 10 vs 58 ± 8 p = 0.009), had a lower BMI (23 ± 3 vs 28 ± 4 p < 0.001) and lower TPI (4.6 ± 1.1 vs 7.1 ± 2.2 p < 0.001). We found a positive correlation between SMI and TPI (r^2 = 0.43; p < 0.001). The AUC for TPI considering sarcopenia by SMI was 0.79.

VARIABLES	SARCOPENIC PATIENTS n = 48 (58%)	NON-SARCOPENIC PATIENTS n = 35 (42%)	P value
Age (years)	64 ± 10	58 ± 8	0.009
Male gender n (%)	42 (%)	25 (87%)	0.06
Etiology of liver disease n (%) Viral Hepatitis NAFLD Alcohol Other	 (48%) (27%) (22%) (3%)	 (50%) (25%) (25%) 0	0.8
BMI (Kg/h²)	23 ± 3	28 ± 4	< 0.0001
Presence of HCC n (%)	25 (%)	15 (%)	0.7
SMI (cm^2/m^2)	42.8 ± 5.1	54.5 ± 8.1	< 0.0001
TPI (mm/m²)	4.6 ± 1.1	7.1 ± 2.2	< 0.0001

Values are expressed as mean ± standard deviation.
Abbreviations: NAFLD = non-alcoholic fatty liver disease; BMI = body mass index; HCC = hepatocellular carcinoma; TPI = quadriceps thickness pressure index.

Table: Characteristics of the patients based on the presence of sarcopenia.

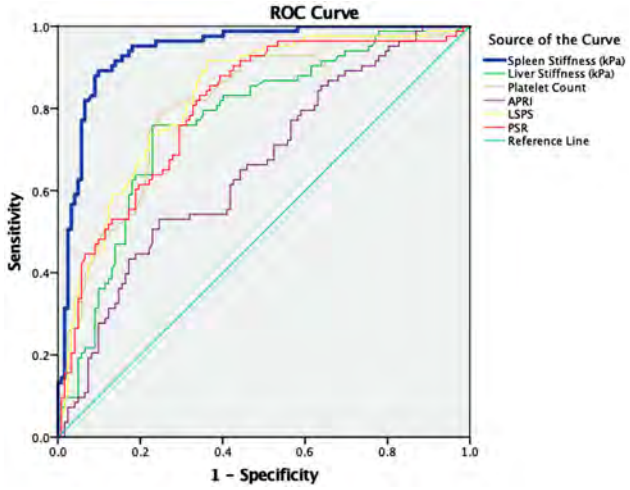
Conclusion: The results of our study show that TPI is an effective index for the assessment of muscle depletion in cirrhotic patients. Ultrasound assessment of sarcopenia may allow monitoring the patients' nutritional status over time.

SAT-040

Is spleen stiffness the new frontier for non-invasive assessment of portal hypertension?

Mauro Giuffrè[1], Daniele Macor[1], Flora Masutti[2], Fabio Tinè[2], cristiana abazia[2], Riccardo Patti[1], Matteo Rossano Buonocore[1], Anna Colombo[1], Alessia Visintin[1], Michele Campigotto[1], Fabio Monica[3], Saveria Lory Croce'[1,2,4]. *[1]Università degli Studi di Trieste, Dipartimento Universitario Clinico Di Scienze Mediche Chirurgiche e Della Salute, Università Degli Studi Di Trieste, Trieste, Italy; [2]Azienda Sanitaria Universitaria Integrata di Trieste, Clinica Patologie del Fegato, Trieste, Italy; [3]Azienda Sanitaria Universitaria Integrata di Trieste, SC di Gastroenterologia ed Endoscopia Digestiva, Trieste, Italy; [4]Fondazione Italiana Fegato, Trieste, Italy*
Email: gff.mauro@gmail.com

Background and aims: Elastography is a cutting-edge methodology, which has brought great enthusiasm to the study of tissue elasticity. Guidelines have been issued on liver stiffness (LS) in the clinical setting of liver cirrhosis and esophagogastroduodenoscopy (EGD) screening for esophageal varices (EVs). Our study aims to analyze spleen stiffness (SS) as a non-invasive method for the diagnosis of clinically significant portal hypertension (CSPH) in order to avoid EGD in low-risk patients for EVs.
Method: we measured the SS and LS in 205 patients with liver cirrhosis who had undergone endoscopic screening for esophageal varices. Besides, we enrolled 100 healthy controls (with previous EGD) who were negative for hepatic and lymphoproliferative disease. We used a 1-5 MHz convex probe for the ultrasound and elastographic (point Shear Wave Elastography, pSWE) examination. We compared SS discriminatory capacity for the presence of EVs to that deriving from other non-invasive procedures (LS, splenic dimensions, platelet count, APRI, PSR and LSPS). Optimal SS cut-offs were sought to exclude the presence of varices. We searched for correlations between SS and indirect signs of portal hypertension such as spleen dimension, platelet count and presence of portal hypertensive gastropathy (PHG).
Results: Cirrhotic patients have significantly higher SS and LS values than controls. SS was higher in cirrhotic patients with EVs (n = 83) v.s. patients without EVs (n = 122) and healthy controls (p < 0.001). SS showed an AUROC of 0.94 (95% C.I., 0.91-0.97), statistically different from the other predictors (p < 0.001). The cut-off, chosen according to Youden's Index of 38.69 kPa, showed sensitivity of 89.2%, specificity of 90.2%, NPV of 92.4%, and PPV of 86%. The cut-off of 30.23 kPa had 100% sensitivity and 100% NPV. The cut-off of 69.73 kPa demonstrated specificity and PPV of 100%. Correlation between SS and LS with PHG was equal to r_{pb} = 0.358 and r_{pb} = 0.286 respectively. The SS demonstrated higher correlation with splenic bipolar diameter (r = 0.363) and area (r = 0.420) if compared to LS (r = 0.263 and r = 0.328). Moreover, SS showed an association with platelet count greater than LS (r = 0.55 v.s. r = 0.38).



Conclusion: SS can play an essential role in the daily clinical management of cirrhotic patients with CSPH. LS has proven to be less performant as a predictor of EVs (AUROC 0.77), whereas both PSR and LSPS showed a slightly better performance (AUROC 0.81 and 0.83 respectively). SS showed significantly higher performance than other parameters, proving to be the best non-invasive test in the screening of EVs. We demonstrated that there is a certain degree of correlation between SS and splenic dimensions, platelet count and PHG; and that the actual correlation is superior to the one present between LS and those parameters. Overall, SS performed as a better surrogate in the study of portal hypertension and its consequences.

SAT-041

The adjunct of sarcopenia with MHE increases the 1 year risk of developing OHE

Rohit Gupta[1,2], James Thomas[1,2], Greg Anderson[2,3], Tony Rahman[1,2,4].
[1]*Centre for Service and Quality Improvement, Department of Gastroenterology and Hepatology, The Prince Charles Hospital, Brisbane, Australia;* [2]*The University of Queensland, Brisbane, Australia;* [3]*QIMR Berghofer Medical Research Institute, Brisbane City, Australia;* [4]*James Cook University, Cairns Campus, Smithfield, Australia*
Email: rogupta85@hotmail.com

Background and aims: Minimal hepatic encephalopathy (MHE) and sarcopenia are both underecognised complications of cirrhosis. Liver cirrhosis leads to sarcopenia by a decrease in muscle substrate production and an increase in muscle breakdown. This occurs by a reduction in the glycogen production by the liver leading to muscle proteolysis for energy, systemic inflammation and the reduction of clearance of metabolites including ammonia. This is particularly important in hepatic encephalopathy as the skeletal muscle is the second largest site for ammonia clearance leading to a cascading cycle. The aim of this study was to assess the incidence of MHE and sarcopenia to the risk of developing overt hepatic encephalopathy (OHE) over a 12 month period.
Method: In this prospective trial, patients were enrolled with liver cirrhosis at The Prince Charles Hospital over a 2 year period and followed for 12 months to assess for the development of OHE. An extensive exclusion criteria was used to reduce confounding factors; this included: active psychiatric condition, IVDU/drug use, neurological conditions, current significant alcohol intake, stroke, dementia, current infection, language barrier, active malignancy, vision impairment, uncontrolled sleep apnoea, electrolyte disturbance and grade 1-4 encephalopathy. Participants were tested for MHE using the Encephalapp Stroop test (Stroop), Psychometric hepatic encephalopathy score (PHES), Critical Flicker Frequency (CFF). Participants were also screened for sarcopenia by measuring handgrip strength using a jammer dynamometer.
Results: A total of 187 patients with cirrhosis were approached for recruitment of the trial. 17 patients declined to be part of the study and a further 98 patients were required to be excluded by the exclusion criteria. This allowed 72 patients to be enrolled in the study and to be assessed for MHE. By using a diagnostic regime of MHE by either an abnormal Stroop, PHES or CFF a total 37 patients were diagnosed with MHE, whilst 35 were classified as no MHE. The rate of OHE was dependent on the presence of sarcopenia and MHE as highlighted in Figure 1 (p value 0.0003). Moreover, th rate of OHE increased when both MHE and sarcopenia were present together.

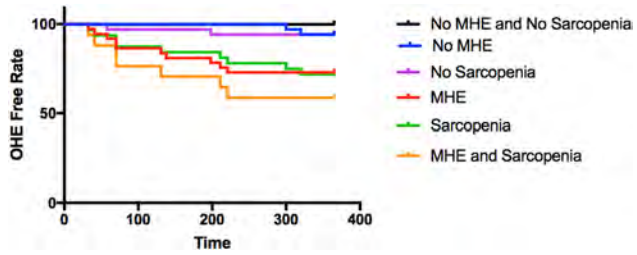


Figure: 12 month OHE Free Rate.

Conclusion: MHE and sarcopenia are important risk factors for the development of OHE. By assessing for MHE and sarcopenia in the outpatient setting, patients at risk of developing OHE can be easily identified allowing for early intervention, monitoring or treatment.

SAT-042

The stroop test is better at predicting the 6-month risk of developing overt hepatic encephalopathy compared to the PHES and CFF tests

Rohit Gupta[1,2], James Thomas[1,2], Greg Anderson[3], Tony Rahman[1,2,4].
[1]*Centre for Service and Quality Improvement, Department of Gastroenterology and Hepatology, The Prince Charles Hospital, Brisbane, Australia;* [2]*The University of Queensland, School of Medicine, Brisbane, Australia;* [3]*QIMR Berghofer Medical Research Institute, Brisbane City, Australia;* [4]*James Cook University, Cairns, Australia*
Email: rogupta85@hotmail.com

Background and aims: Minimal hepatic encephalopathy (MHE) is an underdiagnosed complication of cirrhosis. Whilst there are a number of testing modalities available, there is a paucity of data describing which test is the best at predicting overt hepatic encephalopathy. The current guidelines on hepatic encephalopathy recommend utilising two tests every six months to screen and diagnose MHE. MHE has been shown to be a predictor of progression of liver disease, driving accidents, falls and quality of life. However, the primary reason to test for MHE is to identify those patients at risk of developing overt hepatic encephalopathy (OHE). The aim of this study was to investigate the different outpatient testing modalities for MHE to identify the test with the highest sensitivity of predicting overt hepatic encephalopathy in the subsequent six months.
Method: In this prospective trial, patients with liver cirrhosis at The Prince Charles Hospital were enrolled over a 2 year period. An extensive exclusion criteria was used to reduce confounding factors; this included: active psychiatric condition, IVDU/drug use, neurological conditions, current significant alcohol intake, stroke, dementia, current infection, language barrier, active malignancy, vision impairment, uncontrolled sleep apnoea, electrolyte disturbance and grade 1-4 encephalopathy. Participants were diagnosed with MHE using the Encephalapp Stroop test (Stroop) > 190, Psychometric hepatic encephalopathy score (PHES) < -4 and Critical Flicker Frequency (CFF) < 39.The participants were followed for the subsequent 6 months to assess if they developed OHE.
Results: A total of 187 patients with cirrhosis were approached for recruitment in the trial. 17 patients declined to be part of the study and a further 98 patients were eliminated by the exclusion criteria. This allowed 72 participants to be enrolled in the study and to be assessed for MHE. A total of 7 participants developed OHE in the subsequent 6 months; 6 of these participants had an abnormal Stroop test, 5 had an abnormal CFF test and 4 had an abnormal PHES test. The Stroop test had the highest sensitivity with 85.71% [CI 48.69-99.27%,] compared the CFF sensitivity of 71.43% [CI 35.89-94.92%] and PHES sensitivity of 57.14% [25.02-84.18%], p value < 0.05. The specificity of the Stroop test was 64.62% [CI 52.48-75.12%], PPV was 20.67% [CI 9.84-38.39%] and the NPV was 97.67% [CI 87.94-99.88%] p value < 0.05.
Conclusion: MHE is a predictor of developing OHE independent to the clinical stage. This study highlighted the variation in predicting OHE by using different testing modalities. The Stroop test had the highest sensitivity of predicting OHE in the following six months. Aside from being a simple validated tool to diagnose MHE, it is also can be easily be incorporated into clinical practice allowing for prediction of patients at risk of developing OHE.

SAT-043

Is carvedilol better than propranolol in preventing variceal bleeding

Muhammad Farooq Hanif[1], Khalid mahmud Khan[2], Nooman Gilani[3], Maria Farooq[4], Muhammad Adnan Iqbal[3], Raja Omar Fiaz[1], Muhammad Osama Butt[1], Ommara Jamil[1], Muhammad Omer Qureshi[5], Amjad Khan[5]. [1]*pakistan Kidney and Liver Institute and Research Center, Gastroenterology and Hepatology, Lahore,*

Pakistan; [2]Allama Iqbal Medical College/Jinnah Hospital, Medicine and Gastroenterology, Lahore, Pakistan; [3]Gujranwala Medical College/Dhq Hospital, Gastroenterology and Hepatology, Gujranwala, Pakistan; [4]Fatima Jinnah Medical University/Sir Ganga Ram Hospital, Medicine, Lahore, Pakistan; [5]Pakistan Kidney and Liver Institute and Research Center, Research And Methodology, Lahore, Pakistan
Email: farooqdr@hotmail.com

Background and aims: Cirrhotic patients reporting with hematemesis due to portal hypertension have a 15-50% consequential high death rate with approximately 7% per year development of new varices among this population subgroup
This study compared the effectiveness of carvedilol and propranolol for primary prevention of variceal bleed in cirrhotic patients. Along with that, patient compliance to drugs and side effects of the drugs were also checked.
Methods: CLD patients having varices (small and large without red signs) with no previous history of GI bleed, were randomized to group A (Carvedilol) and group B (Propranolol). The absence of variceal bleeding at the end of one year treatment for each patient was considered as effective treatment response.
Results: Total number of patients included in the study were 80. Overall bleeding occurred in 32.5% and 60% of the patients in group A and B respectively ($p = 0.026$). Bleeding was more common among patient with large as compared to small varices 76.92% versus 31.48% respectively in both groups. Among patients with large varices bleeding occurred in 63.6% and 86.66% of patients in group A and B respectively on follow-up ($p = 0.017$). On the other hand, in patients with small varices, bleeding occurred in 22.22% and 50% in group A and B respectively ($p = 0.03$). Regarding the response of beta blockers on pulse rate, the mean pulse rate dropped from 85.15 ± 5.49 to 69.5 ± 3.35 per minute in Group A while in Group B the initial pulse rate of 83.8 ± 5.33 decreased to 68.5 ± 7.09 per minute on 12 months follow-up ($p = 0.6$). Fatigue was the common side effect in both groups with no significant difference in the side effect profile. Patients were compliant to the treatment in both groups.

Table:

		Study Groups A	B	p value	Total
Controlled Bleeding	Yes	25 (62.5%)	13 (32.5%)	0.026	38 (47.5%)
	No	13 (32.5%)	24 (60%)		37 (46.25%)
	Lost follow-up	02	03		05 (6.25%)
Completed Large varices		04 (36.36%)	02 (13.33%)	0.002	06 (23.07%)
Large varices bleeders		07 (63.63%)	13 (86.66%)	0.017	20 (76.92%)
Completed Small varices		21 (77.77%)	11 (50%)	0.011	32 (59.25%)
Small varices bleeders		06 (22.22%)	11 (50%)	0.034	17 (31.48%)

Conclusion: In our cohort of cirrhotic patients, carvedilol group showed better response compared to propranolol group in the primary prevention of variceal hemorrhage. It was also concluded that in patients with large varices without red sign, combined EVBL and β-blockers should be employed for primary prophylaxis rather than beta blockers alone.

SAT-044

Serum Myostatin in liver cirrhosis: A marker beyond malnutrition

Ayman El Shayeb[1], Akram Deghady[2], essam bedewy[1], Marwa Ibrahim[1], Rewan Hanno[1]. *[1]Alexandria main university hospital, Tropical and infectious diseases, Alexandria, Egypt; [2]Alexandria main university hospital, Clinical and chemical pathological, Alexandria, Egypt*
Email: rewanhanno@yahoo.com

Background and aims: Malnutrition is one of the most common complications of liver cirrhosis and mainly assessed by anthropometric measures (BMI, MAMC, Triceps fold), radiologically (DEXA scan and MRI), subjective measures as Subjective Global assessment (SGA) and Mini Nutritional test and biochemical markers (Myostatin and IGF-1). Myostatin, member of TGF β family, is a critical autocrine/paracrine inhibitor of skeletal muscle growth and mass. Myostatin inhibits skeletal muscle protein synthesis as well as increased proteolysis. The aim of the present work was to elucidate the relationship between Myostatin and the degree of malnutrition and to investigate its importance as a prognostic key in cirrhotics same as MELD score.
Method: A total 80 subjects were included in the study, seventy patients with liver cirrhosis and ten apparently healthy. Serum Myostatin was measured by ELISA.
Results: Serum myostatin was significantly higher in patients than controls ($U = 97$, $P = 0.001$). Among 70 patients with liver cirrhosis (51 were malnourished and 19 well nourished) serum levels of myostatin was significantly higher in malnourished cases ($U = 41.5$, $P = 0.001$). According to SGA (mild in 14 cases, moderate in 17 and high SGA in 20 cases), Serum myostatin was significantly higher in high SGA than moderate and mild SGA ($p = 0.001$). Moreover it was significantly higher in moderate SGA than mild SGA ($p = 0.002$). As regards child score, serum myostatin was significantly higher in Child C than Child B and Child A ($p < 0.05$). Regarding MELD score, a statistical significant positive correlation was found between Myostatin and MELD in malnourished patients groups ($p < 0.05$). Furthermore, serum myostatin was significantly higher in those cases with hepatic encephalopathy than patients without it ($U = 234$, $P < 0.001$). Roc curve analysis revealed that serum myostatin at cut off > 6.1 could discriminate malnourished from well-nourished cases with sensitivity 98.04%, specificity 84.2%, PPV 94.3%., NPV 94.1% and accuracy of 94.3%.
Conclusion: High serum Myostain is associated with profound malnutrition and might be used as a valuable marker as MELD determining poor outcome in patients with liver cirrhosis.

SAT-045

Prevalence, type and risk factors of colonization by multidrug-resistant bacteria in a large series of patients with decompensated cirrhosis

Maria Hernandez-Tejero[1], Fatima Aziz[1], Cristina Pitart[2], Francesc Marco Reverte[2], Irene Campo[2], Adrià Carpio[1], Enric Reverter[2], Angels Escorsell[1], Santiago Ortiz[1], Gabriel Mezzano[1], Pere Ginès[1], Alex Soriano[3], Jordi Vila[3], Javier Fernandez[1]. *[1]Hospital Clínic, Liver Unit, Barcelona, Spain; [2]Hospital Clínic, Microbiology Department, Barcelona, Spain; [3]Hospital Clínic, Infectious Disease Department, Barcelona, Spain*
Email: mhdeztejero@hotmail.com

Background and aims: Rate, type and risk factors of colonization by MDR strains in decompensated cirrhosis are poorly known.
Method: Single center prospective study including 316 consecutive patients (70% were admitted to the regular ward and 30% in the ICU). Rectal and nasal swabs were obtained at admission (48h) and weekly thereafter until discharge and cultured for ESBL-producing *Enterobacteriaceae*, carbapenem-resistant bacteria, MRSA and VRE.
Results: At inclusion, 23% of patients were colonized by MDR strains in rectal swabs and only 2.5% were MRSA nasal carriers. Prevalence of rectal (24% vs. 20%) and nasal (2% vs. 3%) colonization by MDROs was similar between patients admitted to the regular ward and those requiring ICU. Median follow-up was 181 days (70 to 333). Thirty-one percent of non-colonized patients became colonized by MDROs during follow-up in rectal swabs. In contrast, nasal colonization by MDROs was exceptional during follow-up (2%). Remarkably, 35% of MDROs rectal carriers at inclusion developed an over-colonization by a new MDR bacteria during follow-up. ESBL-producing *Enterobacteriaceae* were the most frequent MDROs isolated

in rectal swabs at inclusion (*Escherichia Coli and Klebsiella pneumoniae;* n = 40 and n = 18, respectively) and during follow-up (*Klebsiella pneumoniae and Escherichia Coli;* n = 29 and n = 25, respectively). Carbapenem-resistant-*Enterobacteriaceae* were isolated in 10% of patients colonized by MDROs at baseline, in 18% of those colonized during follow-up and in up to 40% of those overcolonized within the study period (p = 0.003). Multivariate analysis identified norfloxacin prophylaxis (HR: 10.2, p = 0.001), MDROs isolation in the previous 6 months (HR: 7.9, p = 0.005), hospital admission within the last 3 months (HR 5.7, p = 0.02) and long-term care facility (HR 4.2, p = 0.04) as independent risk factors for MDR rectal colonization at admission. The presence of ascites was identified as an independent predictor of MDROs rectal colonization during follow-up (HR: 1.7, p = 0.04).

Conclusion: Rectal colonization by MDR bacteria, mainly ESBL producing *Enterobacteriaceae,* is extremely frequent in patients with decompensated cirrhosis requiring hospitalization and often occurs after hospital admission. Previous contact with the healthcare system, norfloxacin prophylaxis and the presence of ascites are risk factors of MDRO colonization. Studies evaluating preventive strategies of rectal colonization in decompensated cirrhosis are urgently needed.

SAT-046

Clinical impact of rectal colonization by multidrug-resistant bacteria in patients with decompensated cirrhosis

Maria Hernandez-Tejero[1], Francesc Marco Reverte[2], Fatima Aziz[1], Cristina Pitart[2], Irene Campo[2], Adrià Carpio[1], Ester López-Suñé[3], Santiago Ortiz[1], Gabriel Mezzano[1], Pere Ginès[1], Alex Soriano[4], Jordi Vila[2], Javier Fernandez[1]. *[1]Hospital Clínic, Liver Unit, Barcelona, Spain; [2]Hospital Clínic, Microbiology Department, Barcelona, Spain; [3]Hospital Clínic, Clinical Pharmacy Service, Barcelona, Spain; [4]Hospital Clínic, Infectious Disease Department, Barcelona, Spain*
Email: mhdeztejero@hotmail.com

Background and aims: The clinical relevance and prognostic impact of colonization by MDR strains in decompensated cirrhosis is unknown.

Method: Single center prospective study including 316 consecutive patients (70% were admitted to the regular ward and 30% in the ICU). Rectal swabs were obtained at admission (48h) and weekly thereafter during hospitalization (s) and cultured for ESBL-producing *Enterobacteriaceae*, carbapenem-resistant bacteria, MRSA and VRE. Patients were followed up up to 1 year for the development of bacterial infections and mortality. MDR microbiological isolations were considered to guide antibiotic therapy and isolation strategies.

Results: Current median follow-up is 180 days (69 to 330). 156 patients were colonized by MDR strains at admission (23%) or became colonized during hospitalization (27%) with no differences between patients admitted to the regular ward and those requiring critical care. Overcolonization by a new MDR strain was observed in 26 patients (8%). ESBL-producing *Enterobacteriaceae* were the most frequent MDROs isolated followed by carbapenem-resistant-*Enterobacteriaceae*. MDR rectal carriers showed a higher incidence of infections caused by MDROs during follow-up: 37% vs. 6% (p < 0.0001). Median time from colonization to infection by MDROs was 30 days (15-90). The type of resistant bacteria responsible for infection was that colonizing the patient in 81% of the cases. Multivariate analysis identified rectal colonization by MDROs (HR: 9.99; 95%CI: 4.54-22.00; P < 0.0001) and MELD score (HR: 1.05; 95% CI: 1.009-1.09; P = 0.02) as the only independent risk factors for MDR bacterial infections during follow-up. Mortality rate was similar between patients with and without MDR colonization (34% vs. 28%) and with and without infections caused by MDROs (37% vs. 29%), suggesting that empirical antibiotic strategies guided by epidemiological surveillance can attenuate the poor prognosis associated to antibiotic resistance in cirrhosis.

Conclusion: Rectal colonization by MDR bacteria significantly increases the risk of infections caused by resistant strains at short-term. Empirical antibiotic strategies based on rectal colonization data seem to improve the prognosis of patients with decompensated cirrhosis infected by MDROs.

SAT-047

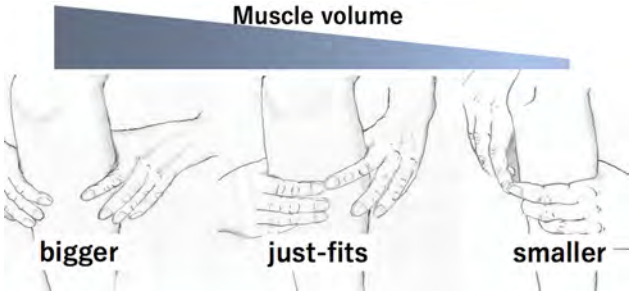
Easy surveillance method without need of special equipment for muscle volume loss in patients with chronic liver disease

Atsushi Hiraoka[1], Kojiro Michitaka[1], Eiji Tsubouchi[1], Tomoyuki Ninomiya[1], Yohei Koizumi[2], Hirooka Masashi[2], Masanori Abe[2], Bunzo Matsuura[2], Yoichi Hiasa[2]. *[1]Ehime Prefectural Central Hospital, Gastroenterology Center, Matsuyama, Japan; [2]Ehime University Graduate School of Medicine, Department of Gastroenterology and Metabology, Toon, Japan*
Email: hirage@m.ehime-u.ac.jp

Background and aims: Muscle volume loss (MVL), a not rare complication in patients with chronic liver disease (CLD), has been reported to play a significant role in the prognosis of CLD patients. However, evaluation of MVL requires special equipment, thus development of an easy surveillance method without such specialized equipment is anticipated. Here, we evaluated the usefulness of the previously reported finger-circle test as screening for MVL in patients with CLD.

Method: We enrolled 358 outpatients with CLD [70.8 ± 10.2 years old; males 234, females 124; chronic hepatitis (CH) 136, liver cirrhosis (LC) 170, Child-Pugh (CP)-A 52; HCV:HBV:HBVandHCV:alcohol: others = 192:49:1:54:62] who underwent CT as screening for hepatocellular carcinoma (HCC) from December 2017 to March 2018. Muscle volume was manually calculated with CT findings using personal computer software and evaluated with previously reported cut-off value for psoas index (PI) that utilized values for psoas muscle area and height of young normal controls (NCs) [psoas index (PI): psoas muscle area (cm^2)/height $(m)^2$] to predict MVL (males: 6.50 ± 1.13 cm^2/m^2, females: 4.30 ± 0.90 cm^2/m^2). MVL was defined as mean-2 standard deviation (SD) of the PI of the NCs, while pre-MVL was defined as mean-1SD.

Each patient was administered the finger-circle test, developed to determine whether the maximum non-dominant calf circumference is larger than the individual subject's finger-circle circumference, formed with the index finger and thumb of both hand. Finger circle testing was carried out with the patient in a seated position, with turning up a hem. Based on those results, they were divided into the bigger, just-fits, and smaller groups.



Results: The bigger, just-fits, and smaller groups were composed of 192, 104, and 62 patients, respectively. The frequency of both pre-MVL and MVL increased with worse finger-circle test results [pre-MVL/MVL: bigger 63/16 (41.1%), just-fits 33/25 (55.8%), smaller 25/17 (67.7%) (p < 0.001)]. The PI values for bigger, just-fits, and smaller in males were 5.64 ± 1.34, 5.00 ± 1.25, 4.83 ± 1.46 cm^2/m^2, respectively (p < 0.001), while those in females were 4.31 ± 1.06, 3.93 ± 0.97, 3.42 ± 0.94 cm^2/m^2, respectively (p = 0.001). In males, the predicted PI value for just-fits was 5.25 cm^2/m^2 (sensitivity 0.619, specificity 0.667, AUC 0.654, 95% CI 0.583-0.724), which was an

approximation for pre-MVL as mean-1SD (5.37 cm^2/m^2) of the PI of the NCs. In females, the predicted PI value for smaller was 3.33 cm^2/m^2 (sensitivity 0.740, specificity 0.583, AUC 0.698, 95% CI 0.583-0.813), which was an approximation for pre-MVL as mean-1SD (3.40 cm^2/m^2).

Conclusion: The finger-circle test is easy to perform and does not require special equipment. Assessment of muscle volume should be considered in males when the finger-circle test result is just-fits or smaller, and in females when the result is smaller.

SAT-048

Changes in the intestinal microbiome during probiotic intervention in cirrhosis

Angela Horvath[1,2], Marija Durdevic[1], Bettina Leber[1], Katharina di Vora[1], Florian Rainer[1], Philipp Douschan[1], Elisabeth Krones[1], Walter Spindelboeck[1], Franziska Durchschein[1], Gernot Zollner[1], Rudolf Stauber[1], Peter Fickert[1], Philipp Stiegler[1], Vanessa Stadlbauer[1]. *[1]Medical University of Graz, Graz, Austria; [2]CBmed, Graz, Austria*
Email: angela.horvath@medunigraz.at

Background and aims: Liver cirrhosis is accompanied by significant changes of the intestinal microbiome including the regression of beneficial and autochthonous taxa. The aim of the study was to test the effects of a multispecies probiotic on gut microbiome composition.

Method: Gut microbiome composition of 58 patients with Child's A cirrhosis who received a daily dose (1.5*10^10 CFU) of a multispecies probiotic or placebo for six months was analysed by 16S rRNA gene sequencing.

Results: Microbiome composition of patients was enriched with probiotic strains Lactobacillus salivarius, Lactobacillus brevis and Lactococcus lactis. Furthermore, the abundance of short-chain fatty acid producing bacteria Faecalibacterium prausnitzii, Syntrophococcus sucromutans and Alistipes shahii was increased in the probiotic group compared to the placebo group. Changes in starch-utilizing bacteria of the species Bacteriodes vulgatus could be observed in both groups.

Conclusion: A six months intervention with a multispecies probiotic enriched the microbiome of cirrhotic patients with probiotic bacteria. The abundance of anaerobic and short-chain fatty acid producing bacteria was increased in patients in the probiotic group and changes in starch-utilizing bacteria were observed in both groups.

SAT-049

Lactate but not hemoglobin is a predictor for mortality in patients with liver cirrhosis and upper GI bleeding

Thomas Horvatits[1], Oliver Seiz[1], Dominik Reher[1], Andreas Drolz[1], Stefan Groth[2], Thomas Rösch[2], Ansgar Lohse[1], Johannes Kluwe[1]. *[1]University Medical Center Hamburg-Eppendorf, I. Department of Medicine, Hamburg, Germany; [2]University Medical Center Hamburg-Eppendorf, Department of Interdisciplinary Endoscopy, Hamburg, Germany*
Email: t.horvatits@uke.de

Background and aims: Acute upper gastrointestinal (GI) bleeding in patients with liver cirrhosis is associated with high mortality. Although lactate as predictor of survival in patients with liver cirrhosis has gained increasing attention, it's prognostic properties on acute upper GI bleeding have not been assessed so far. We therefore aimed to assess the impact of peak serum lactate levels in comparison to established parameters such as lowest hemoglobin or model for endstage liver disease (MELD) in cirrhotic patients with upper GI bleeding.

Method: We analyzed data from 159 consecutive patients with liver cirrhosis and first episode of acute upper GI bleeding who underwent endoscopy at a tertiary care hospital from 2009-2018. Source of bleeding, initial hemodynamics, laboratory values as well as 30-day and 90-day mortality have been assessed. We tested the prognostic performance of peak serum lactate, nadir hemoglobin and MELD score and compared it to $MELD^{Lactate}$, a score incorporating lactate and MELD.

Results: 131 patients (82%) had acute variceal bleeding, 25 (16%) had ligation-induced ulcer bleeding and 3 patients (2%) had peptic ulcers or unclear source of bleeding. Median MELD was 18 (IQR 12-25). Among the studied individuals 30-day mortality was 29% and 90-mortality 37%, respectively.

While peak lactate levels at time of bleeding were significantly higher in 30-day non-survivors (median lactate 6.2 mmol/l (2.0-13.6) versus 2.1 mmol/l (1.5-3.5); $p < 0.001$), nadir hemoglobin levels were not associated with patient's outcome (median hemoglobin 7.3 g/dl (6.6-8.3) vs. 7.1 g/dl (6.3-8.4); p = n.s.). Receiver operating curve analysis revealed highest predictive properties for $MELD^{Lactate}$ (AUROC 0.86), followed by MELD (0.8), peak lactate (0.73) and nadir hemoglobin (0.51), as shown in figure 1.

$MELD^{Lactate}$ predicted short-term mortality independently of age, hemoglobin, mean arterial blood pressure, severity of liver disease (MELD) and the Charlson comorbidity index (cox regression: HR 1.2 per 1-point increase of $MELD^{Lactate}$ score; 95%CI 1.11-1.29; $p < 0.001$).

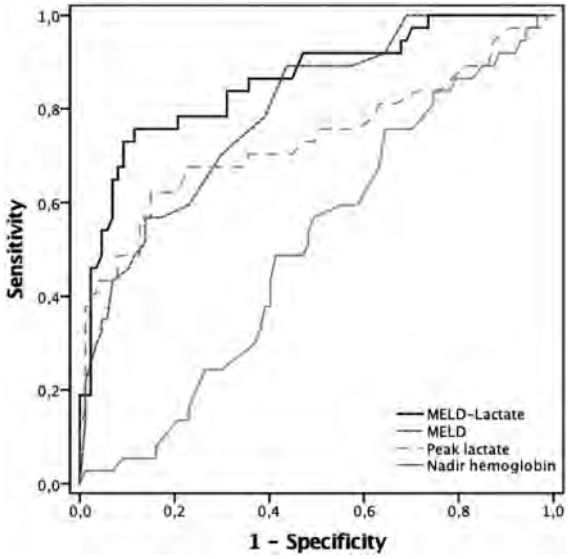


Figure: Receiver operating curve analysis in prediction of 30-day mortality (MELD, model for endstage liver disease)

Conclusion: In contrast to lowest hemoglobin levels at the time of bleeding, peak serum lactate was significantly associated with short-term mortality. Best prognostic properties were observed in combining MELD and lactate, a simple independent marker for mortality in patients with liver cirrhosis and acute upper GI bleeding.

SAT-050

Silymarins significantly improve long term survival in patients with liver cirrhosis regardless of MELD score

Chien-Hao Huang[1], Chun-yen Lin[1]. *[1]Chang-Gung Memorial Hospital, Linkou Medical Center, Taiwan, Gastroenterology and Hepatology, TaoYuan, Taiwan*
Email: chunyenlin@gmail.com

Background and aims: Silymarin, the active ingredient in milk thistle, functions as an antioxidant and may decrease hepatic injury and inhibition of Kupffer cell function. However, despite its theoretical benefit in cultured cells, a systematic review that included 14 studies found no clear evidence showing a reduction in mortality in patients with chronic liver disease [1]. However it is still widely used as a nonprescription agent in patients with chronic liver disease. It is hence intriguing to study whether silymarin has beneficial effect in end stage liver disease.

Method: By analysing big data from the center for big data analytics and statistics of CGMH Hospital, 49380 patients who met the diagnostic criteria of liver cirrhosis (LC) between 2006~2017 were screened. Exclusion criteria included previously diagnosed HCC before enroll, age < 12 years old and no available staging information during follow-up. With silymarin group was defined as consecutive use of 3 tablets of silymarin a day for at least 3 months and came back to hospital for the prescription every month. Others were defined as control group. The primary outcome was 5-year (60 months) mortality analyzed by Cox-regression model after adjusting for time-dependent covariate MELD scores. Age, sex, cirrhotic etiologies, number of admissions and Charlson Comorbidity Index (CCI) were also adjusted in the multivariate analysis.

Results: Totally 12, 616 patients were enrolled after exclusion criteria **(Figure 1).** The mean age was 54.26 ± 15.13 year-old. 8, 462 (67.07%) were male. For the etiology of cirrhosis, 12.46% were HBV, 13.36% were HCV, 4.34% were HBV+HCV co-infection and 12.22% were alcoholic, while 57.62% were other aetiologies including NASH. Mean follow-up time was 62.32 ± 44.22 months. 2, 903 patients died during follow-up (23.01%).

There were 1, 175 patients in the silymarin group and 11, 441 patients in the control group. Age, etiologies of cirrhosis, CCI, number of admissions and MELD score, silymarin use correlated with primary outcome after long-term follow-up by Cox univariable analysis **(Figure 2).** After adjusting the above covariate and time-dependent MELD scores, consecutive silymarin use for at least 3 months were associated with lower hazard ratio (0.879), p = 0.0187 **(Figure 3).** As shown in **Figure 4** by Kaplan-Meier plot, use of silymarin group has better outcome curve than control irrespective of MELD score.

Conclusion: By Cox-regression model after adjustment for time-dependent MELD and other covariates including age, etiologies of cirrhosis, CCI and number of admissions, the hazard ratio for death was lower in the silymarin group. In this big data study, consecutive use of 3 tablets of silymarin a day for at least 3 months in patients with liver cirrhosis correlated with better survival outcome irrespective of MELD score

The effects of portal vein thrombosis to patients with cirrhotic variceal bleeding underwent endoscopic treatment

Xiaoquan Huang[1], Shiyao Chen[1]. [1]*Zhongshan Hospital, Fudan University, Gastroenterology, Shanghai, China*
Email: huangxiaoquan1010@aliyun.com

Background and aims: Portal vein thrombosis (PVT) is frequent in patients with cirrhotic variceal bleeding, which could be a cause or a consequence of the progression of portal hypertension. So we aimed to evaluate the effect of portal vein thrombosis to the prognosis of patients with cirrhotic portal hypertension and underwent endoscopic treatment for the prophylaxis of bleeding.

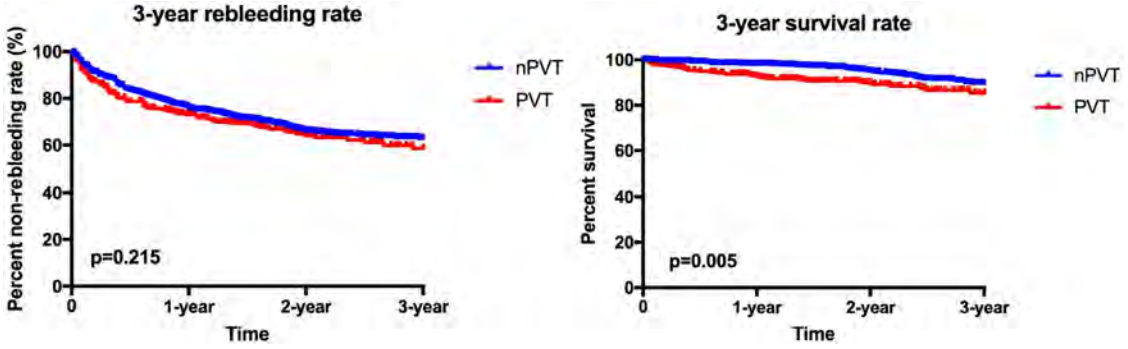

Figure: (abstract: SAT-051)

Method: We enrolled 1198 consecutive non-tumoral cirrhotic patients with cirrhotic gastroesophageal varices and received first endoscopic treatment between Jan 1st, 2008 and Dec 31st 2017. Patients were divided into PVT group (n = 294) and non-PVT (n = 846) group according to computer tomography angiography and follow-up.
Results: The mean age of included patients with cirrhotic gastroesophageal varices was 54.74 ± 36 with the ratio of portal vein thrombosis about 24.54%. There is 141 patients underwent splenectomy previous. At baseline, MELD score was similar between groups (9.25 ± 0.15 vs 9.12 ± 0.08, p = 0.437). And patients with PVT had a higher level of NLR (Neutrophil-lymphocyte ratio) 2.95 ± 0.20 vs 2.55 ± 0.07, p = 0.016). During a median follow-up of 25 months, no significant difference was observed between two groups in regard to variceal bleeding (32.42% vs 30.17%, p = 0.215). While Kaplan-Meier analysis revealed that 3-year mortality for patients with PVT was 10.03%, which was poorer than those without PVT 6.11% (p = 0.005). (Figure). Subgroup analysis showed patients with PVT without splenectomy had a higher rebleeding rate and mortality in 3-year (p < 0.05).
Conclusion: The development of portal vein thrombosis in cirrhotic portal hypertension in patients without splenectomy might influence the prognosis.

SAT-052

Right psoas muscle area: Prognostic factor in patients with cirrhosis Child Pugh class C included on the waiting list for liver transplantation

Speranta Iacob[1,2], Catalina Stanescu[2], Razvan Iacob[1,2], Roxana Vadan[1], Cristian Gheorghe[1,2], Ioana Lupescu[1,2], Liana Gheorghe[1,2]. *[1]Fundeni Clinical Institute, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania*
Email: msiacob@gmail.com

Background and aims: Malnutrition and sarcopenia are frequent complications in cirrhosis and contribute to increased risk of sepsis-related mortality, poor quality of life, post-LT adverse outcomes. Sarcopenia is defined by cross-sectional imaging-based muscular assessment, however computed tomography (CT) scan determinations vary as well as cut-off values. The aim of our study was to identify risk factors for occurrence of infections and death before LT.
Method: All cirrhotic patients admitted on the waiting list for liver transplantation in our Hepatology Unit between years 2016–2017 underwent anthropometric assessments and abdominal CT scan including L3 and umbilical levels for measuring transverse psoas muscle thickness. Multiple regression was used to determine independent risk factors for occurrence of infections and death before LT.
Results: One hundred thirty two patients with liver cirrhosis were included. The average age was 53.9 ± 10.7 years, and 66% of patients were men. Child C class was encountered in 29.3% of patients and associated hepatocellular carcinoma was present in 17.8%. Large ascites (8-10 litres) was present in 27.7%. There is a moderate correlation between right psoas muscle area and adjusted BMI without ascites (r = 0.26, p = 0.007), arm circumference (r = 0.39, p = 0.0001), right hand grip (r = 0.45, p < 0.0001) and a very good correlation with the left psoas muscle (r = 0.85, p < 0.0001). There was no correlation between right psoas muscle area and skin fold. Patients with sarcopenia (defined as arm circumference < 22 mm and hand-grip < 45dyne) and Child Pugh Class C cirrhosis had a significantly lower right psoas muscle area compared to patients with Child Pugh class A/B cirrhosis (624cm3 vs 931.3cm3, p = 0.04). Right psoas muscle area was identified by multiple regression as independent risk factor for both infections and death while on the waiting list for LT (p = 0.03 for each). The value of the AUROC right psoas muscle area for predicting 1-yr mortality was 0.73 for a cut-off value of 608cm3.
Conclusion: Transverse right psoas muscle area was an independent predictor of mortality in cirrhotic patients. Psoas muscle area can be used as another negative prognostic factor in Child Pugh C cirrhosis.

SAT-053

Liver stiffness-spleen size-to-platelet ratio risk score detects esophageal varices and HCC risk in HCV- and HBV-related cirrhosis responsive to DAA

Barbara Imperatrice[1], Wilma Debernardi Venon[1], Claudia Chialà[1], Giorgio Maria Saracco[1], Alfredo Marzano[1]. *[1]San Giovanni Battista Hospital, Division of Gastroenterology, Turin, Italy*
Email: barbara.imperatrice@hotmail.it

Background and aims: Liver stiffness has been correlated to hepatic venous pressure gradient (HVPG). While the accurancy of LS in predicting clinically significant portal hypertension seems good, its discriminative ability in the prediction of esophageal varices (EV) appears inadequate. Thus, combination of different non-invasive methods could ameliorate the diagnostic accuracy. LSPS has been correlated with portal hypertension (mPH), EV and risk of hepatocellular carcinoma (HCC) in cirrhotic patients. The response to antiviral therapy with DAA reduces but does not eliminate the risk of HCC in HBV and HCV-related cirrhosis. The impact of SVR on mPH, clinical outcome and endoscopic monitoring of EVs, could be evaluated with LSPS.
Method: Data are presented from an ongoing longitudinal study, currently performed in 236 cirrhotic patients (115 HCV positive and 121 HBV positive) responsive to antiviral therapy with DAA. They underwent LSPS measurement before therapy and LSPS + HVPG measurement + gastroscopy after SVR 6 off-therapy in HCV and complete virological response (VR) from at least 12 months on therapy in HBV.
Results: LSPS < 0.6 and < 1.2 identified patients without CSPH (HVPG < 10mmHg; PPV 50%, NPV 100%) and without EVs (PPV 71%, NPV 96%), respectively. Patients who did not reach LSPS < 0.93 post SVR or VR were more likely to have appearance, persistence or progression of EVs (PPV 36%, NPV 97%). HCC developed in 29/236 (12%) of the patients, 3 with HCV infection and 26 with HBV infection and a longer

follow-up. LSPS ≤ 0.6 baseline or inducted by antiviral therapy was associated with a lower risk of HCC (NPV 98%).
Conclusion: LSPS is a useful non-invasive tool to exclude the presence of CSPH and Evs. Moreover, it could predict clinical outcomes, such as presence of EV avoiding unnecessary endoscopy and too frequent ultrasound. The impact of DAA therapy on HCC in HBV and HCV cirrhotic patient remains debated and requires a longer follow-up. However, LSPS ≤ 0.6 could identify a lower risk group in cirrhotic patients responsive to antiviral therapy.

SAT-054

A higher prevalence of colorectal adenomatous polyps in patients with liver cirrhosis compared with non-cirrhotics

Mohamed Saleh Ismail[1,2], Manal Hassan[1], Sarah May[3], Abbas Rana[1], Prasun Jalal[1]. [1]*Baylor College of Medicine, Division of Abdominal Transplantation, Houston, United States;* [2]*Ain Shams University, Department of Internal Medicine, Gastroenterology and Hepatology, Cairo, Egypt;* [3]*Michael E Debakey VA Medical Center, Houston, United States*
Email: jalal@bcm.edu

Background and aims: Recent studies suggested that non-alcoholic fatty liver diseases was associated with an increased risk for colorectal adenomas. However, there is paucity of data in literature on the true prevalence of colorectal polyps (CRP) in cirrhotics. We aimed to determine the impact of cirrhosis on the risk of CRP and whether risk may be influenced by sex and grade of cirrhosis.
Method: Over 6 months, colonoscopy (CS) was performed in 212 patients by experienced gastroenterologist at Baylor College of Medicine. Total of 111 men and 101 women were included. The mean age (± SD) was 59.4 ± 11.2 years. Under IRB approval and based on the results of the CS, patients were classified into 2 groups (gp): polyps-free gp (N = 97) and polyps gp (N = 115). Patients with polyps were further classified into adenomatous (N = 63), hyperplastic (N = 49), and others (N = 2). Evidence of cirrhosis was documented in 128 patients (60.4%). STATA was sued for statistical analyses. The associations between cirrhosis and CRP were assessed by multivariate logistic regression analyses. Odds ratio (OR) and 95% confidence interval (95% CI) was estimated after adjustment for confounding effects of epidemiological and clinical factors.
Results: Prevalence of CRP was higher in patients with cirrhosis (62.5%) than in patients without cirrhosis (41.7%), p = .003, indicating that patients with cirrhosis had approximately 3 fold increased risk of CRP as compared to patients without cirrhosis; the estimated OR (95% CI) is 2.6 (1.4-4.7) after controlling for confounding effect of age, sex, race, smoking, alcohol use, diabetes, history of cancers, hypertension, hyperlipidemia and renal diseases. The significant association was observed in women not in men, ORs (95% CI) were 3.3 (1.3-8.1) and 1.7 (.7-4.1) respectively and for adenomatous polyps: 7.4 (2.1-26.7) and not for hyperplastic polyps: 1.4 (.5-3.6), the association was independent of Child-Pugh score of cirrhosis. In the cirrhotic group, forceps and snare polypectomies were done in patients with and without cirrhosis with no significant difference in post-CS complications.
Conclusion: The current study demonstrated that cirrhosis is associated with risk of CRP and that sex may influence the association. Further studies may be warranted to explore the underlying mechanism behind CRP development in patients with cirrhosis. CS in cirrhotic patients is safe and not associated with significant post-colonoscopy complications as compared to non-cirrhotics.

SAT-055

Dobutamine counteracts the decrease in cardiac output after terlipressin in patients with cirrhosis and impaired kidney function but does not improve GFR: A randomised exploratory trial

Mads Israelsen[1,2,3], Emilie Dahl[1], Bjørn Madsen[1,2,3], Signe Wiese[4], Flemming Bendtsen[4], Søren Møller[5], Annette Dam Fialla[1], Prof. Boye L. Jensen[6], Aleksander Krag[1,2,3]. [1]*Odense Universitetshospital, Department of Gastroenterology and Hepatology, Odense, Denmark;* [2]*University Of Southern Denmark, Department of Clinical Research, Odense, Denmark;* [3]*Odense Universitetshospital, FLASH: Fibrosis, Fatty Liver and Steatohepatitis-Elite Research Center, Odense, Denmark;* [4]*Hvidovre Hospital, Gastrounit, Medical Division, Hvidovre, Denmark;* [5]*Hvidovre Hospital, Centre for Functional and Diagnostic Imaging and research, Hvidovre, Denmark;* [6]*University Of Southern Denmark, Cardiovascular and Renal Research, Odense, Denmark*
Email: mads_israelsen@hotmail.com

Background and aims: Acute kidney injury and hepatorenal syndrome (HRS) are frequent complications in patients with cirrhosis and ascites. First line treatment is the V1-receptor agonist terlipressin, that reverses HRS in approximately 40% of patients and reduces mortality, but also lowers cardiac output (CO). We hypothesised that counteracting terlipressins negative effects on CO with β-adrenoceptor agonist dobutamine infusion would potentiate the beneficial effects on the kidneys.
Method: Twenty-five patients with cirrhosis, ascites and impaired renal function (mean GFR = 47 ml/min/m^2; 95%CI 36 to 58) but without HRS, were randomized (2:2:1) into three groups: Group A received terlipressin followed by dobutamine, Group B received dobutamine followed by terlipressin, Group C received placebo. All investigations were performed after seven days on salt restricted diet (80 mEq NaCl) and discontinuation of diuretics and vasoactive drugs. Renal and cardiac function were assessed during 8 clearance periods of 30 minutes. Here we report dynamics of glomerular filtration rate (GFR) assessed by Cr-EDTA clearance, CO by the inert gas rebreathing method and plasma renin concentration (PRC) by radioimmuneassay.
Results: Dobutamine as monotherapy significantly increased CO (0.87 L/min, p = .025) and PRC (74.0 mIU/L, p = .022), but had no significant effects on GFR (−10.35 ml/min/m^2, p = .181) and MAP (−5.03 mmHg, p = .26). Terlipressin as monotherapy significantly improved GFR (18.9 ml/min/m^2, p = .005), MAP (13.8 mmHg, p = .001) and reduced CO (−1.08 L/min, p < .001). In the combined analysis, terlipressin alone had no significant effect on PRC (−25.4 mIU/L, p = .381). Addition of dobutamine on terlipressin significantly improved CO (1.36 L/min, p = .022) and PRC (78.6 mIU/L, p = .050), but the combination of dobutamine and terlipressin had no significant effects on MAP (3.67 mmHg, p = .499) or GFR (9.04 ml/min/m^2, p = .378).
Conclusion: Dobutamine increases CO and reverses the negative inotropic effect of terlipressin. However, combined treatment does not seem to translate into further increase in GFR. This may relate to the fact that combined therapy did not increase arterial pressure and thereby renal perfusion pressure beyond the effect of terlipressin alone. Moreover, dobutamine induce increasement in PRC, which may counteract the beneficial renal effects of terlipressin.
Figure shows the relative effects of dobutamine and terlipressin by group. Terli = terlipressin; Dobu = dobutamine; GFR = glomerular filtration rate; PRC = plasma renin concentration; CO = cardiac output; MAp = mean arterial pressure; SD = standard deviation

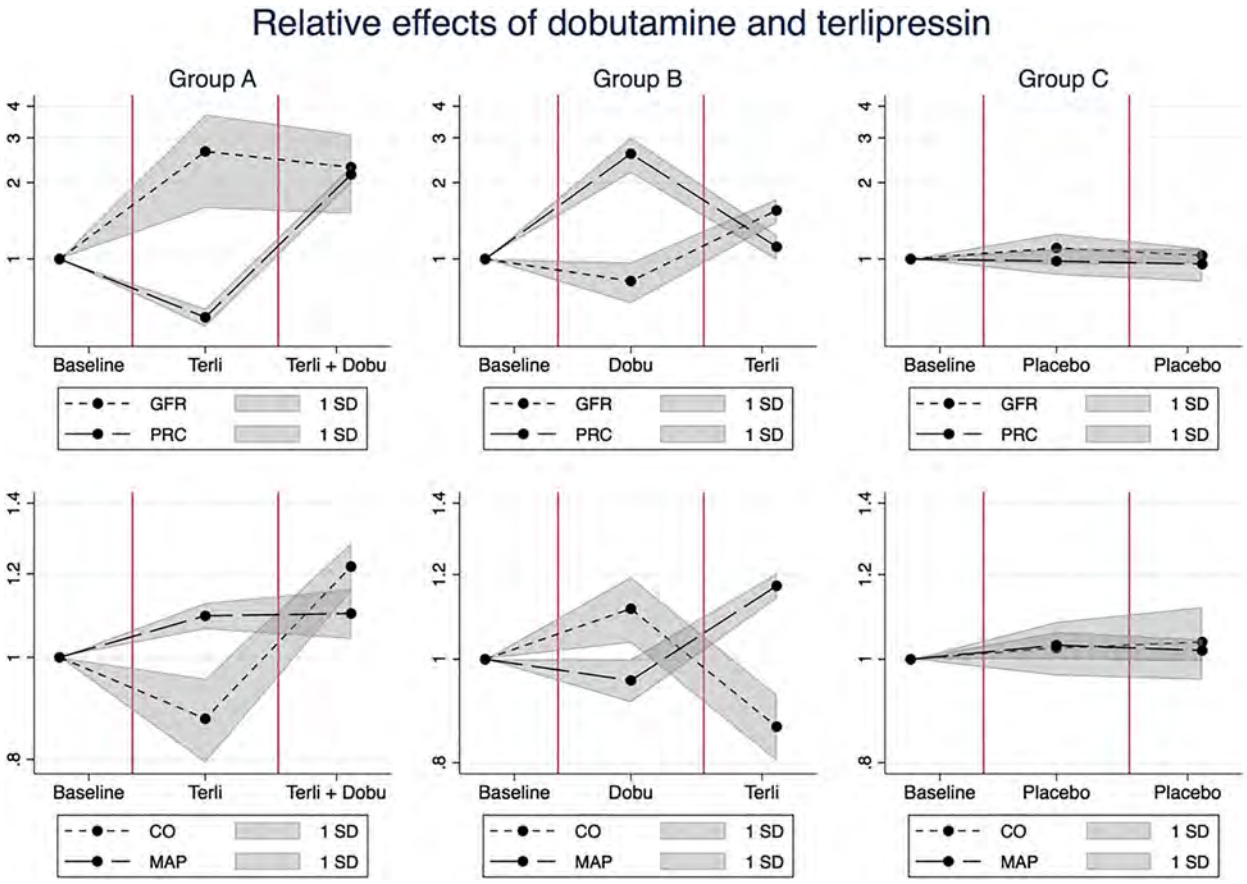

Figure: (abstract: SAT-055)

SAT-056

Development of a novel prognostic model for cirrhotic patients with difficult-to-treat ascites and low MELD scores

Peter Jepsen[1,2], Hugh Watson[3], Stewart Macdonald[4], Hendrik Vilstrup[1], Rajiv Jalan[4]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark;* [2]*Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus, Denmark;* [3]*Sanofi-Aventis RandD, Infectious Diseases Unit, Marcy l'Etoile, France;* [4]*Institute for Liver and Digestive Health, University College London, Liver Failure Group, London, United Kingdom*
Email: pj@clin.au.dk

Background and aims: Cirrhosis patients with difficult-to-treat ascites may have a very poor quality of life and high mortality despite a relatively low MELD score. We aimed to develop a model that is better than the MELD score at predicting survival through 1 year among patients with cirrhosis, MELD score ≤ 18, and difficult-to-treat ascites.

Method: We included stable outpatients included in the multinational SPARe-1 trial, a randomized comparison between satavaptan and placebo on top of diuretic treatment for the treatment of recurrent ascites in patients with cirrhosis. We used Cox regression with stepwise backward selection and fractional polynomial transformation of continuous variables to include the strongest predictors in the prediction model, which we called the SAM (Severe Ascites Mortality) score. Our main outcome was the difference in C index for 1-year mortality between the SAM score and the MELD score (with Na, per current UNOS guidelines). We used the bootstrap to correct for optimism bias in the development cohort, and we validated performance in an external cohort: the SPARe-2 trial participants.

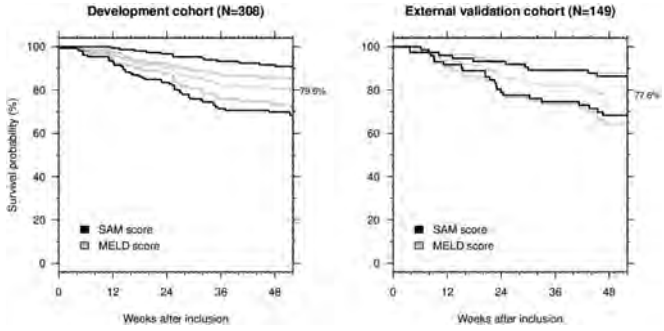

Figure: Observed survival probabilities for patients in the development cohort (left) and external validation cohort (right) divided by median SAM score (black) or by median MELD score (gray). In the development cohort, patients were clearly better separated by the SAM score than by the MELD score. In the external validation cohort, by contrast, the separation was similar for the two scores.

Results: The development cohort included 308 outpatients with difficult-to-treat ascites and MELD ≤ 18. Their overall 1-year survival probability was 79.6% (Figure). The final SAM score was computed as 0.1674 * (bilirubin/10)-0.6792 * (sodium/5); add 1.2866 if the patient has a history of SBP, and add 1.0676 if the patient has diabetes. The physical component score of the SF-36 did not make it into the final prediction model. The SAM score yielded a C index of 0.722, and the MELD score yielded a C index of 0.626. Consequently, the difference was 0.722-0.626 = 0.096. The estimated optimism bias was 0.087, meaning that the bias-corrected estimate of the C index in the development cohort was 0.096-0.087 = 0.009 (95% CI −0.008 to 0.101). The external cohort included 149 patients with refractory ascites and a slightly worse prognosis (Figure). In this cohort, the C

index was 0.690 for the SAM score and 0.664 for the MELD score. Thus, the difference was 0.690-0.664 = 0.026 (95% CI –0.066 to 0.119).
Conclusion: The SAM score includes 4 variables, but it performed better than MELD in these patients with difficult-to-treat ascites and a relatively low MELD score. The difference in C index was not statistically significant, yet the SAM score may be proven to be superior in patients with a low MELD score.

SAT-057

Proton pump inhibitors as a risk factor for hepatic encephalopathy and infections in cirrhotic patients: A clinical evidence

Mafalda João[1], jorge mendes[2], emília louro[2,3], Adelia Simao[2,3], Armando Carvalho[2,3]. [1]*Instituto Português de Oncologia de Coimbra Francisco Gentil, Gastroenterology Department, Coimbra, Portugal;* [2]*Centro Hospitalar e Universitário de Coimbra, Internal Medicine Department, Coimbra, Portugal;* [3]*Faculty of Medicine, University of Coimbra, Internal Medicine Clinic, Coimbra, Portugal*
Email: mafaldacaine@gmail.com

Background and aims: Few non-conclusive studies suggest that long-term use of proton pump inhibitors (PPI) in cirrhotic patients is associated with bacterial translocation, hepatic encephalopathy (HE) and infections. The aim of our study was to evaluate the impact of PPI in the development of infections and HE in these patients.
Method: A cohort of cirrhotic patients admitted between January 2015 and June 2018 in a tertiary centre was retrospectively studied. Demographic, clinical and analytic data were collected, and patients with (group 1) and without PPI use (group 2) were compared regarding the incidence of HE and infections. Statistical analysis was performed by IBM SPSS version 25.
Results: A total of 396 patients were included (group 1: n = 183; group 2: n = 213). In 68.3% of group 1 patients there was no clinical indication for PPI use. Median age (69 ± 19 *vs.* 66 ± 21 years, p = 0.16), gender (male: 69.4% *vs.* 75.6%, p = 0.17), MELD-Na^+ score (18 ± 11 *vs.* 17 ± 11, p = 0.54), Child-Pugh score (B: 54.6% *vs.* 45.5% p = 0.19), aetiology of cirrhosis (ethylic: 73.8% *vs.* 69.5%, p = 0.44), incidence of hepatocellular carcinoma (8.3% *vs.* 17%, p = 0.14) and mortality (14.8% vs. 13.1%, p = 0.64) were not statistically different between groups 1 and 2, respectively. The incidence of HE was significantly higher in group 1 than in group 2 patients (39.3% *vs.* 24.9%, p < 0.01), no differences in its degree were noted (p = 0.67); the most frequent triggering factor in both groups was infection (84.3% vs. 41.5%, p = 0.63). Higher incidence of respiratory tract infections (23.5% *vs.* 15.5%, p = 0.04) and spontaneous bacterial peritonitis (SBP) (10.9% *vs.* 5.2%, p = 0.03) were found in group 1 vs. group 2; significant differences for skin and soft tissue infections (3.8% *vs.* 1.9%, p = 0.24) or urinary tract infections (10.9% *vs.* 12.2%, p = 0.69) were not found. In a multivariate analysis, PPI use was significantly associated with HE (OR: 1.96; 95%CI: 1.27-3.01), SBP (OR: 2.25; 95%CI: 1.05-4.84) and respiratory tract infection (OR: 1.68; 95%CI: 1.01-2.78).
Conclusion: The use of long-term PPI was associated with a greater incidence of respiratory tract infections, SBP and HE, favouring the hypothesis of increased bacterial translocation. Long-term PPI use should be restricted to cirrhotic patients with formal indication.

SAT-058

In hepatic cirrhosis, the systemic levels of short chain fatty acids inversely correlate with the level of endotoxemia, and are negatively associated with an increased inflammatory response, impaired liver function and a higher HVPG

Oriol Juanola[1], José A Ferrusquia[2,3], Pedro Zapater[3,4], Rocío García-Villalba[5], Marta Magaz[2,3], Alicia Marín[5], Pablo Bellot[3,4], Anna Baiges[2,3], Fanny Turon[2,3], Virginia Hernández-Gea[2,3], José M González-Navajas[3,4], Francisco A. Tomás[5], Juan C García-Pagán[2,3], Rubén Francés[1,3,4]. [1]*Miguel Hernández University, Department of Clinical Medicine, Hepatic and Intestinal Immunobiology Group, San Juan, Alicante, Spain;* [2]*Hospital Clinic-IDIBAPS, University of Barcelona, Hepatic Hemodynamic Laboratory, Liver Unit, Barcelona, Spain;* [3]*Carlos III Health Institute, CIBERehd, Madrid, Spain;* [4]*ISABIAL-Univesitary General Hospital of Alicante, Alicante, Spain;* [5]*CEBAS-CSIC, Murcia, Spain*
Email: ojuanola@gmail.com

Background and aims: Short chain fatty acids (SCFA) are microbial products with homeostatic functions at intestinal and systemic levels. The intestinal dysbiosis present in cirrhosis can reduce the production of SCFA favoring inflammation and an increased gut permeability. These events may contribute to the translocation of bacterial products and the worsening of patients' hemodynamic state.
To determine in cirrhotic patients the levels of SCFA in peripheral (PER) and suprahepatic (SH) blood and their relationship with the inflammatory profile, the endotoxin levels and the hepatic venous pressure gradient (HVPG).
Method: We obtained PER and SH samples and, in an additional subgroup, portal vein (PV) blood from patients with cirrhosis to whom HVPG was determined. SCFA levels (acetic, propionic, butyric and isobutyric acids) were measured by mass spectroscopy and serum cytokines, nitric oxide and endotoxin (ETX) levels by ELISAs.
Results: 62 patients were included (71% men), 59 ± 11 years-old. The etiology was alcoholic in 27, HCV in 18, HCV+alcohol in 12, NASH in 3, and others in 2. MELD, CHILD, and HVPG median were 11 (7-29), 6 (5-11), and 16 (6-31) mmHg respectively. 29 patients had previous ascites, 45 esophageal varices (EV), 13 previous upper intestinal bleeding, 14 hepatic encephalopathy (HE) and 5 previous episodes of SBP. Mean values of SCFA (μM) were higher in SH compared to PER in all cases, with statistical significance in the case of acetic acid (32.9 ± 12.8 vs 23.1 ± 5.1, p = 0.001). In the subgroup of patients with PV, the concentrations of all SCFA were higher than SH and PER, confirming the intestinal origin of the SCFA. In this subgroup, the decrease in the concentration of butyric acid between VP and SH was correlated with the HVPG (r = 0.807, p = 0.0001). SCFAs were globally lower in PER and SH of patients with MELD > 11, reaching statistical significance for the butyric acid in PER (14.7 ± 4.0 vs 18.1 ± 4.2, p = 0.002) and SH (16.4 ± 4.6 vs 19.3 ± 5.3, p = 0.02). PER butyric acid levels negatively correlated with TNF-alpha (r = -0.438, p = 0.002), IL-6 (r = -0.477, p = 0.001), nitric oxide (r = -0.408, p = 0.004) and the HVPG (r = -0.409, p = 0.002). 37 patients showed detectable levels of ETX in PER and SH. The levels of all SCFA were lower in these patients compared to patients without ETX, with statistical significance for butyric acid in PER (15.4 ± 4.2 vs 18.1 ± 4.3, p = 0.02) and SH (16.6 ± 4.6 vs. 19.6 ± 5.4, p = 0.03). The concentrations of ETX and butyric acid were inversely correlated in PER (r = -0.609, p = 0.001) and SH (r = -0.761, p = 0.001).
Conclusion: In patients with cirrhosis, the decrease in SCFA concentrations, especially butyric acid, is associated with an increased inflammatory response and higher levels of ETX, as well as with an impaired liver function and increased HVPG, suggesting a possible pathophysiological role of SCFA in these alterations.

SAT-059

Prevalence and clinical characteristics of malnutrition in cirrhosis according to new EASL practice guidelines

Dae Won Jun[1], Jinhwa Park[1], Bo-Kyeong Kang[2], Mi Mi Kim[2], Jaeyoon Jeong[3], Joo Hyun Sohn[3], Hyunwoo Oh[4], Hyo Young Lee[5], Sang Bong Ahn[6], Yong Kyun Cho[7], Dong Hee Koh[8]. Email: noshin@hanyang.ac.kr

Background and aims: Prevalence of malnutrition is common in cirrhosis. EASL clinical practice guidelines on nutrition in chronic liver disease released very recently. We tried to investigate prevalence and clinical characteristics of malnutrition in cirrhosis according to new EASL practice guidelines as well as European Society for Clinical Nutrition and Metabolism (ESPEN) guideline.
Method: One hundred seventy three outpatients (Child A:140, B:24, C:9 subjects) with liver cirrhosis were recruited from the liver clinic between April 2018 and September 2018. Food frequency questionnaire, tetrapolar bioelectrical impedance analysis, hand grip test, subjective global assessment, and anthropometric measurement were performed. We applied the guideline published by ESPEN in 2015 and EASL in 2018 for defining malnutrition.
Results: Prevalence of malnutrition was 31.8% by definition of ESPEN guideline and 11.6% by definition of EASL guideline and two methods showed fair agreement. Prevalence of malnutrition increased according to degree of Child score and showed inverse relation with body mass index (BMI). Prevalence of malnutrition was 55.6% in Child C, and 62.5% in patient with < BMI 18.5 kg/m2. But etiology of cirrhosis did not associated with malnutrition. BMI, protein intake and sarcopenia were independent risk factor for malnutrition according to EASL guideline. Amount of protein intake showed highest AUROC value to predict malnutrition in EASL guideline
Conclusion: Prevalence of malnutrition was 27.9% in Child A, and 55.6% in Child C patients. Protein intake was independent risk factor of malnutrition in patients with cirrhosis.

SAT-060

Prognostic effect of subcutaneous adipose tissue on survival outcome in patients with liver cirrhosis

Seong Hee Kang[1], Moon Young Kim[1], Woo Kyoung Jeong[2], Seung Hwan Cha[3], Soon Koo Baik[1]. *[1]Yonsei University Wonju College of Medicine, Department of Internal Medicine, Wonju, Korea, Rep. of South; [2]Samsung Medical Center, Sungkyunkwan University School of Medicine, Department of Radiology and Center for Imaging Science, Seoul, Korea, Rep. of South; [3]Yonsei University Wonju College of Medicine, Department of Radiology, Wonju, Korea, Rep. of South*
Email: drkimmy@yonsei.ac.kr

Background and aims: Increasing evidence suggests that decreased skeletal muscle mass (sarcopenia) or adipose tissue assessed predicts negative outcomes in patients with cancer. In liver cirrhosis, while there is consensus that sarcopenia has been associated with higher mortality, the prognostic value of adipose tissue is not clear. We investigated the independent prognostic significance of visceral and subcutaneous adiposity in predicting mortality in liver cirrhosis.
Method: The cross-sectional areas (cm^2) of skeletal muscles and subcutaneous and visceral adipose tissues were measured on CT imaging at the level of the third lumbar (L3) vertebra. Adipose tissue markers, including the visceral adipose tissue index (VATI, cm^2/m^2) and subcutaneous adipose tissue index (SATI, cm^2/m^2), were estimated for 486 patients diagnosed with cirrhosis.
Results: Among the patients, most were male (82.9%) with a mean age of 51.9 ± 9 years and model for end-stage liver disease (MELD) score of 10.2 ± 3. The 5-year overall survival in patients with SATI < median ($42.7cm^2/m^2$) was 56.5%, while it was 78.6% in those with SATI ≥ median (p = 0.008). In multivariate analyses, a low SATI was significantly associated with poor overall survival (adjusted HR [aHR] = 1.709, p = 0.031) after adjusting for MELD score and aetiology of cirrhosis. The 5-year overall survival in patients with VATI < median ($38.3cm^2/m^2$) was 67.6%, while it was 60.5% in those with VATI ≥ median (p = 0.657). A low VATI was not associated with overall survival. The 5-year overall survival in patients with sarcopenia (≤ $52.4cm^2/m^2$ in males and ≤ $38.5cm^2/m^2$ in females) was 44.5%, while it was 74.5% in those without sarcopenia (p < 0.001). Sarcopenia was also associated with mortality (aHR = 2.114, P = 0.001). In the low SATI group, the patients with sarcopenia had lower survival rates than those without sarcopenia (p = 0.001).
Conclusion: Subcutaneous adipose tissues, but not visceral adipose tissues, appear to be associated with a reduction in mortality risk, demonstrating the prognostic importance of fat distribution in patients with cirrhosis. Moreover, the effect of subcutaneous adipose tissues on survival was more pronounced in patients with low muscle mass.

SAT-061

Performance of Baveno criteria with shear-wave elastography in patients with compensated advanced chronic liver disease

Seong Hee Kang[1], Moon Young Kim[1], Soon Koo Baik[1]. *[1]Yonsei University Wonju College of Medicine, Department of Internal Medicine, Wonju, Korea, Rep. of South*
Email: drkimmy@yonsei.ac.kr

Background and aims: Baveno VI and extended Baveno VI criteria have been proposed to avoid screening endoscopies. However, this approach has not been validated in the performance of shear wave elastography (SWE). Also, previous studies have validated the Baveno VI, mostly with hepatitis B or C virus. Therefore, further study has been needed to validate in other aetiology, especially alcoholic liver disease. We aimed to validate these criteria by 2D-SWE in compensated advanced chronic liver disease (cACLD) patients with alcohol as main aetiology.
Method: Clinical data from 305 patients with cACLD who underwent a liver stiffness measurement (LSM) with 2D-SWE and endoscopy were collected consecutively. Baveno VI (LSM < 20kPa and PLT > 150, 000 cells/μL) and extended Baveno VI (LSM < 25kPa and PLT > 110, 000 cells/μL) criteria were tested. High-risk varix (HRV) were defined as F2/3 varices or an F1 varix with red signs.
Results: Among the 305 patients, HRV was identified in 21.0% (n = 64). The main aetiology was alcoholic liver disease (61.1%), followed by HBV (29.8%) and HCV (9.1%). The Baveno VI criteria spared endoscopy in 118 of the 305 (21.6%) patients, and 7 (5.9%) presented with HRV and were therefore missed. The expanded Baveno VI criteria spared more endoscopies (60.0%) but missed more HRV (9.8%) compared with the Baveno VI criteria. Overall, the risk of missing HRV was high. The other classification rules described as the modified Baveno VI criteria were LSM < 25kPa and PLT ≥ 150, 000 cells/μL. A total of 131 of the 305 (43.0%) patients were within the modified Baveno VI criteria, of whom seven (5.3%) had missed HRV. And, after adding spleen diameter < 12 cm to the modified Baveno VI criteria, the number of spared endoscopies increased by 106/305 (34.8%), with three (2.8%) presenting with HRV, indicating that the risk of missing HRV was very low.
Conclusion: The Baveno VI and extended Baveno VI criteria with 2D-SWE were insufficient, with an HRV missing rate of over 5%. However, with the modified Baveno VI criteria together with spleen diameter < 12 cm on 2D-SWE, more endoscopies were spared, with a minimal risk of missing HRV in patients with cACLD and alcohol as the main aetiology.

SAT-062

Edema index measured by bioelectrical impedance analysis predicts ascites or acute kidney injury after liver resection for hepatocellular carcinoma

Soon Sun Kim[1], Gil Ho Lee[1], So Young Yoon[1], Bong Wan Kim[2], Hee Jung Wang[2], Jung Woo Eun[1], Chul Won Seo[1], Hyo Jung Cho[1], Jae Youn Cheong[1], Sung Won Cho[1]. *[1]Ajou University School of Medicine, Gastroenterology, Suwon, Korea, Rep. of South; [2]Ajou University School*

of Medicine, Surgery, Suwon, Korea, Rep. of South
Email: cocorico99@gmail.com

Background and aims: Edema index (extracellular water/total body water, ECW/TBW) measured by bioelectrical impedance (BIA) has been reported to increase with decreased liver function in patients with liver cirrhosis. We investigated whether preoperative ECW/TBW values can predict the incidence of ascites or acute kidney injury (AKI) after surgery in patients with hepatocellular carcinoma
Methods: A total of 83 patients who underwent liver resection for hepatocellular carcinoma were prospectively enrolled from July 2016 to June 2018. BIA assessment of edema index was performed on the day of admission using the InBody 770 scale. Definition of postoperative ascites was defined as ascites drainage of more than 500 cc per day, or diuretics needed to control ascites.
Results: Among 83 patients, 39 patients (47%) had ascites or acute kidney injury after liver resection. In multivariate analysis, ECW/TBW > 0.384 was only significant risk factor for development of post-operative ascites or AKI (odds ratio [OR] = 8.11, 95% confidence interval [CI] = 1.56-42.03; p = 0.013). The subgroup analyses showed that pre-operative ECW/TBW > 0.384 is a significant risk factor for development for post-operative ascites or AKI in patients with liver cirrhosis (OR = 9.38, 95% CI = 1.62-54.24, p = 0.012) but not in those without liver cirrhosis (OR = 6.73, 95C CI = 0.79-57.60, p = 0.082).
Conclusion: The preoperative edema index (ECW/TBW) can be used as a predictor for the incidence of ascites or acute kidney injuries after liver resection, particularly in hepatocellular carcinoma patients with liver cirrhosis.

SAT-063

Third-generation cephalosporins are still useful as the empirical antibiotics for spontaneous bacterial peritonitis in Korea

Sun Woong Kim[1], Jeonghoon Lee[1], Sungwon Chung[1], minseok albert kim[1], Young Chang[1], Hyo Young Lee[1], Jun Sik Yoon[1], Yun Bin Lee[1], Eun Ju Cho[1], Su Jong Yu[1], Yoon Jun Kim[1], Jung-Hwan Yoon[1]. [1]*Seoul National University Hospital, Department of Internal Medicine and Liver Research Institute, Seoul National University College of Medicine, Seoul, Korea, Rep. of South*
Email: pindra@empal.com

Background and aims: The third-generation cephalosporins (TGC) are currently recommended as the first-line empirical antibiotics for spontaneous bacterial peritonitis (SBP) in cirrhotic patients. However, recent studies reported that antibiotics with broader spectrum may be necessary, especially for nosocomial SBP. In this study, we aimed to evaluate whether current treatment strategy for SBP is still valid in Korea, where the resistance to antibiotics prevails
Method: This study retrospectively involved consecutive SBP patients at a tertiary center. The prevalence of TGC-resistant organism and treatment outcome among SBP patients was evaluated.
Results: A total of 287 patients with SBP were included: 110 patients (38.3%) were culture-positive. Thirty-eight (34.5%) of culture-positive patients revealed TGC-resistant organisms. As initial empirical antibiotics, 207 patients (71.9%) received the TGCs. Within 4 days of starting empirical antibiotics, 48 patients (23.1%) changed their antibiotics regimen: 22 non-response (< 25% decrease of ascites neutrophil within 48 hours), 9 culture results, and 16 clinical deterioration. Overall survival did not significantly differ between TGC-resistant SBP and TGC-susceptible SBP (hazard ratio [HR] = 0.890%, confidence interval [CI] = 0.580-1.570; P = 0.595) owing to appropriated antibiotics adjustment according to culture study results and/or treatment response at 48 hours. TGC-resistant bacteria was not an independent risk factor for earlier death (adjusted HR = 0.770; 95% CI = 0.494-1200; P = 0.247) after adjustment for CLIF-SOFA score.

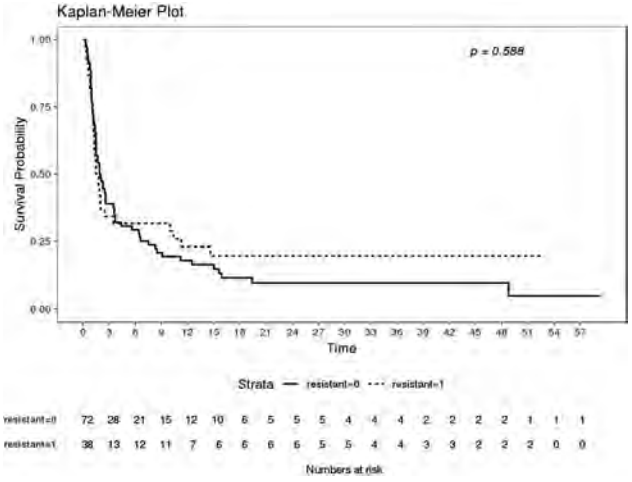

Figure: Overall survival (TGC-resistant SBP vs TGC-susceptible SBP)

Conclusion: Approximately a one-third of patients showed TGC-resistant bacteria in Korean culture-positive SBP patients. However, initial empirical antibiotic treatment with TGC is still effective if the antibiotic regimen is changed following non-response at 48 hours of treatment or culture study results or clinical deterioration.

SAT-064

The prognosis following bacterascites is as poor as spontaneous bacterial peritonitis

Ji Jade King[1], Neil Halliday[2], David Patch[1], Emmanuel Wey[3], Alessio Gerussi[4], Kevin Moore[1], Emmanouil Tsochatzis[1], Jennifer Ryan[1], Rachel Westbrook[1]. [1]*Institute of Liver and Digestive Health Royal Free Hospital, Sheila Sherlock Liver Centre, Royal Free London NHS Trust, University College London, London, United Kingdom;* [2]*Institute of Immunity and Transplantation, University College London, London, United Kingdom;* [3]*Centre for Clinical Microbiology, Division of Infection and Immunity, University College London, Royal Free Hospital, London, United Kingdom;* [4]*Liver Unit, Internal Medicine, Department of experimental and clinical medical sciences, University of Udine, Udine, Italy*
Email: jijadeking@gmail.com

Background and aims: Spontaneous bacterial peritonitis (SBP) is a clinically significant event with associated morbidity and mortality. The clinical and prognostic significance of bacterascites (BA) (the presence of organism on culture but ascitic WCC < 250 cells/mm³) is unknown. The aims of this study were to compare clinical demographics, pathogens and prognostic impact in patients with BA vs SBP.
Methods: Ascitic fluid cultures from consecutive cirrhotic patients over a 10-year period were reviewed to identify patients with SBP/BA. Baseline data obtained, and outcomes collated. Patients with previous SBP/BA were excluded, and only the index case was recorded. If patients progressed from BA-SBP within 72 hours they were classified as SBP. Patients were censored as dead at the time LT or actual death.
Results: 8890 ascitic fluid samples were reviewed identifying 119 cases of SBP and 141 cases of BA. Median age at presentation with SBP or BA was similar (55 vs. 56, p = 0.34) and aetiology was alcohol in 37% of SBP and 39% of BA (NS). Presenting laboratory parameters for SBP vs. BA differed in WCC (11.8 vs. 8.1, p < 0.001) and INR (2.1 vs 1.7, p = 0.01), but not platelets (130 vs 117, p = 0.21), bilirubin (131 vs 128, p = 0.81), creatinine (122 vs 118, p = 0.7), sodium (133 vs 135, p = 0.1) or albumin (29 vs 30, p = 0.16). MELD score was higher in patients with SBP compared to BA (22 vs 20, p = 0.03) as was UKELD score (56 vs 54, p = 0.02). Five patients were lost to follow-up. LT was undertaken in 18/119 (15%) in SBP group compared to 26/141 (18%) in BA group (p = NS). Patient survival was 52/117 (45%) at 1 year and 45/117 (38%) at 3 years in the SBP group compared to 62/138 (45%) and 48/138 (35%) respectively in the BA group (p = NS). Median time

to death in the SBP group was 316 days vs 325 days in the SBP group (NS). In BA 66/141 (44%) of cultures were pathogens, conversely in SBP, 62/119 cases were culture positive, of which 52/62 (84%) were pathogens ($p < 0.001$). The prevalence of bowel flora pathogens were the same in SBP/BA (86vs90%), but were more homogenous in SBP with enetrobacteriacae 78% vs 43% ($p < 0.001$). The overall ESBL rates were similar at 24% (SBP) and 26% (BA). A sub analysis comparing those with pathogens in BA vs SBP, showed no difference in MELD (22vs22) nor 1-year survival (40% vs 44%).
Conclusion: Prognosis following BA is as poor as SBP despite patients with SBP having significantly higher baseline liver severity scores and pathogens isolated. The role of secondary antimicrobial prophylaxis in BA needs to be defined.

SAT-065
Shear wave elastography for skeletal muscle: A novel approach to insulin resistance in cirrhosis
Kazufumi Kobayashi[1], Hitoshi Maruyama[1], Soichiro Kiyono[1], Kengo Kanayama[1], Susumu Maruta[1], Takahiro Maeda[1], Hiroaki Kanzaki[1], Yuko Kusakabe[1], Tomoko Saito[1], Sadahisa Ogasawara[1], Eiichiro Suzuki[1], Yoshihiko Ooka[1], Akinobu Tawada[1], Tetsuhiro Chiba[1], Masato Nakamura[1], Shingo Nakamoto[1], Shin Yasui[1], Naoya Kato[1]. *[1]Graduate School of Medicine, Chiba University, Department of Gastroenterology, Chiba, Japan*
Email: z3m1034k@yahoo.co.jp

Background and aims: Changes in muscle composition with loss of muscle mass have been proposed as additional potential mediators of the association between diabetes and disability. Several factors including decreased muscle mass, changes in muscle architecture and fiber type may account for the reduction of muscle strength in cirrhosis, featuring the development of sarcopenia. Stiffness measurement has attracted attention in clinical practice, and the recent Guidelines suggested that 2 dimensional shear wave elastography (2D-SWE) is a promising technique for the grading of hepatic fibrosis. Against the background, we hypothesized that the alternation of muscle function regarding the glucose metabolism may be reflected in the muscle elasticity. The aim was to examine the effect of muscle elasticity on the insulin resistance (IR) in cirrhosis.
Method: This is an IRB-approved cross-sectional study (October 2016 to October 2018) including cirrhosis patients who underwent both computed tomography (CT) and transcutaneous ultrasound (US); the former for skeletal muscle index at the L3 level (L3-SMI) and the latter for the 2D-SWE on the cross-section image of the right iliopsoas muscle to obtain the elasticity of right iliopsoas muscle (IP-E). IR was defined by homeostasis model assessment of insulin resistance (HOMA-IR) > 3.0.
Results: The study consisted of 99 cirrhosis patients (70.7 ± 9.4 years; 33 females), whose Child-Pugh Score ranging from 5 to 12 (6.2 ± 1.7). Forty patients were defined as having IR. IP-E ranged from 4.1 to 51.7 KPa (10.4 ± 6.0), and showed significant correlation with body mass index (BMI), L3-SMI, and HOMA-IR. There were differences between patients with and without IR, in BMI (25.6 ± 2.6 vs 22.6 ± 3.3, $p < 0.0001$), L3-SMI (44.1 ± 6.5 vs 40.0 ± 7.3, $p = 0.005$), and IP-E (13.3 ± 8.1 vs 8.4 ± 2.5, $p = 0.0005$). Multivariate analysis showed that IP-E and BMI were independent factors for IR. The sensitivity, specificity and area under the receiver operating characteristic curve for the diagnosis of IR were 70%, 76.3%, and 0.779, under the best cut-off value of 9.95.
Conclusion: Muscle elasticity is a target in the evaluation of IR, suggesting the novel aspect of the clinical application of 2D-SWE in cirrhosis.

SAT-066
Modified SAE technique provides a long last sustained hemodynamic response on splenic artery blood velocity in patients with cirrhosis and clinically significant portal hypertension
Sergii Kozlov[1], Petro Fomin[1], Alexander Nikishin[2], Victor Sidorenko[1]. *[1]Bogomolets National Medical University, Chair of surgery#3, Kyiv, Ukraine; [2]National Academy of Medical Science, Endovascular Neuro RI surgery, Kyiv, Ukraine*
Email: sergiinikol@gmail.com

Background and aims: Splenic artery embolization (SAE) is one of the perspective option for variceal bleeding (VB) prophylaxis. We started widely using SAE in cirrhotic patients since the 2003 year and observed, like many others investigators, restoration of VB risks in terms 3-6 months after the procedure. Modified SAE technique, as well as improved quality check protocol, were introduced into practice in our tertiary GI bleeding center since 2009.
Method: We used innovative multi-shaped "soft" coils for reduction of splenic arterial blood flow in 112 cirrhotic patients with clinically significant portal hypertension (CSPH) for VB prophylaxis. In group 1 were 77 patients who had experienced 1 or more (totally 232, or 3.02 per patient) VB episodes. Group 2 included 35 patients with non-bleeding varices, but with present ascites and splenomegaly. According to our prospective study design Doppler examinations (with splenic artery (SA) peak systolic (PSV) and diastolic velocity (DV) measurements) were conducted on the baseline and after SAE in 30 days, 3, 6 and 12 months. Additionally, we evaluated the resistive index (RI), spleen volume (SV), recidive rate (RecR) and recidive free period (RFP).
Results: In group 1 PSV SA mean according to end points (baseline/ 1 m/3 m/6 m/12 m; M cm/s ±SD) in our study were: 151.38 ± 51.037; 86.40 ± 32.889; 86.31 ± 33.321; 90.80 ± 39.380; 96.34 ± 40.420) and showed significant decreasing (–55 cm/s, $p < 0.001$) at final EP "12m". In group 2 we observed the same significant ($p < 0.001$) decreasing of PSV SA mean from 146.40 cm/s (baseline) to 96.17 cm/s (12 m). Decreasing of PSV and DV means started at EP "1m" and lasted till EP "12m". The same tendency was observed in 1 and 2 groups for DV SA (baseline/12 m; M±SD): 55.69 ± 20.645; 36.85 ± 14.042 and 57.09 ± 18.252; 41.61 ± 19.214; respectively, ($p < 0.001$ in both cases). Thus no significant changes were detected in RI calculation on baseline and EP "12 m": it decreased from 0.62 to 0.60 (gr.1) and from 0.61 to 0.57 (gr.2). Introduction of modified SAE technique resulted first of all in clinical benefit-in group 1 RecR of bleeding episodes dramatically decreased from 3.02 per patient/year to 0.4. In group 2 (no previous episodes) occurred single VB episode. The average RFP (in days) was 568 in gr.1 and 759 in gr.2 respectively. Spleen volume downed from 784 to 519 cm^3 in gr.1 and from 1000 to 673 cm^3 in gr 2 ($p < 0.01$).
Conclusion: Modified SAE could be regarded as reliable secondary and primary prophylaxis option in cirrhotic patients with CSPH due to sustained long lasted (1 year and more) decreasing effect on splenic blood flow. Also, it could be considered as "bridge therapy" in cirrhotic and CLD patients in the waiting list for OTP or undergoing another treatment strategy. At the same time, in our study RI doesn`t depict the tendency of hemodynamic changes.

SAT-067
Prospective assessment of sarcopenia as a prognostic factor for survival in patients with liver cirrhosis
Wolfgang Maximilian Kremer[1], Sandra Koch[1], Dorothea Lochner[1], Anna Christina Koch[1], Felix Hahn[2], Annette Grambihler[1], Christian Labenz[1], PD Dr. Schattenberg Jörn[1], Christoph Düber[2], Peter Robert Galle[1], Arndt Weinmann[1], Martin Sprinzl[1]. *[1]University Medical Center, Departement of Medicine I, Mainz, Germany; [2]University Medical Center, Departement of Radiology, Mainz, Germany*
Email: M.Kremer@gmx.net

Background and aims: The Child Turcotte Pugh- and the Model for End Stage Liver Disease- (MELD) Scores are a well-known tool to

evaluate the risk of mortality in patient with cirrhosis. Both do not pay attention to the nutritional status of the patient. Several studies recently showed the correlation between sarcopenia and survival in patients with cirrhosis. However, there is still no consensus on measurement and cut-off values for determining sarcopenia. The aim of this study was to define cut-off values for the PMTH- (psoas muscle thickness height) and the TPMA- (transverse psoas muscle area) index normalized to the height for patients with a minor probability of survival. Moreover, we wanted to find out the correlation between sarcopenia and survival.

Method: Between 2010 and 2013, we included 162 patients with liver cirrhosis presenting at the university hospital of Mainz, Germany. Sectional radiological diagnostics were obtained from 90 patients to measure the PMTH- and TPMA-index. Outcome and survival data were prospectively collected during a 4-year follow-up. Continuous variables (mean±standard deviation) and categorial variables (numbers and percentages) were reported. The t-test for independent variables was calculated. For the multivariate analysis we applied the Kaplan Meier curve and the cox regression to survival rates.

Results: The average age was 57, 1 ± 13, 8 years and 65, 4% were men. Alcoholism (42%) and chronic viral hepatitis (35, 1%) were the most frequent liver diseases. Patients were classified as CTP Group A (45, 7%), B (29, 0%) and C (25, 3%), the average MELD score was 12, 4 points. The optimal TPMA-index cut-off (male 542, 88 mm^2/m, female 360, 45 mm^2/m) and PMTH (male 11, 42 mm/m, female 9, 50 mm/m) were determined by ROC-AUC analysis and Youden-index calculation. Following Kaplan Meier analysis TPMA and PMTH were significantly associated with overall survival ($p < 0.05$). However mutivariable cox regression only showed an influence of sarcopenia on survival for women (HR PMTH 0, 251 (0, 83-0, 0, 763), p = 0, 015).

Conclusion: Sarcopenia plays an important role in the outcome of patients with liver cirrhosis. With our results we can underline the effect of sarcopenia in women. With the help of our cut-off values we might differentiate patients with cirrhosis between a major risk and minor risk group.

SAT-068

Presence of liver cirrhosis is the strongest negative predictor of survival for patients admitted to intensive care unit

Alica Kubesch[1], Kai-Henrik Peiffer[1], Georg Dultz[1], Hannes Abramowski[1], Harald Farnik[1], Stefan Zeuzem[1], Jörg Bojunga[1], Mireen Friedrich-Rust[1]. [1]*Klinikum der Goethe Universität, Medizinische Klinik 1, Frankfurt am Main, Germany*
Email: alica.kubesch@kgu.de

Background and aims: Liver cirrhosis is a systemic disease with strong impact on whole body physiology especially in advanced stages. Accordingly, the outcome of patients with cirrhosis depending on intensive care treatment is poor. Aim of this study was to analyze the impact of cirrhosis on mortality of ICU patients in comparison to other frequent chronic diseases and conditions.

Method: Patients admitted to intensive care unit of the department of medicine of the university hospital Frankfurt in a three year period were included retrospectively into the study. Patients were followed until hospital discharge or death and clinical and laboratory parameters acquired from the electronic patient files. A binary logistic regression model was used to identify parameters associated with survival.

Results: A total of 567 consecutive patients admitted to intensive care unit were included into the study of which 99 (17.5%) had liver cirrhosis. The major reasons for ICU admittance were acute cardiac event (31.7%), infection/sepsis (29.1%) and respiratory failure (14.1%) in the non-cirrhotic group and deterioration of liver function (34.4%), infection (22.2%) and hemorrhage (15.2%) in the cirrhotic group. Median MELD score of patients with cirrhosis was 23 (7-40). In hospital mortality was 22.2% in the non-cirrhotics compared to 47.5% in cirrhotic patients (OR 3.163 95% CI 2.016-4.965), $p < 0.001$). In the multivariate logistic regression model adjusted for age, preexistent cardiac, pulmonary or kidney disease, SAPSII score, MELD score, actual malignancy, diabetes mellitus and immunosuppressive therapy liver cirrhosis remained the strongest independent predictor of in-hospital mortality (OR 5.456 95%CI 2.590-11.494, $p < 0.001$). In the cirrhotic group the need for kidney replacement therapy (48.5% vs. 21.2%, $p < 0.001$) and blood transfusion (47.8% vs. 45.1%, $p < 0.001$) was significantly higher than in non-cirrhotics. In the group of cirrhotic patients mortality increased with MELD score (< 16: 33.3%; 16-25: 46.3%; > 26: 55.0%).

Conclusion: In the presented study liver cirrhosis was the strongest predictor of in hospital mortality in patients needing intensive care treatment even when adjusted for MELD score and other chronic diseases and conditions associated with ICU mortality. Concerted efforts are needed to improve the outcome of cirrhotic patients and prevent disease progression and complications with the need for ICU treatment already in early stages of the disease.

SAT-069

Interleukin 6: A marker for hepatic encephalopathy

Christian Labenz[1], Yvonne Huber[1], Nagel Michael[1], Jens Marquardt[1], Peter Galle[1], PD Dr. Schattenberg Jörn[1], Marcus-Alexander Wörns[1]. [1]*University Medical Center of the Johannes Gutenberg-University Mainz, Department of Internal Medicine I, Mainz, Germany*
Email: christian.labenz@unimedizin-mainz.de

Background and aims: The pathophysiology of hepatic encephalopathy (HE) is not completely understood. Key roles are attributed to increased serum ammonium and systemic inflammation. Recent studies could demonstrate that Interleukin 6 (IL6) is associated with the presence of minimal hepatic encephalopathy and mortality in cirrhotic patients. The predictive value of IL6 for risk stratification of patients with liver cirrhosis regarding first time overt HE (OHE) development has not been investigated yet.

Method: In- and outpatients with an established diagnosis of liver cirrhosis treated between March 2017 and August 2018 at the University Medical Centre Mainz were included into this prospective cohort study. 108 without a history of OHE patients were followed prospectively for 6 months. The primary end point was OHE development. Exclusion criteria were an OHE episode during the previous three months, current alcohol abuse, intake of psychotropic drugs, TIPSS, HCC or an active infection. A diagnosis of CHE was established by means of PHES and/or CFF and the West-Haven Criteria. IL6 was measured at the day of study inclusion.

Results: 297 patients were screened and 210 finally included into the study. Median age was 60 years (IQR 52; 66). 56.2% were male and most patients had compensated stage of liver cirrhosis (Child-Pugh A, B, C; 61%, 31%, 8%; Median MELD: 10). CHE was detected in 81 patients (38.6%). On multivariate logistic regression analysis, IL6 (OR = 1.025, 95% CI 1.010-1.535, p = 0.001) and a previous episode of OHE (OR = 3.653, 95% CI 1.535-8.695, p = 0.003) were independent predictors of CHE. In total, 108 patients without previous OHE were followed for 6 months regarding first time OHE. IL6 values in the highest quartile ($\geq$ 19pg/ml) were predictive for first time OHE after adjusting for MELD-Score, CHE status at study inclusion and CRP (sHR = 27.4, 95% CI 3.4-219.4, p = 0.002). The predictive value of IL6 measured by AUROC was higher (AUROC 0.936) as compared to MELD (0.755) and CRP (0.865) with respect to first time OHE.

Conclusion: IL6 constitutes an important marker to identify uninfected patients at high risk for OHE within the next 6 months.

SAT-070

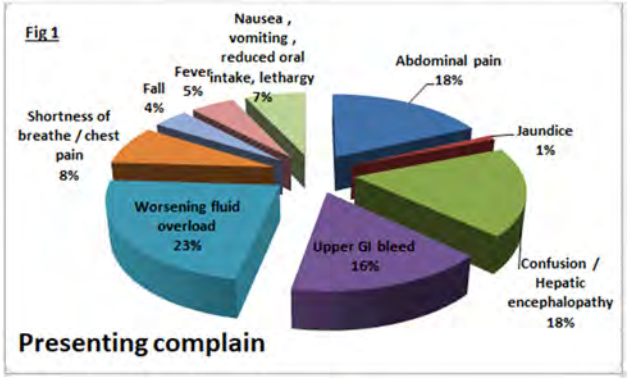
A clinical pathway to manage patients with decompensated cirrhosis: Assessing the level of compliance with evidence based guidelines

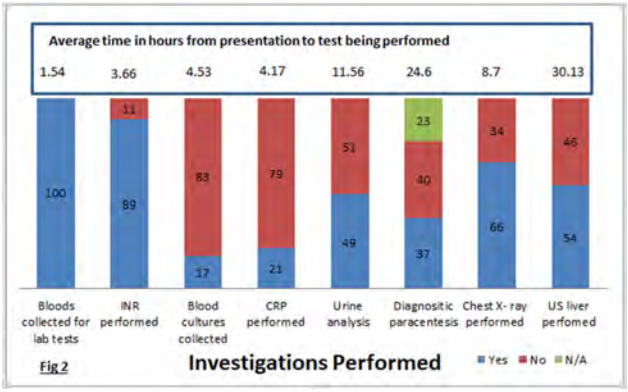
Abdulnasser Lafta[1], Tony Rahman[1]. [1]*The Prince Charles Hospital, Chermside, Australia*
Email: nasserhawas@gmail.com

Background and aims: Acute admission to hospital with decompensated cirrhosis is increasing in Australia. Variable provision of clinical services in Queensland contributes to a 'post code lottery'and may lead to inequitable inferior outcomes with 28-day mortalities recorded at > 30%. To improve outcomes to multidisciplinary admitting teams an adapted 'BASL' tool kit was recommended to ensure evidence-based treatments were consistently delivered. The tool kit guides non- specialists through the acute investigations and management within 24 hours of admission. Implementation delays correlate with an increase in mortality. This study assesses the level of compliance with the recommended evidence-based guidelines in a major teaching hospital in Brisbane

Method: Retrospective observational study. Inclusion Criteria: Patients ≥ 16 years old presenting to the Emergency Department with decompensated cirrhosis between January 2016-January 2017. Data was manually collected from the patient notes.

Results: A total of 100 presentations to the ED by 53 patients with decompensated cirrhosis were included. Figure 1. demonstrates the distribution of presenting complaints. Aetiologies included, alcohol (n = 31, 58%), NASH (n = 9, 17%) and HCV (n = 5, 9%). Males accounted for 71% with a median age of 61 years (range 30-86).





Ascites-Diagnostic paracentesis not performed because: No clinical signs of SBP (n = 8, 20%): No reason given (n = 30, 75%): Risk of bleeding (n = 2, 5%). SBP was found in 5 patients, mean time to diagnostic tap and antibiotics was 27.6 hrs and 31.8 hrs respectively.

AKI: Accounted for 25% of admissions: Diuretics were witheld and fluid challenge administered in 52% (n = 13) and 40% (n = 10) respectively.

GIB: 94% of patients (n = 16), received IV proton pump inhibitors (mean time = 2.2 hrs) and octreotide (mean time = 4.1 hrs). Antibiotic prophylaxis was adminstered in 82% (n = 13) -mean time of 4.54 hrs.

HE: 33 patients presenting with HE underwent adequate investigations to identify common precipitants (n = 31, 94%), with the exception of SBP. 88% received lactulose as initial management (n = 29, 88%) at a mean of 9.3 hrs from presentation. Despite the absence of any contraindications for the administration of venous thromboembolic prophylaxis, it was administered in only 26% (n = 20) of the patients.

Conclusion: The uptake of recommended inital investigations amongst this cohort of patients was suboptimal. Presentations that incited a sense of urgency amongst non-specialist staff, such as GIB and HE faired better. Most presenting complaints warranted the exclusion of SBP, however, 52% (n = 40) of the patients with ascites (n = 77) did not undergo a diagnostic tap. The mean time to diagnostic paracentesis in this cohort was 24.6 hrs. We believe that implementing a care pathway will improve early compliance with investigations and interventions and improve outcomes. This is now being tested.

SAT-071

Insulin resistance in cirrhotic patients: results from a large prospective study

Clarembeau Frédéric[1,2], Peter Stärkel[1,2], Dahlqvist Géraldine[1], Isabelle Leclerq[2], Nicolas Lanthier[1,2]. [1]*Cliniques universitaires Saint-Luc, Service d'Hépato-gastro-entérologie, Brussels, Belgium;* [2]*Université catholique de Louvain, Laboratory of Gastroenterology and Hepatology, Institut de Recherche Expérimentale et Clinique, Brussels, Belgium*
Email: nicolas.lanthier@uclouvain.be

Background and aims: Cirrhosis is a frequent disease inducing high morbidity and mortality. Available data suggest that cirrhosis could be associated with insulin resistance (IR) and diabetes mellitus (DM). We performed a prospective study to answer the following questions: is cirrhosis associated with IR and DM; is IR, independently from diabetes, associated with cirrhosis severity; are the different etiologies of cirrhosis associated with different levels of IR and finally does glucose homeostasis alterations correlate with higher morbidity and mortality?

Method: From February 2016 to September 2017, patients seen at the hepatology clinic were prospectively enrolled in this study. At inclusion, a complete assessment of glucose homeostasis was performed on fasted venous blood to calculate the homeostasis model assessment of insulin resistance (HOMA). Patients were separated in several cohorts, based on the presence or absence of cirrhosis (cirrhosis versus controls), absence or presence of treated DM and IR (HOMA > 2.5). We recorded the cause of the underlying liver disease and the number of hospitalizations due to cirrhosis complication and death during the study period.

Results: 107 patients with cirrhosis and 20 controls accepted to participate in this study. Both groups were comparable in terms of age, body mass index, creatinine and triglyceride levels but cirrhotic patients had significant lower levels of albumin, platelets and cholesterol and significant higher levels of AST and INR. There were 43% of patients with DM within the cirrhotic group compared with 25% of patients within the control group. In cirrhotic patients without DM, IR was more pronounced than in control patients (mean HOMA-IR: 5.9 ± 4.7 vs 2.8 ± 2.2, $p = 0.004$). We also found that IR was correlated with the severity of cirrhosis based on the MELD score ($r = 0.54$, $p < 0.001$). Different etiologies of cirrhosis were shown to exhibit different levels of IR ($p = 0.001$). DM was most prevalent in the NAFLD cirrhotic group with 75.6% of the patients treated for diabetes within this group. IR and DM were also associated with an elevated morbidity and mortality ($p = 0.005$).

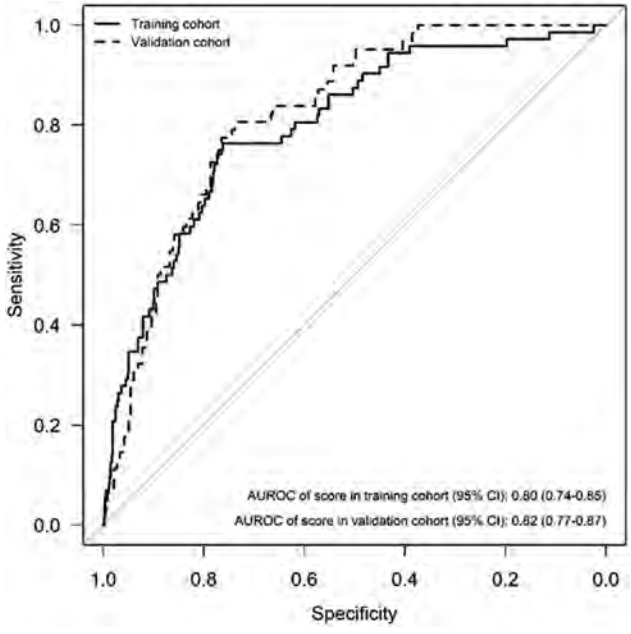
Conclusion: Insulin resistance is more frequent in cirrhotic patients. The level of insulin resistance is correlated with cirrhosis severity and is associated with a higher rate of complications and a lower survival within the cirrhotic group. Whether an early diagnosis of insulin sensitivity in this population and an appropriate treatment will reduce such complications remains to be defined.

SAT-072

Predict improvement of liver cirrhosis after antiviral treatment in patients with chronic hepatitis B

Hye Won Lee[1], Terry CF Yip[2], Grace Lai-Hung Wong[2], Henry Chan[2], Yee-Kit Tse[3], Chung Yan Grace Lui[3], Sang Hoon Ahn[1], Vincent Wai-Sun Wong[2]. *[1]Yonsei University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South; [2]The Chinese University of Hong Kong, Department of Medicine and Therapeutics, Shatin, Hong Kong; [3]The Chinese University of Hong Kong, Institute of Digestive Disease, Shatin, Hong Kong*
Email: wongv@cuhk.edu.hk

Background and aims: Improvement in Model for End-Stage Liver Disease (MELD) score over time under antiviral treatment is associated with reduced hepatic decompensation and death in patients with chronic hepatitis B (CHB)-related cirrhosis. We developed a prediction score for MELD score improvement.
Method: We identified patients with CHB-related cirrhosis and MELD score ≥ 15 at the start of entecavir and/or tenofovir disoproxil fumarate treatment from 2005 to 2016 in Hong Kong and from 2006 to 2017 in Severance Hospital, South Korea. The primary and secondary end points were transplant-free survival with > 5 point improvement in MELD score and with MELD score < 10 after 6 months of treatment, respectively. Patients with cancers up to 6 months of follow-up were excluded. Patients were randomly divided into training (60%) and validation (40%) cohorts. Prediction score was calculated as the weighted sum of selected clinical parameters.



Results: 999 cirrhotic CHB patients were included. During the first 6 months of treatment, 102 (10.2%) patients received liver transplantation and 294 (29.4%) patients died. At month 6, the mean MELD score of 605 patients with transplant-free survival improved from 19.8 ± 4.3 to 14.7 ± 6.0 (paired t test, P < 0.001); 276 (45.6%) patients achieved > 5 point improvement in MELD score. Five predictors including age, creatinine, platelet counts, international normalized ratio, and presence of hepatic encephalopathy were independently associated with improvement in MELD score. The prediction score achieved area under the receiver-operating characteristic curve of 0.80 (95% confidence interval [CI] 0.74-0.85) and 0.82 (0.77-0.87) in the training (N = 605) and validation cohorts (N = 394), respectively, on predicting transplant-free survival with MELD score < 10 at month 6 (Figure). The proportion of patients who achieved the primary and secondary end points at month 6 increased from poor, intermediate to good treatment responders defined by cut-offs of the score (chi-square test for linear trend, P < 0.001). The 1-year transplant-free survival (95% CI) in good, intermediate, and poor responders were 72% (62%-81%), 59% (53%-66%), and 43% (37%-50%) in training cohort, and 76% (64%-86%), 63% (55%-70%), and 43% (36%-51%) in validation cohort.
Conclusion: This simple score predicts on-treatment MELD score improvement and correlates with treatment response and clinical outcomes in patients with CHB-related cirrhosis.

SAT-073

Micronutrient deficiencies in patients with decompensated cirrhosis

Email: gemma.lln4@gmail.com

Background and aims: Patients with cirrhosis usually present malnutrition and micronutrient deficits, which leads to a worse prognosis of their disease and increased mortality.
Our main goal is to assess the deficit of micronutrients (vitamins and oligoelements) in cirrhotic patients admitted due to decompensation.
Method: Prospective unicentric study in patients with liver cirrhosis (LC) of any etiology admitted due to decompensation from October 2017 to October 2018. Demographic data, etiology of LC, presence of diabetes, Child-Pugh and MELD score were analyzed, reason of admission (ascitic decompensation (AD), infection, hepatic encephalopathy (HE), alcoholic hepatitis, acute kidney injury (AKI) and portal hypertensive bleeding (PHB). A blood test including determination of oligoelements (calcium, phosphorus, magnesium, zinc and copper) and vitamins (A, B1, B6, B12, C, D, E, K and folic acid) was performed.
Results: 87 patients were included. Mean age 63 ± 10.8 years, 80% men. The etiology of the cirrhosis was alcohol in 87.4%, 60% of whom had active consumption. Child-Pugh Score was A/B/C in 10.3%/50.6%/39.1%, respectively. Mean MELD of 16.7 ± 6.74. 39.1% were diabetics. The reason for admission was: AD/Infection/HE/alcoholic hepatitis/AKI/PHB in 85.1%/41.4%/21.8%/17.2%/21.8%/13.8%, respectively. The deficits of micronutrients detected were: vitamin A (93.17%), vitamin B6 (57.6%), vitamin C (52.3%), vitamin D (90.7%), zinc (92.9%), phosphorus (39%), magnesium (25%) and iron (40%). The deficits of vitamin B1, E, K and folic acid were 2.5%/14.9%/2.9%/6.3% respectively. Child C patients had lower values of vitamin A (p < 0.001) and zinc (p < 0.001) and higher values of iron (p = 0.015), ferritin (p = 0.05) and vitamin B12 (p < 0.001) in relation to Child A and B. Patients with a higher MELD score had lower values of vitamin

A (p < 0.001), vitamin E (p < 0.001), magnesium (p = 0.021) and zinc (p = 0.001) and higher iron values (p = 0.013), ferritin (p = 0.004) and vitamin B12 (p < 0.014).
Conclusion: Micronutrient deficiencies are common in patients with decompensated cirrhosis. The most frequently deficient vitamins are A, B6, C and D. Zinc deficiency is universal in this population. Severe hepatic insufficiency correlates with lower levels of zinc and vitamin A and higher levels of vitamin B12, iron and ferritin. The impact of systematic supplementation of these deficits should be explored in subsequent studies.

SAT-074

Prevalence and risk factors of colonization by multidrug resistant bacteria in cirrhotic patients admitted to the intensive care unit in a Spanish tertiary hospital

Daniel Abad[1], Beatriz Dendariena[1], Trinidad Serrano[2], Pilar Luque[3], Javier Castillo[4], Alberto Lué[2], Claudia Mendoza[4], Jose Ramón Paño[5], Luis Cortés[2], Sandra García[1], Sara Lorente[2]. *[1]Hospital Clínico Universitario Lozano Blesa, Liver Unit, Department of Gastroenterology, Zaragoza, Spain; [2]Hospital Clínico Universitario Lozano Blesa. ISS Aragón, Liver Unit, Department of Gastroenterology, Zaragoza, Spain; [3]Hospital Clínico Universitario Lozano Blesa, Intensive Care Unit, Zaragoza, Spain; [4]Hospital Clínico Universitario Lozano Blesa, Microbiology, Zaragoza, Spain; [5]Hospital Clínico Universitario Lozano Blesa, Infectious Diseases Unit, Zaragoza, Spain*
Email: slorentep@gmail.com

Background and aims: Recent studies suggest that the prevalence of infections caused by multidrug-resistant (MDR) bacteria is increasing in cirrhosis, as in the general population. However, there are limited data about prevalence, risk factors and clinical impact of colonization by MDR bacteria in the cirrhotic population. In addition, resistance patterns can differ between different areas and hospitals. The objective of our study was to investigate the prevalence of colonization by MDR bacteria in critical patients with cirrhosis who require admission to the Intensive Care Unit (ICU) in our area and to evaluate the risk factors involved in colonization by MDR bacteria.
Method: We conducted a retrospective study including all adult patients with cirrhosis admitted to the ICU between March 2015 and July 2018 and who underwent triple (nasal/pharyngeal/rectal) swabs in order to investigate colonization by MDR bacteria, as part of the "*Zero Resistance*" (ZR) project at our hospital (Garnacho Montero J et al. Critical Care 2015; 19:114).
Results: 165 cirrhotic patients were admitted to the ICU during the study period and sixty five of them underwent triple swabs to investigate colonization by MDR bacteria according to ZR program recommendations at our centre. 15 patients (23%) were colonized by any MDR bacteria. The most frequent MDR isolated bacteria were spectrum β-lactamase- producing *Enterobacteriaceae* (66.7%), followed by methicillin-resistant *Staphylococcus aureus* (MRSA, 20%) and *S. maltophilia*. (13.3%). The presence of more than 3 risk factors from ZR checklist at the admission to the ICU (86.7% vs 48%; p = 0.008, OR 7.04 CI95% [1.44-34.48]), and antibiotic prophylaxis (60% vs 28%; p = 0.023, OR 3.85 CI95% [1.16-128]) were significantly related with MDR bacteria colonization. Although incidence of infection by MDR bacteria intra-ICU was higher in colonized patients, this difference was not statistatically significant (33%vs20% p > 0.05). In colonized patients who developed infection there was a 100% concordance between the colonizing and infectious agents.
Conclusion: MDR bacteria colonization is frequent in patients whit cirrhosis admitted to the ICU in our area. Antibiotic prophylaxis and/or the presence of at least 3 items from the *Zero Resistance* checklist are risk factors for MDR bacteria colonization in this population. There is a clear correlation between the colonizing and infecting bacteria in these patients.

SAT-075

Clinical efficacy of transjugular intrahepatic portosystemic shunt created with expanded polytetrafluoroethylene-covered stent-grafts: 8-mm versus 10-mm

xuefeng luo[1], li yang[1]. *[1]West China Hospital, Gastroenterology and Hepatology, chengdu, China*
Email: luo_xuefeng@yeah.net

Background and aims: Conflicting data exist regarding the appropriate shunt diameter for transjugular intrahepatic portosystemic shunt (TIPS) creation in cirrhotic patients. This study was designed to compare the clinical efficacy of TIPS using stent-grafts with 8- and 10-mm diameters.
Method: In this retrospective study, cirrhotic patients who underwent TIPS technical successfully for the prevention of variceal rebleeding from December 2011 to June 2015 were included. Propensity score matching was performed to minimize baseline confounders.
Results: Baseline characteristics between two groups were comparable. There was no significant difference in variceal rebleeding between the two groups. 8-mm TIPS conferred a significant decrease in hepatic encephalopathy (HE) rate compared with the 10-mm TIPS (16.1% versus 32.6% at 1 year, 27.8% versus 53.2% at 3 years, $p = 0.034$). The cumulative survival rates were similar between the two groups: 93.3% and 79.6% at 1 and 3 years, respectively, in the 8-mm TIPS group vs. 87.3% and 72.1% at 1 and 3 years, respectively, in the 10-mm TIPS group (p = 0.451).

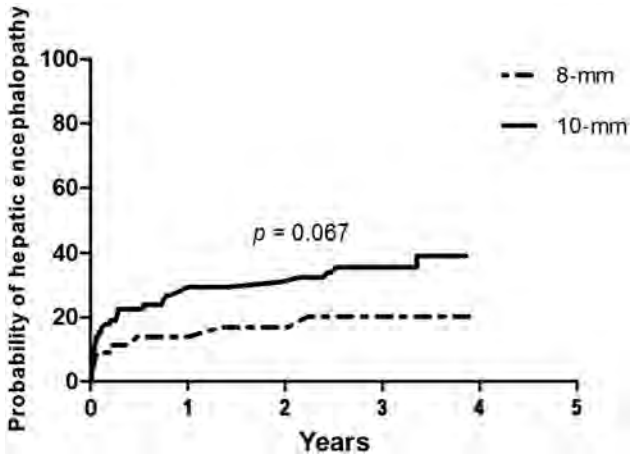

Figure: The probability of free of hepatic encephalopathy in the two groups.

Conclusion: The placement of 8-mm TIPS was sufficient to decompress the portal hypertension and prevent variceal rebleeding. The application of the 8-mm stent-graft can decrease HE rates compared with 10-mm stent-graft, although no survival benefit was observed.

SAT-076

Long term palliative abdominal drains versus large volume paracentesis in refractory ascites due to cirrhosis: a multi-centre feasibility randomised controlled trial (the REDUCe Study)

Lucia Macken[1,2], Louise Mason[2], stephen bremner[1], Heather Gage[3], Morro Touray[3], Catherine Evans[4], Max Cooper[1], Jean Timeyin[2], Shani Steer[2], Debbie Lambert[1], David Crook[1], Mark Austin[2], Nick Parnell[2], Sam Thomson[5], David Sheridan[6], Mark Wright[7], Peter Isaacs[8], Ahmed Hashim[1,2], Sumita Verma[1,2]. *[1]Brighton and Sussex Medical School, Falmer, United Kingdom; [2]Brighton and Sussex University Hospitals NHS Trust, Brighton, United Kingdom; [3]University Of Surrey, Surrey, United Kingdom; [4]King's College Hospital NHS Foundation Trust, London, United Kingdom; [5]Worthing Hospital, Worthing, United Kingdom; [6]Plymouth Hospitals NHS Trust, Plymouth,*

United Kingdom; [7]University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; [8]Blackpool Victoria Hospital, Blackpool, United Kingdom
Email: lucia.macken@bsuh.nhs.uk

Background and aims: Ascites develops in about 90% with advanced cirrhosis; when refractory to medical therapy, standard of care is repeated large volume paracentesis (LVP) with albumin support. Refractory ascites (RA) confers a median life expectancy of six months without liver transplantation (LT). LVP is not an optimal palliative strategy. One alternative is long-term abdominal drains (LTAD), used in advanced malignant ascites, also enabling community management. Our ultimate aim is to improve end of life care (EoLC) in advanced cirrhosis and RA. This feasibility randomised controlled trial (RCT) aimed to resolve uncertainties in designing a definitive RCT.
Method: Multicentre feasibility RCT with 1:1 randomisation between standard of care (LVP) vs. LTAD (Rocket Medical) in adults with RA, ineligible for LT. Both arms received prophylactic antibiotics. LTAD were inserted under ultrasound guidance. Community nurses undertook home visits to drain ascites dependent on symptoms; (maximum 6L/week), without albumin support. Follow-up was 12 weeks with home visits every two weeks for the following assessments: clinical, questionnaire based to include quality of life, palliative care needs, carer burden and health economics (HE). Here we report clinical and HE outcomes.
Results: Thirty six patients were randomised; 19 LVP (two withdrew, wanting LTAD) and 17 LTAD (one withdrew-insufficient ascites). Mean age (years) LTAD vs. LVP 66 + 10.4 vs. 68 ± 12; predominately male (76% vs. 74%). Participants were well matched at baseline in liver tests and prognostic scores: LTAD vs. LVP (serum bilirubin (μmol/L) 26 ± 15.8 vs. 16 ±10, serum albumin (g/L) 33 ± 4.2 vs. 31 ± 3.3, serum creatinine (mmol/L) 113 ± 46.7 vs.118 ± 53.1; MELD 14 ± 4.6 vs. 16 ± 7.2). One LTAD participant required hospitalisation for repeated LVP. Serum albumin (g/L) in the LTAD arm declined to 29 ± 3.3 at week two, subsequently remaining stable LTAD vs. LVP (29 ± 5.6 vs. 31 ± 5.5). Serum creatinine remained stable in both arms. There were no LTAD related serious adverse reactions. LTAD related adverse reactions included mild cellulitis (n = 4) and small volume leakage around LTAD insertion site (n = 3), all resolving rapidly. Peritonitis was rare, LTAD (possible) n = 1 and LVP n = 2. Overall mortality was 36% (12/33). Mortality and median survival (days in those who died) were 7/16 (44%) vs. 5/17 (29%), 53 days (IQR 43) vs. 61 days (IQR 35) in LTAD vs. LVP respectively. All but one death was liver related. Those in LTAD arm spent ≈20% less time in hospital. All nine alive in the LTAD arm at end of study elected to keep LTAD in. Detailed clinical and HE analysis is underway.
Conclusion: Preliminary data from the REDUCe study supports the safety and efficacy of palliative LTAD in RA due to advanced cirrhosis. LTAD allows successful management in the community with reduction in health resource utilisation. Proceeding to a definitive RCT is justified.

Intraperitoneal activation of blood coagulation via tissue factor-exposing extracellular vesicles in patients with advanced chronic liver disease

Mattias Mandorfer[1], Johannes Thaler[2], Lena Hell[2], Philipp Schwabl[1], Lukas Wisgrill[2], Cihan Ay[2], Peter Quehenberger[3], Ton Lisman[4], Rienk Nieuwland[5], Ingrid Pabinger[2], Thomas Reiberger[1]. *[1]Medical University of Vienna, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria; [2]Medical University of Vienna, Division of Hematology and Hemostaseology, Department of Internal Medicine I, Vienna, Austria; [3]Medical University of Vienna, Department of Laboratory Medicine, Vienna, Austria; [4]University of Groningen, Surgical Research Laboratory and Section of Hepatobiliary Surgery and Liver Transplantation, Department of Surgery, University Medical Center Groningen, Groningen, Netherlands; [5]Academic Medical Center, Laboratory of Experimental Clinical Chemistry, Vesicle Observation Centre, Amsterdam, Netherlands*
Email: mattias.mandorfer@meduniwien.ac.at

Background and aims: In patients who underwent peritoneovenous (e.g., LeVeen) shunting for refractory ascites, overt disseminated intravascular coagulation occurred due to infusion of ascites into the blood circulation. More recently, procoagulant extracellular vesicles (EVs) exposing tissue factor (TF), the main initiator of blood coagulation, were identified in different body fluids.
We hypothesized that TF-exposing EVs may also be present in ascites, and that such EVs may activate coagulation in patients with advanced chronic liver disease (ACLD) and ascites.
Method: We determined routine and experimental coagulation parameters and performed clotting experiments to investigate bi-directional interactions between ascitic fluid and blood in patients with ACLD with (n = 25) or without (n = 25) ascites, who were matched for the severity of portal hypertension as assessed by hepatic venous pressure gradient (HVPG)-measurement.
Results: We found that ascitic fluid contains TF-exposing EVs that shorten the clotting time of plasma (panel A). EV-associated TF activity was high in ascitic fluid while activities of other measured coagulation factors were low (panel B). The opposite was observed in plasma of the same patients (panel C). Parameters of coagulation activation and fibrinolysis, however, were higher in ascitic fluid as compared to plasma (panels D/E). A constant dissemination of coagulation factors from plasma into ascitic fluid was indicated by strong correlations between albumin levels and coagulation factor activities in ascitic fluid (panels F/G). The procoagulant potential of ascitic fluid was completely abolished by filtration through a 0.1 μm membrane (panel H). Taken together with the finding of low EV-associated TF activity in plasma (panel C), our findings indicate that TF-exposing EVs did not pass the peritoneum and therefore did not enter the blood circulation. Yet, the thrombin generation potential in plasma was significantly increased in patients with ascites compared to HVPG-matched patients without ascites (panels I/J).
Conclusion: In patients with ACLD and ascites, the coagulation system gets activated intraperitoneally via TF-exposing EVs. TF-exposing EVs seem to be too large to pass the peritoneum, however, smaller intraperitoneally activated coagulation enzymes are likely to re-enter blood circulation. This may be the cause for the increased thrombin generation potential found in plasma of patients with ascites, indicating a procoagulant state.

SAT-078

Characterizing compensated cirrhosis patients with potential etiology of non-alcoholic fatty liver disease/non-alcoholic steatohepatitis: Findings from large Italian administrative databases

Giulio Marchesini Reggiani[1], Jie Ting[2], Stefania Saragoni[3], Valentina Perrone[3], Shreay Sanatan[2], Salvatore Petta[4]. *[1]University of Bologna, Department of Medical and Surgical Sciences, Bologna, Italy; [2]Gilead Sciences, Inc., Health Economics and Outcomes Research, Foster City, United States; [3]CliCon S.r.l. Health Economics and Outcomes Research, Ravenna, Italy; [4]University of Palermo, Section of Gastroenterology and Hepatology, Di.Bi.M.I.S., Palermo, Italy*
Email: jie.ting@gilead.com

Background and aims: Cirrhosis due to NAFLD/NASH often is recognized only following a decompensation event. Patients with cirrhosis will benefit from timely identification of the underlying cause of cirrhosis. This study described the characteristics of patients with CC who have an underlying diagnosis of NAFLD/NASH vs those without.
Method: Hospitalized adult patients with first CC diagnosis via ICD-9-CM (index date) from 2011-2017 with and without NAFLD/NASH diagnosis were identified from 8 administrative databases of Italian local health units. Patients in both groups were excluded if they ever

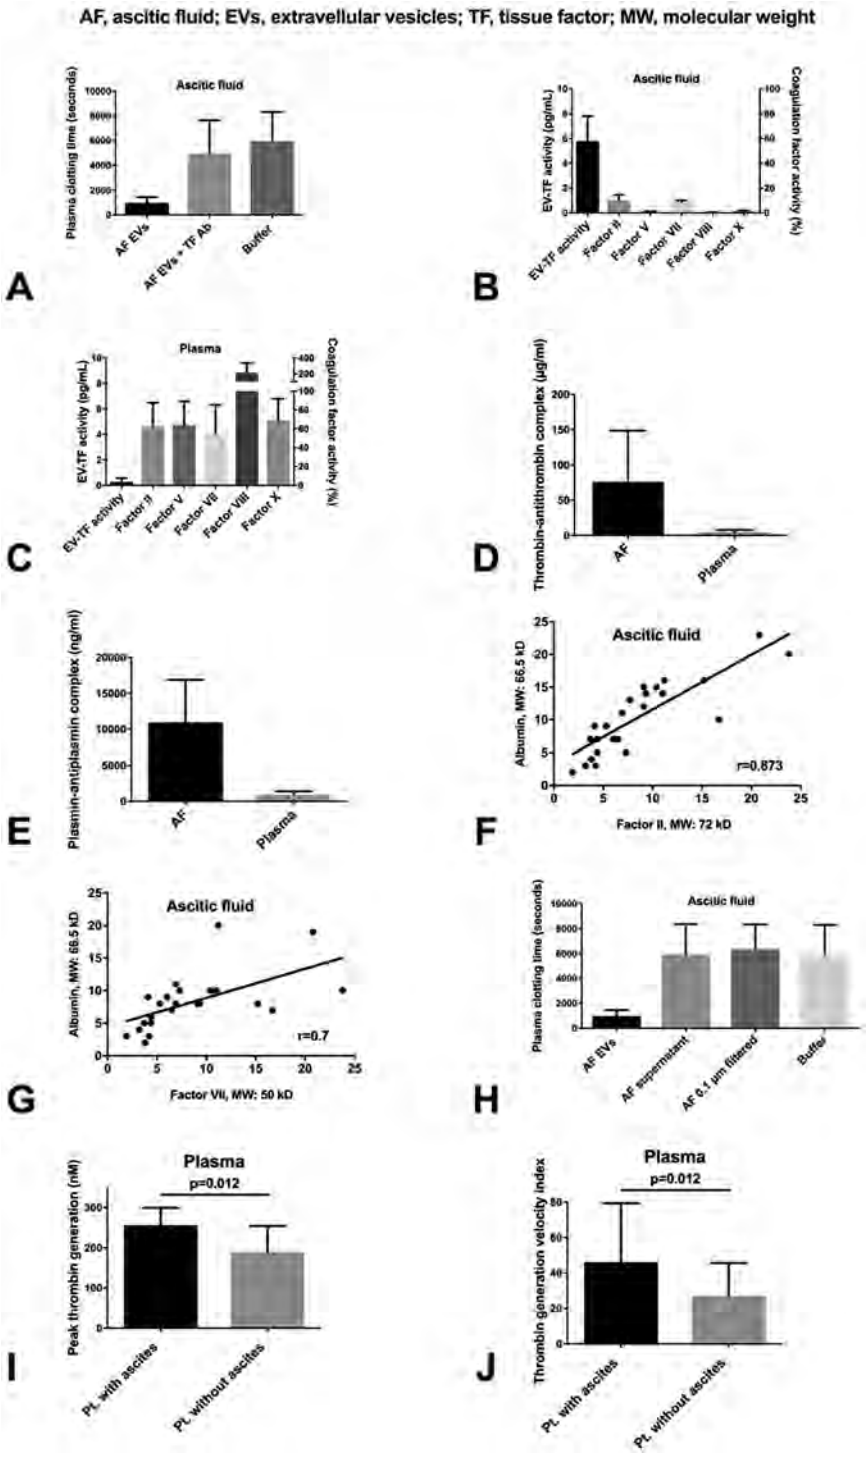

Figure: (abstract: SAT-077)

had viral or autoimmune hepatitis, HIV, alcoholism or alcoholic liver disease, toxic liver disease, Wilson's disease, Gaucher's disease, LAL-D, primary biliary or sclerosing cholangitis, or hemochromatosis. Remaining patients were followed from index date until the earliest of disease progression, end of coverage, death, or end of study period. Demographics, comorbidities, healthcare resource use and costs were compared between the two patient groups.

Results: A total of 3, 804 CC without a diagnosis of NAFLD/NASH (mean age 70.7 years, 49% female) and 131 CC-NAFLD/NASH (mean age 71.3 years, 50% female) patients were identified. Liver biopsy prevalence in the year before or 6 months after index date was 8% in CC without NAFLD/NASH and 11% in CC-NAFLD/NASH. The comorbidity burden appeared lower among CC without NAFLD/NASH — type 2 diabetes (CC without NAFLD/NASH: 37%, CC-NAFLD/NASH: 40%), cardiovascular disease (88%, 92%), both $p > 0.05$, renal impairment (12%, 23%), and hypertension (28%, 47%), both $p \leq 0.05$ [Figure]. Mean annual number of hospitalizations was lower in CC without NAFLD/NASH vs. CC-NAFLD/NASH (3.6 vs 4.2, $p \leq 0.05$). Similar trends were

observed in outpatient visits and pharmacy fills. Mean total annual costs was €17, 803 in CC without NAFLD/NASH, and €19, 681 in CC-NAFLD/NASH (p = 0.4).

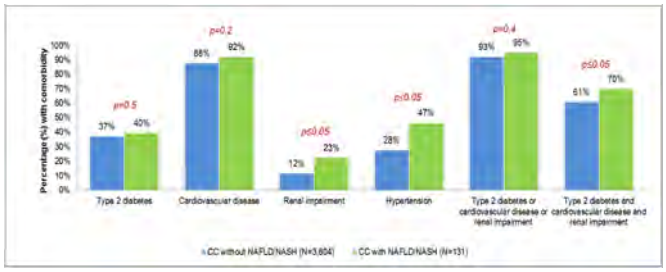

Figure: Comorbidity burden among hospitalized CC patients without and with NAFLD/NASH diagnosis in Italy

Conclusion: Upon exclusion of common liver disease etiologies such as viral or autoimmune hepatitis, or alcoholic liver disease, many CC cases in Italy may be due to unrecognized NAFLD/NASH. A higher comorbidity burden could potentially be driving identification of CC due to NAFLD/NASH. In anticipation of future treatments for NAFLD/NASH, patients would benefit from better identification of CC when due to NAFLD/NASH.

SAT-079

Respiratory infection in patients with cirrhosis and acute variceal bleeding on antibiotic prophylaxis: A multicenter observational study of 2138 patients

Javier Martinez[1], Tellez luis[1], Virginia Hernandez-Gea[2], Bogdan Procopet[3], Alvaro Giraldez-Gallego[4], Lucio Amitrano[5], Candid Villanueva[6], Dominique Thabut[7], Luis Ibañez[8], Gilberto Silva-Junior[2], Joan Genesca[9], Bureau christophe[10], Elba Llop[11], Wim Laleman[12], Jose María Palazon[13], José Castellote[14], Susana G. Background and aims: Antibiotic prophylaxis is recommended to reduce the high risk of bacterial infection in patients with acute variceal bleeding (AVB). The aim of this study was to evaluate the incidence and risk factors of bacterial infection in patients with AVB receiving antibiotic prophylaxis.

Method: Sub-analysis of a multicenter, international, observational study of 2138 patients with cirrhosis admitted for AVB from October 2011 toMay 2015 to address the efficacy of pre-emptive TIPS. We excluded patients with infection at admission (368)and those who did not received antibiotic prophylaxis (114, 5%). Finally, 1656 patients were included in the analyses.

Results: Third generation cephalosporins (1263 patients, 76.3%) and quinolones (308 patients, 18.6%) were the main antibiotics used for prophylaxis. Bacterial infection developed in 336 out of the 1656 patients (20%): respiratory (156 patients, 46%), urinary (52, 3%),

bacteriemia (34, 10%), SBP (29, 9%), cellulitis (12, 3%), others (53, 16%) and unknown (30, 9%). We specifically analyzed the risk factors of respiratory infection, the most frequent infection observed. Patients that developed respiratory infection (n = 156; 9, 4%) were similar to non-infected patients (n = 1320) regarding etiology of cirrhosis (alcohol, 52 vs. 45%), Child (B/C, 51/30 vs. 52/24%), previous antibiotic use (12 vs. 11%). Respiratory infection rates were independent of the type of antibiotic prophylaxis. Differences between groups were associated with active alcohol abuse (44 vs. 34%; p = 0.01), oro-tracheal intubation (41 vs. 17%; p = 0.001), nasogastric tube (44 vs. 30%; p = 0.001), and balloon tamponade (8 vs. 2%; p = 0, 02). In multivariate analysis, active alcohol abuse (OR 1.7; 95%CI 1.4-2), nasogastric tube (OR 1.7; 95%CI 1.2-2.4), oro-tracheal intubation (OR 3.1; 95%CI 2.1-4.3) and balloon tamponade (OR 2.6; 95%CI 1.8-5.1) were independently associated with respiratory infection. Further, in multivariate analysis, oro-tracheal intubation (OR 1.5; 95%CI 1.1-2.1) and nasogastric tube (OR 1.3; 95%CI 1.0-1.7) were also independently associated with the development of any type of bacterial infection.
Conclusion: Five percent of patients with AVB do not receive antibiotic prophylaxis. Respiratory infection is the most common bacterial infection in patients on antibiotic prophylaxis, and its risk factors are airway manipulation and active alcohol use. Current recommendations of antibiotic prophylaxis show rather low efficacy to prevent respiratory infection in patients with AVB at high-risk.

SAT-082
Cholemic nephropathy is a cause of acute kidney injury in patients with liver disease and accompanied by loss of epithelial barrier in distal tubuli

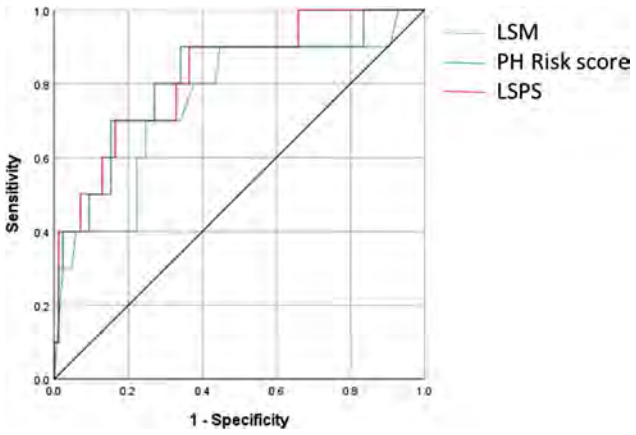
Young-Seon Mederacke[1], Jan Hinrich Bräsen[2], Jessica Schmitz[2], Michael P. Manns[1], Roland Schmitt[3], Ingmar Mederacke[1]. [1]*Hannover Medical School, Gastroenterology, Hepatology, and Endocrinology, Hannover, Germany;* [2]*Hannover Medical School, Pathology, Hannover, Germany;* [3]*Hannover Medical School, Nephrology and Hypertension, Hannover, Germany*
Email: mederacke.ingmar@mh-hannover.de

Background and aims: Impairment of renal function often occurs in patients with liver disease. The most common cause of acute kidney injury (AKI) in patients with liver disease is hepatorenal syndrome (HRS). Causes of non-HRS AKI include cholemic nephropathy (CN), a disease entity that is characterized by intratubular cast and tubular injury. Data from animal studies suggest bile acids as a trigger of CN. As data on patients with CN is mostly obtained from case reports or autopsy studies, we aimed to investigate the frequency, clinical course and histological characteristics of CN.
Method: We identified 149 patients who underwent kidney biopsy from 2000 to 2016 at the Department of Gastroenterology, Hepatology and Endocrinology. Of these 79 had a history of liver disease and deterioration of renal function, 45 of them fulfilled the criteria for AKI according to recent EASL guidelines and were included into this study. Laboratory values and clinical course of the patients were obtained by chart analysis. To characterize the tubular injury observed in the patients with CN, we evaluated kidney biopsies in a subset of patients (AKI with normal bilirubin (AKI-NB), AKI with elevated bilirubin (AKI-EB), and patients with CN) for inflammatory markers (CD4, CD8, CD15, CD68, CD163) and markers of tubular integrity (Aquaporin 2 (AQP2), alpha/beta-tubulin). Statistical analysis was performed using SPSS.
Results: The mean age of the 45 patients with AKI was 51.9 ± 10.7 years and 78% were male (35/45). Renal biopsy revealed the diagnosis of CN in 17.8% of the patients (8/45). Despite significantly higher MELD score at baseline (31 vs 22, p < 0.01), mortality in patients with CN was not increased. Univariate logistic regression analysis identified bilirubin higher than 5x the upper limit of normal (ULN), alkaline phosphatase higher than 3x the ULN as well as detectable bilirubin and urobilinogen in the urine as independent risk factors for the development of CN. The subset of patients with AKI included in the histological study (AKI-NB (n = 5), AKI-EB (n = 6), CN (n = 6)) did not differ in creatinine level, but was characterized by different bilirubin levels (11 vs 134 vs 525 µmol/l, p < 0.001). There was no difference in the inflammatory infiltrate or alpha/beta tubulin expression between the three different groups, but CN patients had lower numbers of M2 macrophages/monocytes (CD163) compared to patients with AKI-NB (p < 0.05). AQP2 expression was significantly reduced in patients with AKI-EB and patients with CN compared to patients with AKI-NB (p < 0.01).
Conclusion: CN is a significant cause of AKI in patients with liver disease. Loss of AQP2 was observed in patients with AKI and hyperbilirubinemia and might be a pathophysiological link between biliary cast and tubular injury. The observed lower numbers of M2 macrophages identified by CD163 in CN patients might explain an impaired renal repair capacity in patients with CN.

SAT-083
Simple non-invasive surrogates of portal hypertension predict clinical decompensation in overweight/obses patientes with cACLD

Yuly Paulin Mendoza[1], Sila Cocciolillo[2], Giuseppe Murgia[1], Tianyan Chen[2], Cristina Margini[1], Giada Sebastiani[2], Annalisa Berzigotti[1]. [1]*Inselspital, Hepatology, UVCM, Inselspital, University of Bern, Bern, Switzerland;* [2]*McGill University Health Centre, Division of Gastroenterology and Hepatology, McGill University Health Centre, Royal Victoria Hospital, Montréal, Canada*
Email: annalisa.berzigotti@insel.ch

Background and aims: In patients with compensated advanced chronic liver disease (cACLD) and overweight/obesity, the prognostic value of simple non-invasive surrogates of portal hypertension (PH) for predicting first clinical decompensation has not been assessed in detail.
Method: Consecutive patients with cACLD (liver stiffness measurement (LSM) ≥ 10 kPa by XL probe) and overweight/obesity observed between 11/2015 and 01/2018 in two University hospitals (Berne, Switzerland; Montreal, Canada) were retrospectively studied. Clinical decompensation (ascites, PH bleeding, jaundice, hepatic encephalopathy) and severe bacterial infections were considered clinically relevant events and were recorded on follow-up. The association among clinical factors, LSM x spleen size/platelet count (LSPS), Portal Hypertension risk score (PH risk score), LSM and clinically relevant events was assessed. Areas under the receiver operating characteristic curves (AUROCs) were used to compare the discriminative ability of non-invasive tests for clinical decompensation.
Results: 202 patients (NASH = 52.2%; BMI 34.2 ± 7.0 Kg/m2, median Child score 5 [range 5-8]; median LSM = 16.8 kPa [IQR 12.2-24.3]) were followed up for a median (IQR) of 17 months (11-75). 15 of them developed clinically relevant events (10 decompensation, 5 severe bacterial infections). These patients had higher LSM (median: 27.4 vs.15.7 kPa, *P* < 0.001), lower platelet count (median: 113 ± 46 vs.179 ± 71G/L, *P* = 0.001), higher LSPS (median: 4.33 vs.1.21, *P* < 0.001), higher PH risk score (median: 4.17 vs. 0.26, *P* < 0.001) and worse liver function as compared to patients remaining compensated. LSM, LSPS and PH risk score showed a high discriminative ability (AUROC curve) to differentiate between patients developing or not clinical events in the follow-up: LSM 0.780 (95%CI 0.665-0.894; *P* <.0001), PH risk score 0.796 (95%CI, 0.688-0.904 *P* <.0001), and LSPS 0.828 (95%CI 0.734-0.921; *P* <.0001). Similar results were obtained in the subgroup of patients with NASH etiology (n = 105): LSM 0.754 (95%CI 0.583-0.924; *P*.008), PH risk score 0.811 (95%CI 0.654-0.97; *P*.001), and LSPS 0.825 (95%CI 0.690-0.959; *P*.001) (Figure).



Conclusion: Simple and readily available non-invasive surrogates of portal hypertension help identify patients with cACLD and obesity/overweight who are at increased risk of developing first clinical decompensation. The LSPS, (LSM by XL probe, platelet count and spleen size), is a useful simple predictor of clinical events in patients with cACLD due to NASH.

SAT-084

Validation of hand grip strength as a nutritional assessment tool for patients with advanced liver fibrosis

Topan Mirabela-Madalina[1], Mirela Danila[1], Roxana Sirli[1], ana-maria ghiuchici[1], calin burciu[1], Ioan Sporea[1]. *[1]Victor Babes University of Medicine and Pharmacy, Timișoara, Romania*
Email: mirabelamadalina1990@gmail.com

Background and aims: Hand grip strength (HGS) is a non-invasive, simple and quick method to assess nutritional status on patients. Malnutrition frequently co-exist in patients with advanced liver disease and is associated with a significant increase in morbidity and mortality so it is important to find the right methods to diagnose and treat it. The purpose of this study was to explore the efficacy of hand grip strength measured by hand grip dynamometer as a nutritional assessment tool in patients with liver cirrhosis.
Method: Data were collected from 86 patients with advanced liver disease of different etiologies admitted in our Department. 34 (39.5%) were decompensated liver cirrhosis and 52 (60.5%) were compensated. We also had a control group which included 40 healthy volunteers with almost similar ages. We assessed the nutritional status of these groups according to the subjective Global Assesment (SGA) and the score PG-SGA and anthropometric measurements (skinfold-thickness, Body Mass Index, mid arm circumference and hand grip strength).
Results: The prevalence of malnutrition was 84% in patients with decompensated liver cirrhosis and only 10% in those with compensated disease. The ability of hand grip strength to predict malnutrition was highly significant (p = 0, 003), with a specificity of 85% and sensitivity of 65%. Multiple regression analysis showed that, together, the Scored Patients-Generated Subjective Global Assessment (PG-SGA), mid arm muscle area and HGS are significantly better than hand grip strength alone, specificity of 90% and 78% sensitivity.
Conclusion: The prevalence of malnutrition in cirrhotic patients is high in our area (84% in patients with decompensated liver cirrhosis). Hand grip strength is an accurate and simple nutritional assessment tool that is suitable for clinical practice, but for better assessment of the patients it should be used together with other complementary methods.

Email: cmontoliu@incliva.es

Background and aims: Minimal hepatic encephalopathy (MHE) in cirrhotic patients is associated with specific changes in parameters of the immune system reflecting a more pro-inflammatory environment than in patients without MHE. The aims of this work were to assess the effects of rifaximin treatment of cirrhotic patients with MHE on: 1) MHE; 2) intermediate ($CD14^{++}CD16^{+}$) pro-inflammatory monocytes; 3) expression of early activation marker CD69 in T lymphocytes; 4) autoreactive $CD4^{+}CD28^{-}$ T lymphocytes; 5) differentiation of $CD4^{+}$ T lymphocytes to Th follicular and Th22; 6) serum IgG levels; and 7) levels of some pro-inflammatory cytokines.
Method: These parameters were measured by immunophenotyping and cytokine profile analysis in 30 controls without liver disease, 30 cirrhotic patients without MHE and 22 patients with MHE. Patients with MHE were treated with rifaximin and the same parameters were measured at 3 and 6 months of treatment. We assessed if changes in these parameters are different in patients who improve MHE (responders) and those who remain in MHE (non-responders).
Results: Rifaximin improved MHE in 59% of patients with MHE. In these responder patients rifaximin normalized all alterations in the immune system measured while in non-responders it normalizes only IL-6, CCL20, and differentiation of T lymphocytes to Th22. Non-responder patients do not show increased expression of CD69 before treatment.
Conclusion: Rifaximin normalizes changes in the immune system in patients who improve MHE but not in non-responders. Some alterations before treatment are different in responders and non-responders. Understanding these differences may identify predictors of the response of MHE to rifaximin.

Opioid use is common among non-surgical inpatients with cirrhosis and is associated with increased length of stay and persistent use post-discharge

Andrew Moon[1], Shari Rogal[2], Yue Jiang[3], Jasper Becker[4], A. Sidney Barritt[1]. *[1]University of North Carolina School of Medicine, Gastroenterology and Hepatology, Chapel Hill, NC, United States; [2]University of Pittsburgh, Gastroenterology, Hepatology, and Nutrition, Pittsburgh, PA, United States; [3]University of North Carolina School of Public Health, Biostatistics, Chapel Hill, NC, United States; [4]University of*

North Carolina School of Medicine, North Carolina Translational and Clinical Sciences Institute, Chapel Hill, NC, United States
Email: andrew.moon@unchealth.unc.edu

Background and aims: Little is known about the prevalence and safety of opioid use among hospitalized patients with cirrhosis. We aimed to describe the patterns and complications of opioid use in this population.
Method: This retrospective cohort study included adult patients with cirrhosis admitted to a single hospital system from 4/2014 to 9/2015. We excluded hospitalizations with a surgery, invasive procedure or palliative care/hospice consult. We determined opioid use before hospitalization, during hospitalization, at discharge and 90 days post-discharge. We performed univariate analyses of opioid use and created logistic regression models for inpatient opioid use, intensive care unit transfer and in-hospital mortality. We used Poisson regression models to assess factors associated with length of stay.
Results: Of 217 inpatients with cirrhosis, 118 (54.4%) received opioids during hospitalization (median morphine milligram equivalent 9.8 mg/day), including 41.7% of patients without pre-existing outpatient opioid prescriptions. Younger age, depression and outpatient opioid prescription were independently associated with receipt of inpatient opioids. Hospitalization was longer among opioid recipients (mean 5.4 vs 3.7 days, p = 0.001) and this difference remained after adjusting for age, cirrhosis severity and medical comorbidities. There was no difference in intensive care unit transfers between opioid recipients and non-recipients. No deaths occurred. At discharge, 22 patients were newly started on opioids of whom 10 (45.5%) had opioid prescriptions at 90 days post-discharge.

Table: Multivariable Model of Inpatient Opioid Use

Characteristic	OR (95% CI)
Age	**0.96 (0.94, 0.99)**
Gender (Female = referent)	
Male	0.67 (0.35, 1.26)
Race (Black = referent)	
White	0.78 (0.31, 1.94)
Other	0.26 (0.06, 1.02)
Outpatient opioid prescription	**3.89 (2.09, 7.44)**
MELD	0.97 (0.91, 1.02)
Depression	**1.90 (1.01, 3.63)**
Charlson Comorbidity Index	0.97 (0.89, 1.07)

Conclusion: In non-surgical patients with cirrhosis, inpatient opioid use was common and associated with prolonged length of stay. A high proportion of patients newly discharged on opioids remained on opioids at 90 days post-discharge.

SAT-087

Screening endoscopy in patients with advanced chronic liver disease beyond portal hypertension: Higher prevalence of upper gastrointestinal neoplasia in comparison to a healthy screening population

Rui Morais[1], Margarida Marques[1], Rui Gaspar[1], Rosa Alves[2], Joel Silva[1], Emanuel Dias[1], João Antunes[1], Pedro Pereira[1], Susana Lopes[1], Hélder Cardoso[1], Rodrigo Liberal[1], Guilherme Macedo[1]. [1]*Centro Hospitalar São João, Gastroenterology, Porto, Portugal;* [2]*Hospital Garcia da Horta, Internal Medicine, Porto, Portugal*
Email: rui_morais20@hotmail.com

Background and aims: The Baveno VI criteria were proposed to help identify patients with compensated advanced chronic liver disease (cACLD) who could safely avoid screening esophagogastroduodenoscopy (EGD) for clinically significant varices. Although several studies have validated those criteria, all failed to acknowledge the possible role of the avoided EGD for the same time screening of upper GI neoplasia. We aimed to evaluate the presence, type and pathological characteristics of upper GI neoplasia in patients with cACLD who underwent screening EGD in a country with intermediate gastric cancer risk.
Method: This retrospective case-control study enrolled all asymptomatic cACLD patients who underwent EGD for varices screening from January 2008 to June 2018. Cases were matched with asymptomatic healthy individuals who underwent EGD for gastric cancer screening at the same time as colonoscopy performed for colorectal cancer screening.
Results: We included 1974 subjects (610 patients, 1364 controls), 46.3% male, with a median age of 58 (50-66) years. Besides a male predominance in cases (69.0% vs. 45.6%, p < 0.001), no other demographic characteristic differed between groups. The leading aetiology of ACLD was alcoholic liver disease (53.3%), followed by chronic hepatitis C (16.2%), and non-alcoholic fatty liver disease (7.9%). Of the 610 patients with cACLD, 1 (0.2%) had squamous-cell esophageal carcinoma, 13 (2.1%) gastric neoplasia [gastric cancer, n = 10; high-grade dysplasia (HGD), n = 2; low-grade dysplasia (LGD), n = 1], 1 (0.2%) duodenal neoplasia (LGD) and 3 (0.5%) ampullary lesions (LGD). Compared to controls, cACLD patients had a higher prevalence of gastric neoplasia [2.1% vs. 1%, p = 0.044; gastric cancer 1.6% vs. 0.8%, p = 0.08) and ampullary lesions (0.5% vs. 0%, p = 0.01). The prevalence of Helicobacter pylori infection was lower in patients compared to controls (36.2% vs. 47.2%, p = 0.004). In the 18 cACLD patients in whom were detected neoplastic lesions, 9 (50%) were diagnosed on the initial screening endoscopy. Five of these patients had transient elastography < 20 kPA and platelet count > 150000 before EGD.
Conclusion: The prevalence of esophagogastroduodenal neoplastic lesions, particularly gastric neoplasia, in cACLD patients who underwent screening EGD is significant, being higher compared to controls. EGD should therefore still be considered in patients with ACLD from countries with intermediate gastric cancer risk, independent of the Baveno criteria.

SAT-088

Sarcopenia and Myosteatosis are associated with minimal and overt hepatic encephalopathy in patients with liver cirrhosis

Silvia Nardelli[1], Barbara Lattanzi[1], Stefania Gioia[1], Lorenzo Ridola[1], Manuela Merli[1], Oliviero Riggio[1]. [1]*Sapienza University of Rome, Clinical Medicine, Rome, Italy*
Email: nardelli.silvia@gmail.com

Background and aims: Myosteatosis and sarcopenia are frequent in cirrhosis and related to some complications included overt hepatic encephalopathy. The aim of our study was to investigate the relationship between muscle alterations and minimal hepatic encephalopathy (MHE) and their respective role on the risk of overt HE.
Method: 64 cirrhotic patients (48M/16F) were included and submitted to Psychometric Hepatic Encephalopathy Score (PHES) and to Animal Naming Test (ANT) to detect MHE. Computed tomography was used to analyse the skeletal muscle index (SMI) and muscle attenuation. The incidence of the first episode of HE, taking into account the competing risk nature of the data (death or liver transplantation), was estimated.
Results: Myosteatosis was observed in 24 patients (37.5%), sarcopenia in 37 patients (58%) and MHE in 32 patients (50%). Both myosteatosis and sarcopenia were more frequent in patients with MHE (Table). At multivariate analysis, the variables independently associated to the presence of MHE were: sarcopenia (p = 0.05), previous overt HE (p = 0.04) and myosteatosis (p = 0.04). Thirty-one (48%) patients developed overt HE during 14.9 ± 12.5 months; myosteatosis was detected in 68% and sarcopenia in 84% of them. Variables independently associated to the development of overt HE were: sarcopenia (p = 0.001), previous HE (p = 0.03), MHE (p = 0.04) and myosteatosis (p = 0.03). Venous ammonia was significantly higher in sarcopenic patients (62.6 ± 17.7 vs 41.4 ± 16.1 μg/dl; p < 0.001) and in myosteatosic patients (65.2 ± 19.2 vs 46.7 ± 17.1 μg/dl; p < 0.001). The

incidence of HE was significantly higher in patients with sarcopenia or myosteatosis than in those without (p < 0.001).

Table: Comparison of demographic and clinical characteristics between patients with and without MHE.

	MHE- (n = 32)	MHE + (n = 32)	P value
Age (y)	56.2 ± 9.7	57.2 ± 10.5	0.69
Aetiology (virus/alchol/ other)	21/6/5	24/7/1	0.22
MELD	13.3 ± 5.2	14.2 ± 5.7	0.48
Previous HE (no/yes)	28/4	16/16	0.001
NH3	43.5 ± 16.3	63.8 ± 18.1	< 0.001
Animal Naming Test (n° of animals)	15.3 ± 5.2	11.4 ± 2.5	< 0.001
SMI (cm^2/m^2)	50.7 ± 10.9	41.8 ± 7.7	< 0.001
Sarcopenia (no/yes)	22/10 (31)	5/27 (84)	< 0.001
Muscle attenuation (HU)	37.2 ± 8.1	29.1 ± 7.4	< 0.001
Myosteatosis (no/yes) (%)	28/4 (12.5)	12/20 (62.5)	< 0.001

Conclusion: Myosteatosis and sarcopenia, probably by reducing the handling of ammonia, are independently associated to MHE and to the risk of overt HE in cirrhotics. In malnourished patients, the amelioration of nutritional status may be a possible goal to decrease these complications.

SAT-089

Evaluating the impact of non-selective beta-blocker use in decompensated cirrhosis based on setting of patient care

Rooshi Nathwani[1], David Kockerling[1], Sharmili Balarajah[1], Roberta Forlano[1], Nowlan Selvapatt[1], Pinelopi Manousou[1], Ameet Dhar[1]. *[1]Imperial College London, Department of Surgery and Cancer, London, United Kingdom*
Email: rooshi_n@hotmail.com

Background and aims: Non-selective beta-blockers (NSBBs) are well established in the prevention of variceal haemorrhage in cirrhosis. Amelioration of bacterial translocation, implicated in sepsis, has also been described. NSBB use in decompensated cirrhosis however remains controversial. This study aimed to identify effects of NSBB use on mortality and infection rates in decompensated cirrhotics based on the setting of their care.
Method: A single-centre, UK based, retrospective analysis from November 2015-2017, identified two cohorts of decompensated cirrhotics; (a) patients attending a specialist cirrhosis clinic (b) cirrhotic patients acutely presenting to hospital, without specialist outpatient care prior to or after hospitalisation. Cohorts were stratified by Child-Pugh (CP) grading and disease severity matched.
Results: 213 patients (138 outpatients and 75 inpatients) with decompensated cirrhosis were identified (see Table 1). 112/138 outpatients (81%), and 46/75 (61%) inpatients survived at 1 year. In CP-B+C outpatients, NSBB use (versus non-use) favoured survival (p = 0.012), reduced 1-year incidence of primary infections requiring hospitalisation (p = 0.03), and reduced the need for all cause admission (p = 0.02). On binary logistic regression, factors independently associated with 1-year survival in CP-B+C outpatients were NSBB use [p = 0.004, OR 5.18 (CI 1.67-16.01)], lower baseline MELD score [p = 0.0001, OR 1.25 (CI 1.11-1.41)] and lower infection rates [p = 0.007 OR 1.72 (CI 1.17-2.58)].
In CP-B+C inpatients, NSBB use was not associated with reduced survival (p = 0.554) and no influence on infection was observed in these patients (p = 0.26). However, a lower proportion of NSBB users were readmitted to hospital at 6 months post discharge compared to non-users (10.5% vs 42.1%, p = 0.024).

Table 1: Patient demographics

	Outpatient Cohort (n = 138)	Inpatient Cohort (n = 75)
Sex		
Male	95/138 (69%)	48/75 (64%)
Female	43/138 (31%)	27/75 (36%)
Age (median, IQR)	58 (50-66)	56 (48-67)
Main aetiology		
Alcohol	91/138 (66%)	49/83 (59%)
Hepatitis C	19/138 (14%)	11/83 (13%)
NSBBs Use		
CP-B	61/89 (69%)	7/21 (33%)
CP-C	28/89 (31%)	14/21 (67%)

Conclusion: In patients with decompensated cirrhosis, NSBB use reduced mortality, need for admission and infection rates in the outpatient setting, and reduced readmission rates in inpatients. This supports a rationalised approach to the use of NSBBs based on disease severity and setting of care. The mechanism of this observed effect also warrants further investigation including the impact of NSBBs on immunological responses and bacterial translocation in cirrhosis.

SAT-090

Location of onset of acute kidney injury in cirrhosis affects survival

David Foxwell[1], Janardhan Navaratnam[2], Gareth Roberts[3], James Chess[1], Andrew Yeoman[2], Marek A Czajkowski[2], Lydia Guha-Niyogi[2]. *[1]Wales Kidney Research Unit, Department of Nephrology, Cardiff, United Kingdom; [2]Royal Gwent Hospital, Department of Hepatology and Gastroenterology, Newport, United Kingdom; [3]Royal Gwent Hospital, Department of Nephrology, Newport, United Kingdom*
Email: andrew.yeoman@wales.nhs.uk

Background and aims: The importance of acute kidney injury (AKI) as an independent predictor of outcomes in patients with cirrhosis is becoming increasingly clear with subtle changes in serum creatinine associated with adverse outcomes. The point at which AKI develops appears to influence outcomes in general hospital admissions, with hospital acquired AKI (HA-AKI) having worse outcomes than community acquired AKI (CA-AKI). With more refined diagnostic criteria for AKI in cirrhotics now being utilised, this study aims to describe the outcome for cirrhotic patients diagnosed with CA-AKI vs HA AKI.
Method: Patients hospitalised in a district general hospital in South-Wales (UK) with a confirmed diagnosis of liver cirrhosis of any aetiology over a 30 month period were analysed in this retrospective observational study. AKI was diagnosed and staged in accordance with KDIGO AKI criteria 2012 and the International Club of Ascites 2015 then divided into CA-AKI (criteria met < 48 hours of admission) and HA-AKI (criteria met ≥ 48 hours following admission).
Results: 542 admission episodes occurred during the study period with 171 episodes of AKI. CA-AKI contributed to 72.5% (n = 124) and HA-AKI 27.5% (n = 47). Inpatient mortality in the AKI group was 40.4% (n = 69), non-AKI group mortality 3.8% (n = 14). Inpatient mortality increased with each stage (Stage 1-3) of AKI in both the CA-AKI and HA-AKI group in a linear-by-linear association. Overall inpatient mortality in the CA-AKI group was 35.5% compared to the HA-AKI group of 53.2% (p = 0.04). 1 year mortality following incident admission was; non-AKI 36.8% (43/117), CA-AKI 54.4% (31/57), HA-AKI 71.4% (15/21) (p = < 0.01). AKI event (OR 7.29), rising bilirubin (OR 3.76) and advancing age (1.07) associated with increased mortality. Reduced mortality was seen in those with higher sodium (OR 0.94), higher albumin (OR 0.92) and the presence of alcohol related liver disease (OR 0.38).
Conclusion: Increasing AKI severity in the cirrhotic population is an independent predictor of adverse outcomes. In particular, patients

developing HA-AKI appear to be at a particular high risk of mortality. Efforts should be made to identify and mitigate risks of developing AKI amongst hospitalised cirrhotics and appropriate prompt escalation of treatment for those experiencing AKI in the context of cirrhosis.

SAT-091

The collagen hormone Endotrophin, a biomarker of type VI collagen formation-is associated with severe decompensation and predicts transplant-free survival in patients with trans-jugular intrahepatic portosystemic shunt

Mette Juul Nielsen[1], Federica Genovese[1], Jennifer Lehmann[2], Robert Schierwagen[2,3], Christian Jansen[2], Michael Praktiknjo[2], Diana Leeming[1], Morten Karsdal[1], Jonel Trebicka[2,3,4,5,6]. *[1]Nordic Bioscience A/S, Herlev, Denmark; [2]University of Bonn, Department of Internal Medicine I, Bonn, Germany; [3]University of Frankfurt, Department of Internal Medicine I, Frankfurt, Germany; [4]University Clinic Odense, Department of Hepatology, Odense, Denmark; [5]European Foundation for Study of Chronic Liver Failure, Barcelona, Spain; [6]Institute for Bioengineering of Catalonia, Barcelona, Spain*
Email: mju@nordicbio.com

Background and aims: In cirrhosis, the structural fibrillar type I, III and V collagens are known to be the predominant consequence of disease. However, a new understanding of the extracellular matrix (ECM) is emerging, in which fragments have been shown to hold important signaling functions, such as the collagen hormone Endotrophin, the pro-peptide of type VI collagen. Endotrophin has been shown to be associated with insulin resistance and induce fibrosis directly in other pathological settings. Here we investigated the association of Endotrophin and severe decompensation and predictor of mortality in patients with trans-jugular intrahepatic portosystemic shunt (TIPS).
Method: In 110 patients with decompensated liver cirrhosis, plasma samples were taken from portal and hepatic veins at time of TIPS insertion and two weeks later at an invasive TIPS control. Circulating levels of Endotrophin (PRO-C6) was assessed in plasma using specific monoclonal ELISA. PRO-C6 was stratified according to presence of ascites, hepatorenal syndrome (HRS), Child-Pugh category and MELD score. Kaplan-Meier and Cox regression analyses were used to investigate the association of PRO-C6 with 5-year transplant-free survival.
Results: Before TIPS insertion, similar levels of PRO-C6 were found in portal and hepatic vein ($p = 0.376$). However, two weeks after TIPS, PRO-C6 level was significantly higher in hepatic vein compared to portal vein ($p < 0.001$). Before TIPS, portal venous PRO-C6 levels were significantly higher in patients with HRS ($p < 0.001$), increasing degree of ascites ($p < 0.001$), MELD score > 11 ($p < 0.001$) and Child-Pugh class C ($p < 0.05$). Interestingly, no difference between the groups were observed when assessed in hepatic vein at TIPS insertion. Patients with PRO-C6 level above the median in portal vein before TIPS had significantly shorter transplant-free survival compared to patients with low PRO-C6 levels ($p < 0.05$) and was independently associated with survival in multivariate Cox adjusted for age, gender and MELD score. PRO-C6 was not associated with survival in hepatic vein.
Conclusion: The study shows for the first time that a non-structural collagen is associated with severe decompensation and is an independent predictor of mortality in liver cirrhotic patients with TIPS. PRO-C6 could be a potential prognostic marker to identify patients likely to deteriorate after TIPS. The signaling of collagens and in particularly Endotrophin warrants further investigation in the fibrosis field.

SAT-092

The efficacy and safety of rifaximin-a: a 2-year observational study of overt hepatic encephalopathy

Rosalie Oey[1], Lennart E.M. Buck[1], Nicole Erler[2], Henk Van Buuren[1], Robert De Man[1]. *[1]Erasmus MC University Hospital, Gastroenterology and Hepatology, Rotterdam, Netherlands; [2]Erasmus MC University Hospital, Biostatistics, Rotterdam, Netherlands*
Email: r.oey@erasmusmc.nl

Background and aims: Five years after rifaximin-α registration as secondary prophylaxis for overt hepatic encephalopathy (HE) in the Netherlands, we aimed to evaluate the efficacy and safety of rifaximin treatment in a real-world pattern.
Method: After prospective identification of all patients using rifaximin-α for overt HE, the hospital resource use and adverse events were retrospectively registered in the first 6 months after initiation and compared to the prior 6 months.
Results: This study included 127 patients (71.7% male; median age 60.8 years (IQR 56.2-66.1); median MELD score 15.0 (IQR 12.1-20.4); 97.6% concomitant lactulose use). When comparing the first 6 months after rifaximin-α initiation to the prior 6 months, HE-related hospital admissions reduced (0.86 to 0.41 admissions/patient; $p < 0.001$), as well as the mean length of stay (8.85 to 3.79 bed days/admission; $p < 0.001$). No significant differences were found in the mean number of HE-related intensive care unit admissions (0.09 to 0.06 admission/patient; $p = 0.253$), the mean length of stay on the intensive care unit (0.43 to 0.57 bed days/admission; $p = 0.661$), emergency department visits (0.66 to 0.51 visit/patient; $p = 0.220$), and outpatient clinic visits (2.49 to 3.30 bed visit/patient; $p = 0.240$). Non-serious adverse events were recorded in 2.4% of patients.

	6 months prior to rifaximin-α initiation	6 months after rifaximin-α initiation	*p value*
HE-related admissions on the general ward per patient in 6 months, *mean (SD)*	0.86 (0.81)	0.41 (0.80)	< 0.001
HE-related hospital bed days on the general ward per admission in 6 months, *mean (SD)*	8.85 (11.20)	3.79 (9.37)	< 0.001
HE-related admissions on the intensive care unit per patient in 6 months, *mean (SD)*	0.09 (0.29)	0.06 (0.23)	0.253
HE-related hospital bed days on the intensive care unit per admission in 6 months, *mean (SD)*	0.43 (1.64)	0.57 (3.17)	0.661
AandE department visits per patient in 6 months, *mean (SD)*	0.66 (1.06)	0.51 (1.11)	0.220
Outpatient clinic visits per patient in 6 months, *mean (SD)*	2.94 (2.64)	3.30 (3.21)	0.240

Conclusion: The addition of rifaximin-α to lactulose treatment significantly reduces the number and length of HE-related hospitalizations for overt HE. Rifaximin-α treatment was safe and well tolerated.

SAT-093

Underutilization of hospice in inpatients with cirrhosis: The NACSELD experience

Kamath[8], Benedict Maliakkal[9], Jennifer Lai[10], Michael Fallon[11], Paul J. Thuluvath[12], Ram Subramanian[13], Hugo E. Vargas[14], Leroy Thacker[15,16], Jasmohan Bajaj[15,16]. *[1]Baylor Universiy Medical Center, Dallas, United States; [2]Dallas VA Medical Center, Dallas, United States; [3]University of Pennsylvania, Philadelphia, United States; [4]University of Alberta, Edmonton, Canada; [5]University of Washington, Seattle, United States; [6]University of Toronto, Toronto, Canada; [7]Yale University, New Haven, United States; [8]Mayo Clinic, Rochster, Rochester, United States; [9]The University of Tennessee, Memphis, United States; [10]UCSF, San Francisco, United States; [11]University of Arizona, Phoenix, United States; [12]Mercy Medical Center, Baltimore, United States; [13]Emory University, Atlanta, United States; [14]Mayo Clinic, Scottsdale, Scottsdale, United States; [15]McGuire VA Medical Center, Richmond, United States; [16]Virginia Commonwealth University, Richmond, United States*
Email: dr_jackieo@yahoo.com

Background and aims: The number of patients with cirrhosis continues to grow, resulting in an increasing rate of hospital admissions and liver related deaths. Little is known about patients discharged to hospice following hospitalization for complications of cirrhosis. Our aim was to understand the current pattern of hospice utilization in patients with cirrhosis by evaluating the North American Consortium for the Study of End-stage Liver Disease (NACSELD) cohort.

Method: Patients from 14 tertiary-care hepatology centers across North America prospectively consented non-electively hospitalized patients with cirrhosis. Patients were excluded if they had HIV, a transplant or non-hepatic malignancy. 2718 patients were consented, 5% (132) of whom were discharged to hospice. Random computer based propensity score matching was undertaken in a 1:2 ratio based on admission MELD score ± 3 points.

Variable	OR (95% CI)	P value
HE Grade III or IV HE	2.98 (1.36, 6.52)	0.006
Discharge Creatinine	1.49 (1.18, 1.88)	0.0008
Child Score	1.40 (1.15, 1.70)	0.0007
Discharge Bilirubin	1.05 (1.01, 1.09)	0.007
Na	0.94 (0.90, 0.99)	0.03
Maximum MELD Score during admission	0.91 (0.86, 0.99)	0.001
History of SBP	0.35 (0.14, 0.85)	0.02
On Transplant List	0.25 (0.10, 0.60)	0.002

Results: Patients discharged to hospice were older (60 vs. 56 years, p = 0.004), more likely to have NASH cirrhosis (27% vs. 16%, p = 0.02), more likely to have had ascites (80% vs. 71%, p = 0.05), but less likely to have had SBP (13% vs. 25%, p = 0.008) and be listed for liver transplantation (10% vs. 31%, p < 0.0001). Gender, percent with diabetes, body mass index, liver-related medications (with the exception of SBP prophylaxis) were similar among the groups. Because of propensity score matching, admission MELD was equivalent, but Child score was higher (10.9 vs. 10.1, p = 0.0007), and serum sodium was lower (132 vs. 134, p = 0.009) between the groups. Although the percentage of patients with a prior large volume paracentesis and prior hospitalization were similar between groups, patients discharged to hospice were more likely to have had a prior infection (41% vs. 29%, p = 0.03). Patients discharged to hospice had a longer length of index hospitalization (15.9 vs 12.7 days, p = 0.006), a higher discharge creatinine (2.62 vs. 1.60, p < 0.0001) and were more commonly diagnosed with hepatorenal syndrome (HRS; 40% vs. 18%, p < 0.0001). Table 1 shows multivariable modelling that found variables associated with discharge to hospice in our prospective multicenter cohort.

Conclusion: Patients with more advanced liver disease, hepatic encephalopathy, renal dysfunction, and those not candidates for liver transplantation were more likely to be discharged to hospice. However, in this sick multinational cohort of cirrhotic patients, it seems that hospice is underutilized (5%).

SAT-094

Effects of branched-chain amino acids on the progression of advanced liver disease: A Korean nationwide, multicenter, prospective, observational, cohort study

Jung Gil Park[1], Won Young Tak[2], Soo Young Park[2], Young Oh Kweon[2], Se Young Jang[2], Yu Rim Lee[2], Si Hyun Bae[3], Do Young Kim[4], June Sung Lee[5], Ki Tae Suk[6], In Hee Kim[7], Heonju Lee[1], Woo Jin Chung[8], Byoung Kuk Jang[8], Jeong Ill Suh[9], Jeong Heo[10], Hyun Young Woo[10], Myung Jin Oh[11], Won Kee Lee[12]. *[1]Yeungnam Univ. Email: gsnrs@naver.com

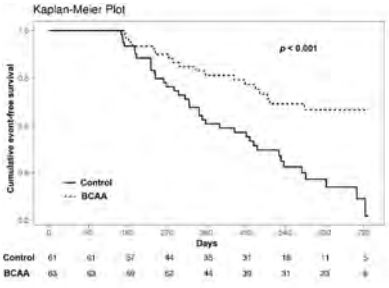
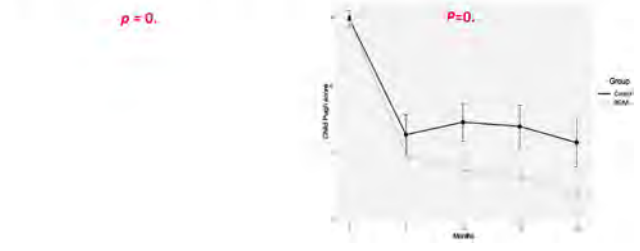
Background and aims: Malnutrition is a potential risk factor for progression of advanced liver disease. This study is to evaluate potential benefits of long-term oral branched amino acids (BCAAs) supplements in advanced liver disease





Method: Liver cirrhosis patients with Child-Pugh (CP) score from 8 to 10 were prospectively recruited from 13 medical centers. The patients supplemented with 12.45 g of daily BCAAs over 6 months or regular diet were assigned to either BCAA group or control group, respectively. We evaluated the effect of BCAAs therapy on the model

for end-stage liver disease (MELD) score, CP score, serum albumin, serum bilirubin, incidence of cirrhosis-related events, and event-free survival over 96 months.

Results: A total of 124 patients was enrolled (n = 63 in the BCAA group and n = 61 in the control group). Baseline characteristics of the patients including age, sex, CP score, and MELD score were not significant different between two groups. The MELD score (p = 0.009) and CP score (p = 0.011) were significantly improved in the BCAA group compared to the control group over time. However, serum albumin and bilirubin levels in the BCAA group failed to be improve over study period. Cumulative event-free survival in the BCAA group was significantly better than that in the control group (HR = 0.389, 95% CI 0.221-0.684, P < 0.001).

Conclusion: Long-term supplements of oral BCAAs could improve hepatic reservoir and delay the liver cirrhosis related complications in patients with advanced liver disease.

Background and aims: Spontaneous portosystemic shunts (SPSS) frequently develop during the progressive course of liver cirrhosis. Recent data suggested that the presence of a single large SPSS is associated with complications, especially with hepatic encephalopathy (HE). However, in cirrhotic patients the presence of more than one SPSS is common. This study aimed to evaluate the impact of total cross-sectional SPSS area (TSA) on the outcome of patients with liver cirrhosis.

Method: This is a retrospective international multicentric study, in which computed tomography (CT) scans of 724 patients with liver cirrhosis were evaluated for TSA. Clinical and laboratory data were recorded. The radius of each detected SPSS was measured and TSA was calculated. The clinical events during follow-up after the index CT-scan were recorded. Primary end point was 1-year survival. Secondary end points were acute decompensations (HE, variceal bleeding, ascites).

Results: A total of 301 patients (169 male) were included in the training cohort. 30% of all patients presented with more than one SPSS. Using a TSA cut-off at 83 mm^2 patients were classified as small TSA (S-TSA) or large TSA (L-TSA). L-TSA patients had significantly higher MELD (11 vs. 14) and MELD-Na (14 vs. 16) as well as higher prevalence of HE (12% vs. 21%) at baseline. During follow-up L-TSA patients showed significantly more episodes of overt HE (47% vs. 33%, p < 0.05). L-TSA patients had significantly higher 1-year mortality as compared to S-TSA patients (28% vs. 14%, p < 0.01). Multivariate analysis identified L-TSA (HR 1.737, 1.036-2.742) next to MELD (HR 1.181, 1, 142-1.220) and CLIF-C AD (HR 1.192, 1.100-1.292) score as independent predictors of mortality. These results were confirmed in an external multicentric validation cohort of 423 patients.

Conclusion: This study, for the first time, highlights the prognostic importance of TSA for mortality in patients with liver cirrhosis. Our results may have impact on the clinical decision to consider embolization of SPSS.

SAT-097

Non-invasive estimation of intravascular volume status in cirrhosis by dynamic size and collapsibility Indices of the inferior vena cava using bedside echocardiography

Madhumita Premkumar[1,2], Devaraja Rangegowda[3], Kamal Kajal[4], Jelen Khumuckham[5]. *[1]Institute of Liver and Biliary Sciences, Hepatology, Delhi, India; [2]Post Graduate Institute of Medical Education and Research, Chandigarh, Hepatology, Chandigarh, India; [3]Institute of Liver and Biliary Sciences, Cardiology, Delhi, India; [4]Post Graduate Institute of Medical Education and Research, Chandigarh, Anaesthesia and Critical care, Chandigarh, India; [5]Institute of Liver and Biliary Sciences, Cardiology, New Delhi, India*

Email: drmadhumitap@gmail.com

Background and aims: Echocardiographic assessment of the inferior vena cava (IVC) diameter and collapsibility index (IVCCI) is a non-invasive point-of-care tool for the individual's intravascular volume status (IVS) but needs validation in cirrhosis. We evaluated IVC dynamics in cirrhosis and correlated it with conventional tools like central venous pressure (CVP), pulmonary capillary wedge pressure (PCWP) and right atrial pressure (RAP). The IVC collapsibility index (IVCCI) was the difference between the maximum ($IVCD_{max}$) and

minimum IVC diameters ($IVCD_{min}$) divided by the maximum IVC diameter, expressed as a percentage ([$IVCD_{max}$-$IVCD_{min}$]/$IVCD_{max}$ × 100%).

Method: A total of 673 consecutive cirrhotics were screened by 2D echocardiography with M mode and the IVC measurements including IVCD and IVCCI were performed. Of these, 125 patients underwent right heart catheterisation with recording of hepatic venous pressure gradient (HVPG), RAP, pulmonary artery (PA) pressure and PCWP. The CVP data was available in 80 (64%) patients, and finally 76 patients (84% male, 50% ethanol related, mean age 52.1 years, 57.8% with ascites, 39.4% with prior variceal bleed) with complete data were enrolled.

Results: The mean CVP measured was 12.8 ± 4.8 mmHg and the IVCCI was 29.5 ± 10.9%. The IVCD ranged from 0.97 to 2.26 cm during expiration and from 0.76 to 1.84 cm during inspiration with a mean of 1.8 ± 0.9 cm. The mean IVCD correlated with RAP (r = 0.633, p = 0.043), but not with HVPG (r = 0.344, p = 0.755), PCWP (r = 0.562, p = 0.072) or PA pressure (r = 0.563, p = 0.588). A strong negative linear correlation was observed between the CVP (mean 10.3 ± 4.4mmHg) and the IVCCI (r = -0.827, p = 0.023) in all patients and sub-stratified for those with (r = -0.748, p = 0.039) and without ascites (r = -0.761, p = 0.047). A strong positive correlation was revealed between the CVP and the $IVCD_{max}$ (r = 0.671, p = 0.037) and $IVCD_{min}$ (r = 0.612, p = 0.040), which remained significant even in presence of ascites. The $IVCD_{min}$ < 1.5 cm predicted CVp < 10 mmHg and indicated the need for further volume resuscitation with sensitivity of 91%, specificity of 79% and 96% negative predictive value.

Conclusion: IVCD and collapsibility index provides non-invasive volume status assessment in cirrhosis, independent of HVPG or ascites. Future prospective studies could be focused to bring about a steadfast formula for calculating fluid requirements in cirrhosis using dynamic IVC criteria.

SAT-098

Transjugular intrahepatic portosystematic shunt with 7 mm covered stent reduces hepatic encephalopathy without losing shunt function for prevention of portal hypertensive rebleeding

Xiaolong Qi[1,2], Yifan Wu[1], Chuan Liu[2], Zhendong Yue[1], Hongwei Zhao[1], Lei Wang[1], Xiaoxue Du[2], Fuliang hE[1], Fuquan Liu[1].
[1]Beijing Shijitan Hospital, Capital Medical University, CHESS Group, Department of Interventional Therapy, Beijing, China; [2]Nanfang Hospital, Southern Medical University, CHESS Group, Hepatic Hemodynamic Lab, Institute of Hepatology, Guangzhou, China
Email: qixiaolong@vip.163.com

Background and aims: Transjugular intrahepatic portosystemic shunt has been recommended by the Baveno consensus and the American Association for the Study of Liver Diseases guidance for portal hypertensive bleeding in cirrhosis. However, there is no international consensus yet regarding the priority diameter selection of the covered stents. The study aims to explore whether the 7 mm covered stents would equip with more advantages than 8 mm covered stents for the prevention of portal hypertensive bleeding in cirrhosis.

Method: In this retrospective study, cirrhotic patients receiving transjugular intrahepatic portosystemic shunt procedure with a 7 mm or 8 mm covered stent for the treatment of variceal rebleeding between January 2011 and September 2015 in a high volume center in China were analyzed. During a 24-month follow-up, the incidence and grade of hepatic encephalopathy were recorded. Covert hepatic encephalopathy (minimal or grade I) and overt hepatic encephalopathy (≥ grade II) were respectively defined. Propensity score matching was used to control for preoperative baseline characteristic imbalances. In addition, shunt dysfunction, variceal rebleeding, survival and a composite end point of all-cause rebleeding and death were assessed as outcome measures.

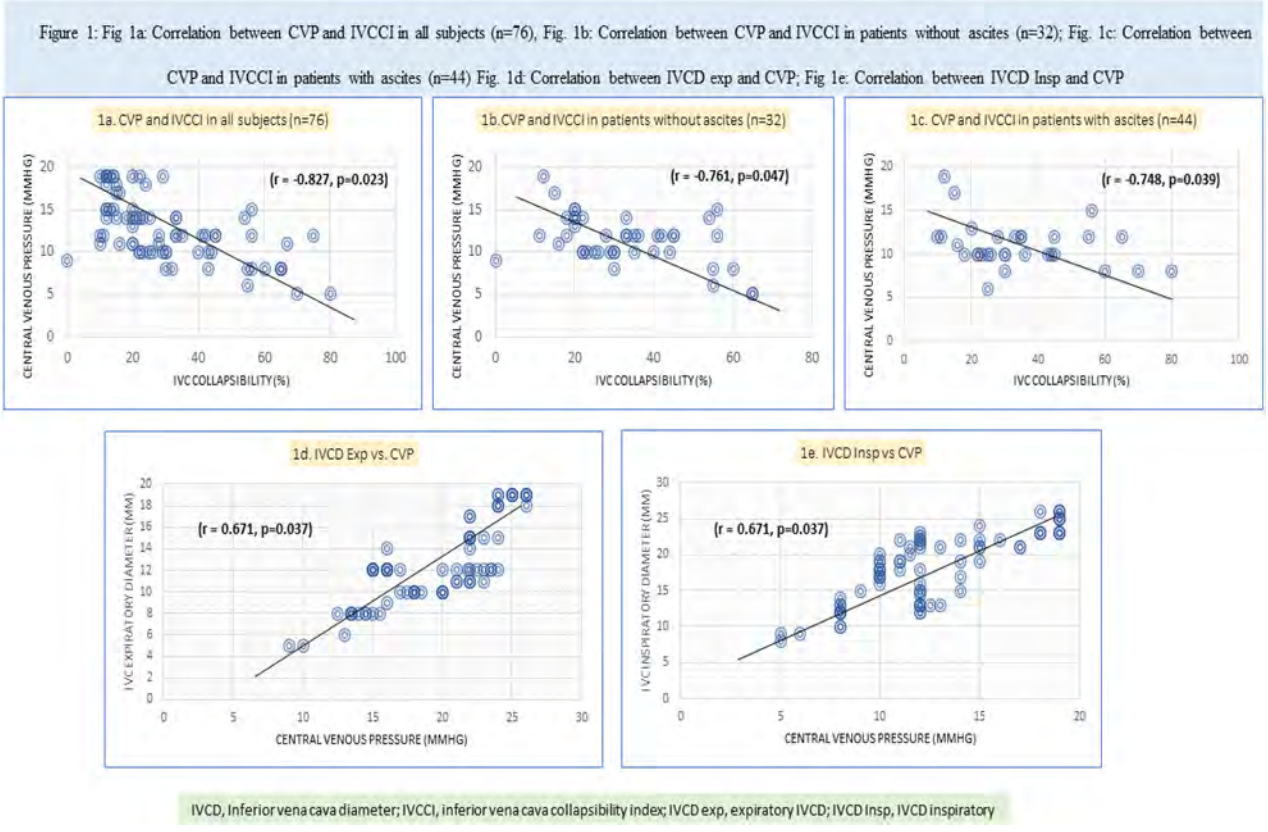

Figure: (abstract: SAT-097): Correlation between different IVC parameters and CVP

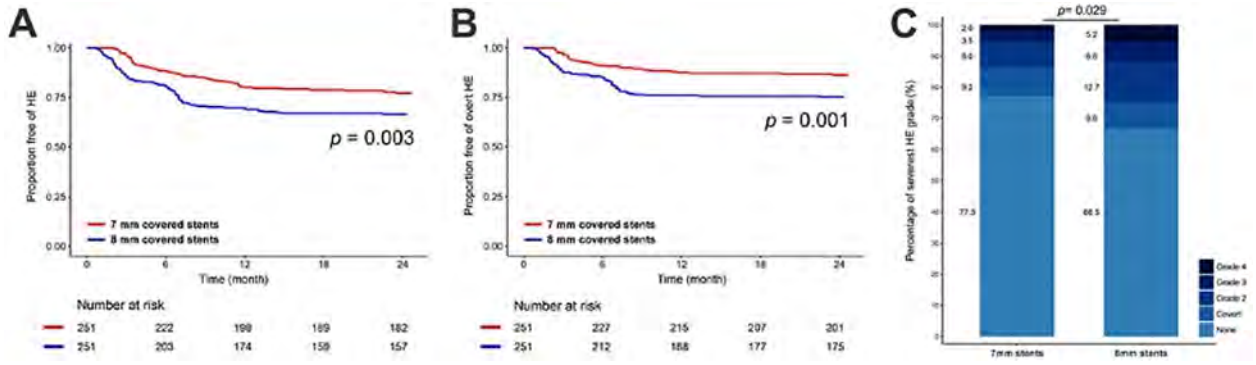

Figure: (abstract: SAT-098)

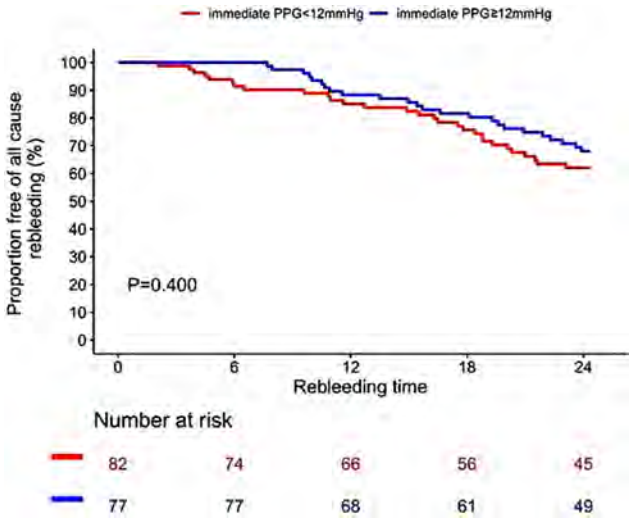
Results: A total of 502 eligible patients were enrolled. Accordingly, 251 patients with 7 mm covered stent were recruited, and patients with 8 mm covered stent were matched in a 1:1 ratio. During a 24-month follow-up, there was no significant difference between the 7 mm and 8 mm stents groups considering the free of shunt dysfunction rates, free of rebleeding rates, survival rates, free of all-cause rebleeding and death rates with p value equals to 0.915, 0.840, 0.735, 0.237 respectively. Notably, the group with patients receiving 7 mm covered stent had a higher free of hepatic encephalopathy rate (77.1% vs 66.4%, p = 0.003, Figure 1A) and overt hepatic encephalopathy rate (86.3% vs 75.2%, p = 0.001, Figure 1B) over the group with patients receiving 8 mm covered stent. Moreover, the percentages of severest grade hepatic encephalopathy episodes were significantly different between the groups (p = 0.029, Figure 1C).
Conclusion: Our study suggested a favorable overall outcome with 7 mm covered stents compared with 8 mm covered stents in transjugular intrahepatic portosystemic shunt procedure for portal hypertension rebleeding prevention in patients with cirrhosis.

SAT-099

Portal pressure gradient measured immediately after transjugular intrahepatic portosystematic shunt placement: Poor in predicting rebleeding in patients with portal hypertension

Fuquan Liu[1], Fangze Huang[2], Chuan Liu[2,3], Xinlong Lin[2], Xiangbo Zeng[2], Yanna Liu[2,3], Xiaolong Qi[2,3]. *[1]Beijing Shijitan Hospital, Capital Medical University, CHESS Group, Department of Interventional Therapy, Beijing, China; [2]Nanfang Hospital, Southern Medical University, Hepatic Hemodynamic Lab, Institute of Hepatology, Guangzhou, China; [3]Lanzhou University, CHESS Frontier Center, Lanzhou, China*
Email: qixiaolong@vip.163.com

Background and aims: A portal pressure gradient above 12 mmHg after transjugular intrahepatic portosystemic shunt placement can indicate a postoperative rebleeding in patients with variceal bleeding caused by portal hypertension. A recent study has verified that measure timing influenced the accuracy of portal pressure gradient, which also found that portal pressure gradient measured immediately after transjugular intrahepatic portosystemic shunt placement (immediate portal pressure gradient) under general anesthesia and deep sedation could not be an indicator for rebleeding during follow-up. This study aimed to analyze the direct relationship between immediate portal pressure gradient measured under local anesthesia and postoperative rebleeding to investigate whether immediate portal pressure gradient could predict a rebleeding after transjugular intrahepatic portosystemic shunt in portal hypertension.
Method: This retrospective study included eligible patients receiving transjugular intrahepatic portosystemic shunt between January 2011 and September 2015 in China. Immediate portal pressure gradient was measured after transjugular intrahepatic portosystemic shunt placement under local anesthesia. A propensity score matching analysis was performed in 159 cases to match bleeding patients with non-bleeding patients at a ratio of 1:2 to reduce the confounding factors. Relationship between immediate portal pressure gradient with a threshold of 12 mmHg and a postoperative rebleeding was analyzed both in pre- and post-match samples.
Results: A total of 502 consecutive patients were enrolled. No significant difference was observed in occurrence of rebleeding between patients with immediate portal pressure gradient ≥ 12 mmHg and < 12 mmHg neither before nor after (8.7% vs. 12.8%, p = 0.09; 31.2% vs. 35.3%, p = 0.4) matching by a propensity score (Figure 1). Predictive performance of immediate portal pressure gradient for rebleeding was poor with the area under survival receiver operating characteristic curve of 0.415 (95% CI: 0.332-0.514).



Conclusion: Our study analyzed the direct association between immediate portal pressure gradient and a postoperative rebleeding. And we found that a threshold of 12 mmHg for portal pressure gradient measured immediately after transjugular intrahepatic portosystemic shunt placement under local anesthesia could not predict rebleeding after transjugular intrahepatic portosystemic shunt in portal hypertension.

SAT-100

Expanding the Baveno VI criteria for the screening of varices in advanced liver disease patients

iulia ratiu[1], Sporea Ioan[1], Roxana Sirli[1], lupusoru raluca[1], barbulescu Andreea[1], Miutescu Bogdan[1], danila mirela[1]. [1]*University of Medicine and Pharmacy V. Babes Timisoara, Gastroenterology, Timisoara, Romania*
Email: iulia.ratiu@gmail.com

Background and aims: The updated Baveno VI guidelines recommend that screening for EGD can be avoided in patients with compensated advanced chronic liver disease (cACLD), who have liver stiffness < 20 kPa and a platelet count > 150, 000/μL.
The aim of this study was to validate the Baveno VI criteria in patients with chronic liver disease in order to determine their ability to rule out the presence of esophageal varices (EV) and avoid unnecessary endoscopies. We also searched for the best cut-off values in our center, to rule out the patients with significant portal hypertension category.
Method: This was a retrospective study of patients with liver cirrhosis admitted in our Department between January 2009 and September 2018. Patients were included in the study if Transient Elastography (TE), laboratory tests and upper endoscopy were performed in the same year. The study group (829 patients) was used to validate the Baveno IV criteria to predict significant esophageal varices. In the group of patients situated in the "gray zone" (between the cut-offs rule in and rule out significant esophageal varices) we searched for additional predictive factors. A cohort of 124 cirrhotic patients was used as a control group, to validate the cut-off values calculated for our center.
Results: The best thresholds to rule in significant esophageal varices in our study group (829 patients) were identified at PLT < 150, 000/mm3 and LSM > 29.5 kPa, and the best thresholds to rule out significant esophageal varices were identified at PTL > 150.000/mm3 and LSM < 19.4 kPa. In the validation cohort of 124 patients if we used the cut-off for ruling out, 25/124 met the criteria, and none of them had EV, Se = 100%. If we used the rule in cut-off, 36/124 met the criteria, but 1 of them didn't have EV, leading to Se = 97.2%. Diagnosis accuracies were 100% and 97.2%. Regarding the "grey zone" between 19.4 kPa and 29.5 kPa, 330/829 (39.8%) patients from the study group were in this zone. Albumin was associated with the presence of EV in the "grey zone". The best cut-off value for predicting significant EV was 3.4 g%. Adding the serum albumin to the Baveno VI criteria we increased the NPV from 98.4% to 99.3%.
Conclusion: Baveno VI criteria in our large cohort of cirrhotic patients had 98.4% accuracy. Adding serum albumin levels (< 3.4 g%) we increase the performance of Baveno VI criteria. We propose a new cut-off value of TE < 19.4 kPa in patients with platelets > 150.000 mg/dl, with an 100% accuracy in our center to rule out significant varices.

SAT-101

Detrimental effect of proton pump inhibitors in cirrhosis depends on common genetic variation

Matthias Reichert[1], Christina Schneider[1], Roman Liebe[1], Edith Vandieken[1], Markus Casper[1], Beate Appenrodt[1], Robin Greinert[2], Alexander Zipprich[2], Cristina Ripoll[2], Frank Lammert[1]. [1]*Saarland University Medical Center, Department of Medicine II, Homburg, Germany;* [2]*Martin-Luther University Halle-Wittenberg, Department of Medicine I, Halle, Germany*
Email: matthias.reichert@uks.eu

Background and aims: Proton pump inhibitors (PPI) increase adverse events and potentially mortality in patients with cirrhosis. Common risk variants in the Patatin-like phospholipase domain-containing protein 3 (*PNPLA3*) and Membrane-bound O-acyltransferase domain-containing protein 7 (*MBOAT7*) genes contribute to progressive chronic liver disease. We aimed to investigate the impact of PPI intake on survival and the development of hepatic complications in patients with cirrhosis stratified for the risk variants.
Method: Overall, 998 patients with cirrhosis in two German academic medical centers in Homburg and Halle were included between 2014 and 2017. We defined PPI use as a daily dose ≥ 20 mg pantoprazole (or an equivalent dose of other PPI) taken continuously. Patients were genotyped for the risk variants rs738409 (*PNPLA3*) and rs641738 (*MBOAT7*) by allelic discrimination assays. Prospective follow-up was conducted, and transplant-free survival and complications were recorded, stratified by the presence of risk genotypes.
Results: In total, 700 PPI users (70%) were identified. Median age was 61 (53–68) years, and median MELD score was 11 (8–15). Cirrhosis was alcoholic in 537 (54%), viral etiology was present in 166 (17%) and other etiologies in 295 (29%) patients. Among the patients on PPI, 94% received pantoprazole (63% 40 mg, 30% 80 mg and 7% 20 mg daily, data available in 54%). In univariate Cox regression analyses were female sex, bilirubin, creatinine, albumin, INR, PPI, and alcoholic liver disease were associated with transplant-free survival. In multivariate Cox regression models, independent predictors in carriers of the wild-type variant were PPI (adjusted hazard ratio [aHR] 0.48, 95%

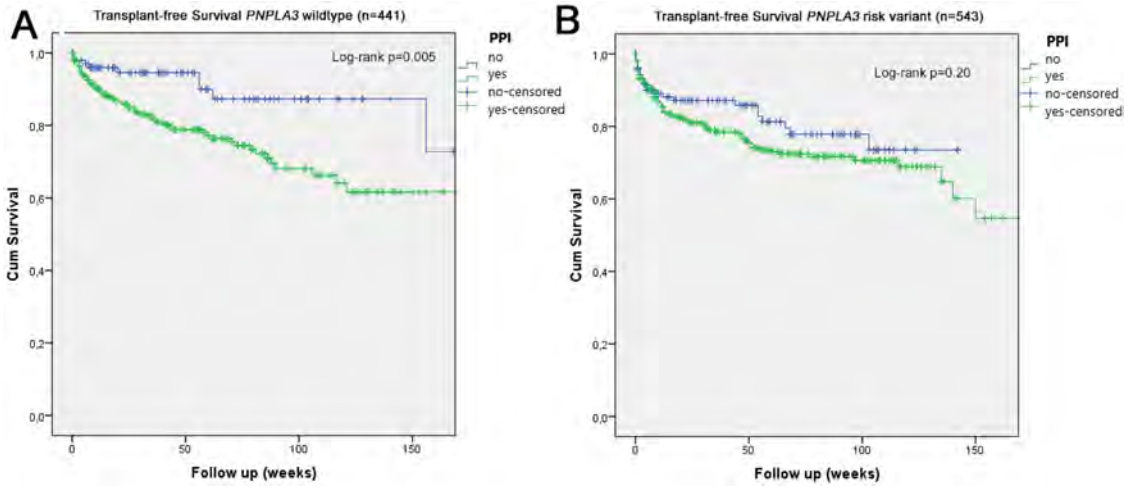


Figure: (abstract: SAT-101)

confidence interval [CI] 0.23-0.96; p = 0.039) and MELD (aHR 1.17, 95% CI 1.13-1.22; p < 0.001), whereas in carriers of the *PNPLA3* risk variant only MELD (aHR 1.16, 95% CI: 1.13-1.19; p < 0.001) was associated. The Presence of an *MBOAT7* variant, as well as the dose and type of PPI did not yield differences in the outcome. For hepatic complications in association with PPI intake, only bacterial infections were associated with a similar increased risk in patients with (Odds ratio [OR] 2.20, 95% CI 1.23-3.93; p = 0.007) and without (OR 2.23, 95% CI 1.23-4.05; p = 0.007) *PNPLA3* risk alleles.
Conclusion: In this large prospective cohort, reduced transplant-free survival in patients with cirrhosis taking PPI was present only in carriers of wild-type alleles of the *PNPLA3* risk variant. Mechanistic studies of this gene-environment interaction are warranted.

SAT-102
Cirrhotic patients with vitamin d deficiency fail to respond to oral replacement therapy
Freya Rhodes[1], Olivia Greenham[1], Emma Hunt[1], Sheetal Shah[1], Jennifer Ryan[1], David Patch[1], Rachel Westbrook[1]. [1]*Royal Free Hospital, Hepatology, London, United Kingdom*
Email: F.rhodes@doctors.net.uk

Background and aims: Vitamin D deficiency and bone disease are highly prevalent in patients with advanced chronic liver disease. For bisphosphonate treatment for osteoporosis to be effective vitamin D levels must be replete. Moreover, vitamin D deficiency has been associated with an increased risk of infections and increased rejection rates following liver transplantation. The optimal dose and route of vitamin D replacement in cirrhosis is unknown. BSG guidance currently recommends 800 IU/day orally for all patients with cirrhosis/cholestatic liver disease.
Method: Retrospective review of 299 patients with chronic liver disease undergoing evaluation for liver transplant between 2015 and 2017. Vitamin D 'severe deficiency' was defined as < 25 ng/ml, 'deficiency' 25-50 ng/ml and normal > 50 ng/ml. Response to oral vitamin D therapy was recorded.
Results: 273 patients had vitamin D levels recorded. The prevalence of vitamin D deficiency in these patients was 57% (156/273) with 65/273 (24%) 'severely deficient' and 91/273 (33.3%) 'deficient'. Vitamin D therapy was being prescribed in 69 patients with levels < 50 ng/ml (44%), and 77 patients (66%) with levels > 50 ng/ml. Daily doses of prescribed vitamin D therapy did not significantly differ depending on the degree of deficiency, with median doses of 1, 000iu, 800iu and 800iu in those patients with vitamin D levels > 50 ng/dl, 25-50 ng/dl and < 25 ng/dl respectively (p = 0.53).
Data on vitamin D levels pre and post 3 months of treatment with Vitamin D therapy were available in 111 patients. Vitamin D therapy did not positively impact on Vitamin D levels at three months (Δ vitamin D) when comparing those on therapy (n = 64) to those not on therapy (n = 47) (1 vs −3, p = 0.13). Patients with vitamin D levels < 50 (n = 30) had a significantly greater increment in vitamin D at three months if they were taking > 1500 iu/day compared to those taking < 1500 iu/day (17 vs 2, p = < 0.05), however only 23% augmented their vitamin D levels to within the normal range of > 50 ng/dl with therapy. Advanced liver disease (MELD > 15) did not impact on response to vitamin D therapy (p = 0.74).
Conclusion: Vitamin D deficiency is prevalent, affecting over 50% of patients with advanced cirrhosis. Oral vitamin D replacement therapy is ineffective in cirrhotics at repleting stores over a 3 month period irrespective of dose given or MELD score. Evaluation of response to IM vitamin D therapy in cirrhotic patients is urgently required to guide guidelines to ensure effective therapy.

SAT-103
Bone disease does not correlate with severity of liver disease in cirrhosis
Freya Rhodes[1], Olivia Greenham[1], Emma Hunt[1], orla kearney[1], Jennifer Ryan[1], David Patch[1], Rachel Westbrook[1]. [1]*Royal Free Hospital, Hepatology, London, United Kingdom*
Email: F.rhodes@doctors.net.uk

Background and aims: Patients with chronic liver disease have increased risk of bone disease with reported prevalence of osteoporosis between 20–56% and a high prevalence of Vitamin D deficiency. The aetiology is poorly understood with a complex interplay between endocrine, metabolic, nutritional and physical abnormalities. We aim to evaluate the influence of epidemiological parameters on bone mineral density and vitamin D levels in chronic liver disease.
Method: Retrospective review of consecutive patients with chronic liver disease undergoing assessment for liver transplantation between 2015–2017. Data were collected on aetiology, liver severity, body mass index, functional assessment alongside vitamin D level and bone mineral density. Bone disease (Osteoporosis/osteopenia) was defined as per WHO classification and Vitamin D deficiency as a Vitamin D level < 50 nmol/L with severe deficiency < 25 nmol/L.
Results: 299 patients (72% male) with a median age 57-years (IQR 49-63) were included. Aetiology was alcohol (n = 96), viral hepatitis (n = 66), PBC/PSC (n = 62), NAFLD (n = 34), AIH (n = 22), and 'other' (n = 19). Median UKELD and MELD scores were 53 (IQR 50-57) and 14 (IQR 10-18.5) respectively.
At the time of evaluation for liver transplant, 199 (66.6%) patients had bone disease with 64/299 (21%) osteoporotic and 135/299 (45%) osteopenic. The prevalence of bone disease varied across aetiologies (ANOVA p = < 0.005), with PBC/PSC (69%) and AIH (82%) having the highest prevalence and NAFLD the lowest (37%). The overall prevalence of Vitamin D deficiency was 62%. Viral hepatitis (72%) had the highest rates and PBC/PBC (41.5%) the lowest (ANOVA p = < 0.005). Overall the MELD/UKELD score did not correlate with bone disease or Vitamin D deficiency, nor did it correlate in subgroup analysis of alcohol, viral, autoimmune or cholestatic disease aetiology. Predictors of bone disease included a low BMI (p < 0.01), reduced hand grip strength (p < 0.01), older age (p = 0.01) and autoimmune aetiology. Vitamin D deficiency conversely was associated with female sex (p = 0.02) but not BMI, hand grip strength or older age.
Conclusion: Bone disease and vitamin D deficiency are prevalent in chronic liver disease. Disease severity does not correlate with bone disease or vitamin D whereas more functional markers of frailty such as hand grip strength do. Further prospective research is needed to look at the role of vitamin D in cirrhosis.

SAT-104
Factors associated with renal replacement therapy and mortality following first episode of acute kidney injury in inpatients with cirrhosis
Susana G. Rodrigues[1], Annalisa Berzigotti[1]. [1]*Swiss Liver Center, UVCM, Inselspital, Department of Biomedical Research, University of Bern, Switzerland, Bern, Switzerland*
Email: annalisa.berzigotti@insel.ch

Background and aims: Renal injury is associated with poor outcomes in cirrhosis. Prediction of renal replacement therapy (RRT) and mortality remains difficult in patients presenting the first episode of acute kidney injury (AKI). We aimed to compare the existing formulas to estimate glomerular filtration rate (eGFR), (MDRD-6, CKD-EPI, Royal Free Hospital-RFH) and assessed which predict outcomes.
Method: We retrospectively studied hospitalized patients with cirrhosis presenting a first AKI episode at our centre in 2012-2018. Patients on RRT, with HCC outside Milan criteria at baseline and who previously received OLT were excluded. Laboratory values used to estimate GFR were collected at diagnosis of AKI (D0) and D2 and in-hospital RRT, and death or OLT at 30 and 90-d were assessed.

Results: 143 patients were included (Age 59 ± 11 years, 62% male, BMI: 27.3 ± 5.8 kg/m^2, MELD score: 14.7 ± 5.7 and Child score 9 ± 2; aetiology: alcohol 29%, alcohol + metabolic component 25%, viral 21%, NASH 13%) and were followed-up for a median of 10 months (IQR 1-25). Males had higher creatinine at AKI presentation (p = 0.04 vs. females), but eGFRs were not significantly different (RFH-GFR 24.8 vs. 24.1 ml/min/1.73 m2 , p = 0.67). At AKI diagnosis, the grade of renal failure was 1 in 57%, 2 in 22% and 3 in 21%. Infection at admission (56%) was the strongest predictor of AKI grade (OR for grade ≥ 2: 2.9 95%CI 1.4-6.0, p = 0.004). RRT was performed in 15.4% and was associated with 55% 90-d mortality rate. Predictors of RRT were baseline creatinine (OR 1.009; 95%CI 1.005-1.014, p < 0.001), D0 urinary-Na (OR 0.998; 95%CI 0.997-0.999, p = 0.02), D0 presence of urinary casts (OR 3.7; 95%CI 1.3-10.4, p = 0.013) and alcohol +metabolic aetiology (p = 0.049 vs. other aetiologies). Death or OLT rate at 30-d and 90-d was 23% and 37% respectively. RRT and kidney function by creatinine and by all the proposed eGFR formulas predicted mortality; the strongest association was obtained on day 2 from the diagnosis of AKI. Among creatinine, MDRD-6, RFH-GFR and CKD-EPI, RFH-GFR showed the highest predictive value for RRT, 30-d and 90-d mortality.
Conclusion: Patients with alcohol aetiology and added metabolic component of cirrhosis have more severe AKI, requiring RRT more frequently and resulting in a higher mortality. RFH-GFR calculated on the second day after AKI diagnosis is a strong predictor of need for RRT and 30-d and 90-d mortality.

SAT-105
Rising economic burden following the diagnosis of compensated cirrhosis among hospitalized patients with Non-alcoholic fatty liver disease/non-alcoholic steatohepatitis in Spain
Manuel Romero Gomez[2], Nandita Kachru[3], Ahmet Burak Ozbay[3], Josep Darba[4]. [1]*BCN Health Economics and Outcomes Research, Barcelona, Spain;* [2]*Hospital Universitario Virgen del Rocio, Instituto de Biomedicina de Sevilla., Sevilla, Spain;* [3]*Gilead Sciences, Health Economics Outcomes Research, Foster City, United States;* [4]*Department of Economics, University of Barcelona, Barcelona, Spain*
Email: Nandita.Kachru@gilead.com

Background and aims: NAFLD/NASH is a growing concern due to its increased prevalence and incidence in Spain. However, Spain-specific data is lacking. This study examined the demographics, comorbidities and healthcare costs among NALFD/NASH patients once they develop CC in Spain.
Method: Adult patients with NAFLD/NASH diagnosis (ICD-9/10-CM) between 2006 and 2017 were identified retrospectively from the Spain hospitalization database that covers 192 private hospitals and 313 public hospitals, with more than 38 million patients. Following the initial NAFLD/NASH diagnosis, development of CC was identified using the first diagnosis date (CC index date). Patients were excluded if they had evidence of viral hepatitis, Wilson's disease, Gaucher disease, LAL-D, alcoholism including alcoholic liver disease, HIV, hemochromatosis or primary biliary or sclerosing cholangitis. Baseline measures were reported during 6 month pre-index duration, and healthcare costs were reported during 6 months pre-index and 6 months post-index duration. Mean per patient per month healthcare costs were obtained. Patients were followed from index date to earliest of 6 months, progression to different cohort, end of coverage, or end of study period.
Results: The study population included 8, 205 NAFLD/NASH patients (mean age 58.4 years; 54% males) and 139 CC patients (1.7% of NAFLD/NASH patients) (mean age 65.2 years; 59% males). The most common comorbidities were hypertension, diabetes, and hyperlipidemia with prevalence rates of 28%, 21%, 15%, respectively among NAFLD/NASH patients, and 32%, 27%, 12% respectively among CC patients. 45% of NAFLD/NASH patients and 24% of CC patients have ≥ 1 condition out of hypertension, hyperlipidemia, diabetes, renal impairment or cardiovascular diseases. The mean (± SD) per patient per month all-cause healthcare costs for CC patients averaged €3, 738 (± €1, 835) in the pre-index period and €5, 414 (± €2, 658) in the post-index period (+45%) (p < 0.001). The cost driver were inpatient costs, representing 41% of the total cost (€1, 529±€750) in the pre-index and 55% of the total cost (€2, 972±€1, 457) in the post-index period.

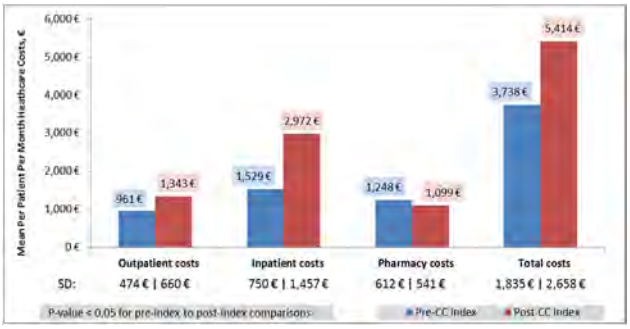

Figure: Mean Per Patient Per Month All-cause Healthcare Costs for NAFLD/NASH-CC patients

Conclusion: Hospitalized Spain NAFLD/NASH patients with CC have a high comorbidity burden. Per patient per month healthcare costs are high, following the CC diagnosis (+45%), with inpatient costs as the primary driver. Novel treatment options are needed to improve patient outcomes and limit the increasing costs in Spain due to NAFLD/NASH.

SAT-106
Prevalence and survival of fungal peritonitis in decompensated cirrhosis
Noam Roth[1], Jade King[1], Emmanuel Wey[1], Jennifer Ryan[1], Rachel Westbrook[1]. [1]*Sheila Sherlock Liver Centre, Royal Free Hospital, Department of Hepatology, London, United Kingdom*
Email: noam.roth.09@gmail.com

Background and aims: Fungal peritonitis in decompensated cirrhosis is exceedingly rare and little is known regarding true prevalence, presentation, clinical markers, pathogens and prognosis. The aim of this study was to evaluate all cases of fungal peritonitis in decompensated cirrhosis over a 10-year period at our institution.
Method: Retrospective review of ascitic fluid cultures from consecutive cirrhotic patients over a 10-year period were reviewed to identify patients with fungal peritonitis. Baseline demographic and clinical data at presentation alongside pathogens and outcomes were collated and compared to a matched control group of spontaneous bacterial peritonitis (SBP).
Results: 8890 ascitic fluid samples were reviewed; 213 had positive fungal cultures of which 8 occurred in the context of cirrhotic ascites. Underlying aetiology of cirrhosis was alcohol in 6 cases, median age 50, MELD 24 and 7/8 were CPS C. Indication for the ascitic tap was either pyrexia, abdominal pain or distension and 6/8 cases had had an invasive intervention in the 48 hours prior to the ascitic tap (paracentesis/gastroscopy) and 2 cases subsequently evolved with bowel pathology (obstruction/perforation). Ascitic WCC was predominantly neutrophils (> 90%) with total ascitic WCC counts > 1000cells/mm^3 in the majority of cases. All fungal cultures were Candida species (Candida albicans n = 8, glabrata n = 1), median culture time for positive result 48 hours (24-168 hours) and all albicans were sensitive to fluconazole; the glabrata was resistant. Two patients had a concurrent candidaemia. Seven out of the eight cases required escalation to ITU; 2/8 were alive at 90 days. In comparison to a control group of 119 SBP cases collated over the same time period patients with fungal peritonitis had non statistical differences in MELD (24 vs 22; p = 0.1) and peripheral WCC (13.5vs 11.7; p = 0.7), however there was trend towards significance in UKELD (62 vs 56; p = 0.07) and INR (2.3 vs 2.0; p = 0.07) and ascitic WCC (4870 vs 2765; p =

0.06). Death or LT at 1-year was 52/117 (44%) and 2/8 (25%) for SBP and fungal peritonitis respectively (p = 0.4).
Conclusion: Fungal peritonitis in the context of cirrhosis is an exceedingly rare but has a significantly poor prognosis perhaps related to delay in recognition of fungal pathogen. Validation of fungal biomarkers and incorporation into clinical practice may allow earlier recognition and treatment.

SAT-107

Effect of a multifactorial intervention (non-alcoholic beer, diet and exercise) on endothelial function, nutritional status and quality of life in patients with cirrhosis

Astrid Ruiz-Margain[1], May E. Espin-Nasser[1], Silvia L. Ríos-Torres[1], Berenice M. Román-Calleja[1], Elizabeth Moreno-Tavarez[1], Gabriela Fernández-del Rivero[1], Nayelli C. Flores-Garcia[1], Gretel Galicia_Hernández[1], Aldo Torre[1], Samantha González-Rodríguez[1], Osvely Méndez-Guerrero[1], Jose Luis Rodriguez[1], Ricardo Macias-Rodriguez[1]. [1]*Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Gastroenterology, Mexico City, Mexico*
Email: ricardomacro@yahoo.com.mx

Background and aims: The implementation of nutritional strategies targeting several variables at once could benefit patients with cirrhosis. Non-alcoholic beer has different compounds derived from hops that exert antioxidant, anti-inflammatory and nutritional properties. The aim of this study was to evaluate the effect of diet + exercise and non-alcoholic beer on nutritional status, endothelial function and quality of life in patients with cirrhosis.
Method: Randomized open clinical trial conducted from 2015 to 2018. Patients with cirrhosis were randomized into two groups: A) Intervention (non-alcoholic beer +diet +exercise) B) Control (water +diet +exercise). Treatment consisted of 330 ml non-alcoholic beer per day or the same amount of water, plus an individualized dietary program and an exercise program with a pedometer-based bracelet to reach at least 5000 steps/day during 8 weeks. Endothelial function (flow-mediated dilation), biochemical and nutritional variables and quality of life (CLDQ) were evaluated.
Results: 40 patients were included in the study. The mean age was 53 ± 7 years, 65% were women, the main etiologies were HCV 32.6%, AIH 23.3% and NASH 20.9%. Mean MELD was 9 ± 2.2 and most patients were CTP A (86%). The adherence to the interventions was > 90% in both groups. Liver function tests, serum electrolytes, platelets and renal function remained stable throughout the study. No adverse events were observed in either group. PhA remained stable in the control group and showed a trend towards improvement in the intervention group; a higher proportion of improvement on nutritional status was observed in the intervention group. Quality of life improved in both groups, but predominantly in the intervention group and endothelial function improved in both groups. (Table 1)

Table 1: Changes on the study variables after intervention

	Control (n = 20)		Intervention (n = 20)	
	Baseline	Final	Baseline	Final
Child-Pugh	5.5 ± 0.9	5.4 ± 0.7	5.7 ± 0.9	5.3 ± 0.5*
MELD score	8 ± 2.3	8 ± 1.9	9 ± 2.2	8.1 ± 1.7
Phase angle	6 ± 0.7	6 ± 0.6	5.6 ± 0.5	5.7 ± 0.7
Improvement of nutritional status		28.6%		57.9%*
Number of steps	8593 ± 3020	11326 ± 4399	8522 ± 4068	11025 ± 3781
CLDQ (Global)	5.20 ± 0.9	5.5 ± 0.9	4.6 ± 0.9	5.3 ± 0.9*
Endothelial dysfunction	52%	16%*	32%	0%*

* p = < 0.05

Conclusion: Our intervention is safe and well tolerated in patients with cirrhosis, and shows improvement in nutritional status, endothelial function, severity of the disease and quality of life. The long-term benefits of this intervention should be further assessed.

SAT-108

Sarcopenia and nutritional status predict mortality in patients with cirrhosis undergoing liver transplant assessment

John Ryan[1,2], Davide Roccarina[1], Francesco Arico'[1], Laura Iogna Prat[1], Mohamed Zuhair[1], Matthew North[1], orla kearney[1], Emmanuel Tsochatzis[1]. [1]*Royal Free London NHS Foundation Trust, Sheila Sherlock Liver Centre, London, United Kingdom;* [2]*University of Oxford, Translational Gastroenterology Unit, Oxford, United Kingdom*
Email: john.ryan@ndm.ox.ac.uk

Background and aims: The presence of sarcopenia has been shown to predict adverse outcomes in advanced liver disease. Here we examined the association of a validated nutritional assessment tool, and sarcopenia diagnosed by imaging, with short-term mortality in patients undergoing assessment for liver transplantation.
Method: 882 patients undergoing assessment for elective, first-time, liver transplantation at the Royal Free Hospital, London, were included in this study. Nutritional status and sarcopenia were assessed using the Royal Free Hospital-Global Assessment (RFH-GA) tool, which incorporates body anthropometrics and dietary intake, and the L3-psoas muscle index (L3-PMI) on CT, respectively. Individuals in the lowest quartile of L3-MPI were deemed sarcopenic.
Results: Of the study cohort, 32% were female, with a mean age of 53 (±11) years. 88% were listed for transplantation, while 56% received a liver graft. 20% of the study population died during the study period, which involved a mean follow-up of 183 (± 349) days. 94% of deaths were liver-related. The main liver disease aetiologies were alcohol (29.6%), viral hepatitis (29.6%), PSC (12.3%), NAFLD (7.9%), while hepatocellular carcinoma (HCC) was present in 28% cases. The Child-Pugh score A/B/C breakdown was 8%/46%/46% respectively, and the mean MELD score was 14 (±8). The RFH-GA indicated well-nourished in 35%, and mild/moderate or severe malnourishment in 40% and 25%, respectively. L3-PMI correlated significantly with body anthropometrics (eg. lean mass and dry weight), liver synthetic function (eg. Child Pugh), and RFH-GA (all p < 0.001). Both sarcopenia and RFH-GA were significant, independent predictors of mortality based on multivariate cox regression analysis of the overall cohort [hazard ratios of 1.96 (95% CI, 1.4-2.8, p < 0.001), and 1.6 (95% CI, 1.07-2.4, p = 0.02), respectively]. The combination with sarcopenia did not increase the predictive power of the MELD score for 3-month mortality.
Conclusion: This study demonstrates that poor nutritional status as indicated either by sarcopenia on imaging or by detailed nutritional assessment is a useful adjunct when evaluating patients with advanced liver disease. As this is a theoretically correctable condition, the optimisation of nutrition remains a key area for future study and novel therapeutic approaches for individuals with liver disease.

SAT-109

Spontaneous bacterial peritonitis: Will the diagnostic follow-up paracentesis be essential in approaching these patients?

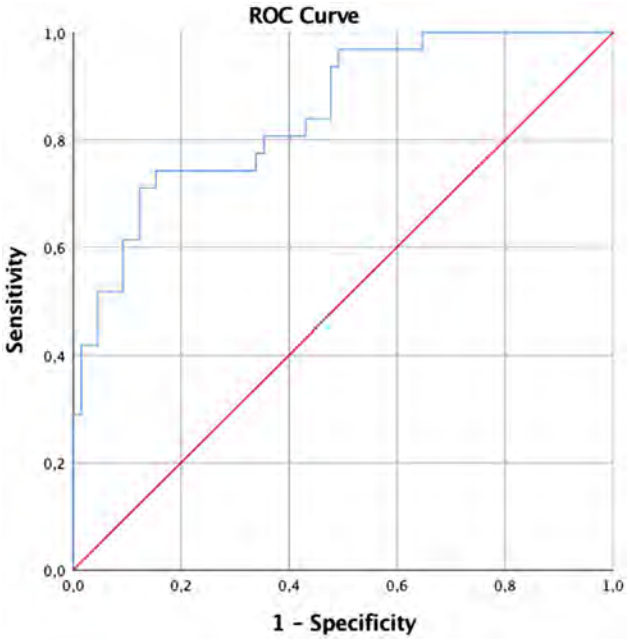
Ana Santos[1], Rosa Coelho[1], Marco Silva[1], Rui Gaspar[1], Hélder Cardoso[1], Guilherme Macedo[1]. [1]*Centro Hospitalar de São João, Porto, Portugal*
Email: anaasantos89@gmail.com

Background and aims: The European Guidelines advocate that, in cases of spontaneous bacterial peritonitis (SBP), another paracentesis should be performed to confirm the response to antibiotic therapy. Recent studies suggest that follow-up paracentesis, should only be performed if there is a clinical and/or analytic worsening. Our aims were to evaluate which patients with SBP benefit from the diagnostic follow-up paracentesis, according to clinical and analytical predictive factors of an inadequate response at the third day of treatment.

Method: Retrospective study conducted in a tertiary center, included the patients with SBP between January 2011 and June 2018. Clinical and analytical data was obtained at baseline and at the third day of antibiotic therapy. An adequate response to therapy, at the third day, was defined by a decrease of ≥ 25% in neutrophil count of the ascitic fluid.

Results: We included 103 cases of SBP (mean age of 61 ± 11 years; 78.6% men). Most patients (81.6%) had known ascites and 27.2% had a history of previous SBP. In 30.1% of cases the patients were under antibiotic prophylaxis for SBP. At the third day, 30.1% had an inadequate response to antibiotic therapy. At admission, the presence of diabetes mellitus (p = 0.034), a higher serum neutrophils count (p = 0.043), a lesser level of serum total proteins (p = 0.040) and a positive culture in ascitic fluid (p < 0.001) were related to inadequate response. At day 3, a higher level of serum urea (p = 0.018), creatinine (p = 0.030), CRP (p = 0.001), a higher count of serum leucocytes (p = 0.001) and neutrophyles (p = 0.001), the presence of fever (p = 0.047) and abdominal pain (p < 0.001) were associated to absence of response, too.

In the multivariate analysis, diabetes mellitus (OR = 5.33; 95% CI:1.24-22.96), positive ascitic fluid culture at admission (OR = 15.66; 95% CI:2.41-101.94), abdominal pain at day 3 (OR = 3.94; 95% CI:0.94-16.45; p < 0.06) and CRP at day 3 (OR = 1.02; 95% CI:1.00-1.03) were independently and significantly associated to inadequate response at the third day of empiric therapy. The predictive model presented good accuracy [AUROC of 0.85 (p < 0.001) (Fig. 1)]-a cutoff of 0.055 had a sensitivity, specificity, positive predictive value, and negative predictive value for absence of response to antibiotic of 100%, 35%, 42%, and 100%, respectively. With this model cutoff, 24% of repeated paracentesis could be precluded in our population sample.



Conclusion: These results evidence that, in approach of SBP, the performance of follow-up paracentesis, three days after the beginning of empiric therapy, should be individualized, according the conjugation of clinical and analytic variables. With our model a considerable number of unnecessary procedures may be avoided.

SAT-110

Impact of rifaximin monotherapy or rifamixin plus lactulose on markers of inflammation in patients with cirrhosis and a history of hepatic encephalopathy

Arun Sanyal[1], Zeev Heimanson[2], Steven Flamm[3]. [1]*Virginia Commonwealth University and McGuire VA Medical Center, Richmond, United States;* [2]*Salix Pharmaceuticals, Bridgewater, United States;* [3]*Northwestern Feinberg School of Medicine, Chicago, United States*
Email: arun.sanyal@vcuhealth.org

Background and aims: Systemic inflammation plays an important role in hepatic encephalopathy (HE) pathogenesis. Rifaximin, a nonsystemic antibiotic, may be used alone or in combination with lactulose for reducing the risk of overt HE recurrence in adults. This analysis evaluated impact of rifaximin alone or rifaximin plus lactulose (combo) on inflammatory markers in patients with history of overt HE.

Table: Median Inflammatory Marker Levels[a]

	Rifaximin Alone (n = 113)	Rifaximin + Lactulose (n = 108)
CRP		
Bsl, mg/L	2.6	3.7
EOT, mg/L	3.1	4.5
% change	20.4	38.5
IL-1beta		
Bsl, ng/L	17.2	26.6
EOT, ng/L	36.6	55.2
% change	20.4	21.3
IL-2		
Bsl, ng/L	57.0	65.5
EOT, ng/L	87.8	89.0
% change	48.7	118.4
IL-6		
Bsl, ng/L	13.7	12.8
EOT, ng/L	18.0	17.1
% change	24.2	24.4
IL-12		
Bsl, ng/L	9.1	9.0
EOT, ng/L	13.7	10.7
% change	-31.0	15.4
IL-13		
Bsl, ng/L	54.5	50.8
EOT, ng/L	56.4	54.0
% change	-12.8	-17.2
TNF-alpha		
Bsl, ng/L	35.5	33.0
EOT, ng/L	37.2	37.9
% change	38.5	28.1
Endotoxin		
Bsl, EU/ml	1.8	1.4
EOT, EU/ml	2.2	1.8
% change	7.7	14.8

[a]Statistical comparisons for differences between baseline to EOT not available for within treatment groups. Between-group differences from baseline to EOT levels for the inflammatory markers were not statistically significant (mean data [not shown]; p > 0.05).

Method: In a randomized, open-label trial, adults with cirrhosis with history of ≥ 1 overt HE episode during previous 6 months, currently in HE remission (Conn score ≤ 1), received rifaximin 550 mg twice daily (BID) or rifaximin 550 mg BID plus lactulose (titrated to 2-3 soft stools/d) for 24 wks. Blood samples were collected at baseline (bsl) and wks 4, 8, 12, 16, 20, and 24/end of treatment (EOT). Serum inflammatory markers (C-reactive protein [CRP], interleukins [IL-1beta, IL-2, IL-6, IL-12, and IL-13], tumor necrosis factor (TNF)-alpha, and endotoxin) were analyzed using a particle-based cytometric bead array immunoassay.

Results: 221 patients received rifaximin alone (n = 113) or rifaximin plus lactulose (n = 108); mean age was 58.1 vs 58.8 years and mean bsl Model End Stage Liver Disease score was 11.9 vs 11.8. Median bsl inflammation marker levels were comparable for rifaximin alone vs combo groups (**Table**). When assessed q 4 wks, change from bsl in each marker level was minimal for 2 groups, and between group-differences were not significant with the exception of IL-2 levels at wk 12 (rifaximin alone vs combo mean change: –76.7 vs 596.7 ng/L; p = 0.04). Bsl to EOT in inflammatory marker levels for rifaximin alone vs combo were not significantly different between 2 treatment groups (**Table**).
Conclusion: Low levels of inflammatory markers and no significant differences between the rifaximin alone and rifaximin plus lactulose groups suggest that rifaximin with or without lactulose has no deleterious impact on systemic inflammatory markers; the benefits of rifaximin may be independent of the status of systemic inflammation in this population cohort.

SAT-111

Procalcitonin level is a prognostic marker in patients with liver cirrhosis

Sho Sato[1], Shunsuke Sato[1], Hironori Tsuzura[1], Takuya Genda[1].
[1]*Juntendo University Shizuoka Hospital, Gastroenterology and Hepatology, Shizuoka, Japan*
Email: sho-sato@juntendo.ac.jp

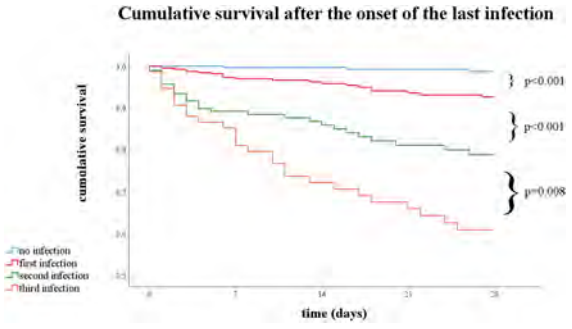
Background and aims: Bacterial infection is one of the critical complications of liver cirrhosis as well as gastrointestinal (GI) bleeding and refractory ascites. It leads not only to decompensation of liver cirrhosis and acute on chronic liver failure but also to multiple organ failure. Procalcitonin (PCT), a protein secreted in response to bacterial infection, has been widely used as a diagnostic marker of bacterial infection. The aim of this study was to investigate the association between serum PCT level and the prognosis of patients with liver cirrhosis.
Method: A total of 236 hospitalized patients with liver cirrhosis were retrospectively enrolled. Serum PCT levels were measured on admission using the Elecsys BRAHMS ® PCT automated immunoassay (Roche Diagnostics GmbH, Mannheim, Germany).
Results: Elevation of serum PCT level to ≥ 0.05 ng/ml was observed in 151 patients (64%) regardless of the focal bacterial infection. Serum PCT level showed significant differences according to the Child-Turcotte-Pugh (CTP) classification, cause of hospitalization, and etiology. Serum PCT level was significantly higher in the patient with CTP-C, admitted for refractory ascites, GI bleeding or infection, and with alcoholic liver cirrhosis. Next, we investigated prognostic factors by using the Cox proportional hazard model. During the median follow-up time of 2.1 years, the 3-year cumulative survival rate was 62.4%. In the multivariate analysis, serum PCT level (≥ 0.05 ng/ml) was an independent prognostic factor of liver cirrhosis (hazard ratio, 1.78; 95% confidence interval, 1.16-2.74; p = 0.009). The 3-year cumulative survival rates of the patients with normal and elevated serum PCT levels were 72.9% and 56.0%, respectively (p < 0.001). In the subgroup analyses, serum PCT level was significantly associated with the prognosis of the patients with liver cirrhosis who were stratified by age, CTP classification, and presence of liver cancer.
Conclusion: Elevation of serum PCT level was observed in patients with liver cirrhosis regardless of the presence of bacterial infections and was significantly associated with poor prognosis.

SAT-112

Each additional infection significantly increases mortality in patients with decompensated liver cirrhosis

Marie Schultalbers[1], Tammo Lambert Tergast[1], Abdul-Rahman Kabbani[1], Markus Kimmann[1], Hans Laser[2], Nicolas Simon[2], Michael P. Manns[1,3,4], Markus Cornberg[1,3,4], Benjamin Maasoumy[1,3]. [1]*Hannover Medical School, Gastroenterology, Hepatology and Endocrinology, Hannover, Germany;* [2]*Hannover Medical School, Centre for Information Management (ZIMt), Hannover, Germany;* [3]*German Centre for Infection Research (Deutsches Zentrum für Infektionsforschung DZIF), Partner-site Hannover-Braunschweig, Hannover, Germany;* [4]*Centre for Individualised Infection Medicine (CIIM), c/o CRC Hannover, Hannover, Germany*
Email: schultalbers.marie@mh-hannover.de

Background and aims: Bacterial infections are a hazardous complication in patients with liver cirrhosis. Mortality is four times increased. Moreover, patients with advanced liver cirrhosis suffer from an immune dysfunction that predisposes them for infectious complications. It is not uncommon that an individual patient develops several different infections during a single hospital stay. Here we aimed to investigate the impact of recurrent infectious episodes on mortality in patients with decompensated liver cirrhosis.
Method: Patients were recruited from the well-defined Hannover Ascites cohort. Overall, 669 consecutive patients with decompensated liver cirrhosis and ascites were eligible for the current analysis. Patients were followed up for the onset of bacterial or fungal infections from the time of hospital admission. Up to three infections were considered in each patient. 28-day mortality was calculated from the time of diagnosis of the last infectious episode. Multivariate Cox regression was performed including age, sex, MELD, platelets and the presence of esophageal varices to adjust for potential confounding factors.
Results: A number of 240 women (36%) and 429 men (64%) with a mean age of 56 years and median MELD of 17.5 were included. Only 224 (33%) individuals had no infection during the first 28 days of hospitalization. A single infection was diagnosed in 249 (37%) patients, 121 (18%) subjects developed a second infection and in 75 (11%) individuals at least a third infection was documented during follow-up. The most frequent infections were a spontaneous bacterial peritonitis and urinary tract infections. More than half of the patients (73%) developed the first infection within the first week after hospital admission. Following infections usually occurred shortly after the previous one (median 6-6.5 days). Each additional infection had a dramatic impact on mortality (Figure). The probability of a fatal outcome within the following 28 days increased significantly after each infection (first infection, Hazard Ratio; HR: 5.11; p = 0.009, second infection, HR: 20.90; p < 0.001; third infection, HR: 40.60; p < 0.001). In the multivariate analysis only MELD and the number of infections were associated with mortality.



Conclusion: In patients with decompensated liver cirrhosis mortality significantly increases after each additional infection. An adequate monitoring and preventive strategies are urgently required in this highly vulnerable group of patients.

SAT-113

Non-invasive assessment of HVPG with quantitative MRI measures of liver T1 and superior mesenteric artery velocity at 3T

Robert Scott[1], Christopher R Bradley[2], Eleanor F Cox[2], Naaventhan Palaniyappan[1], Gregory Ramjas[3], Peter Thurley[4], Neil Guha[1], Susan Francis[2], Guruprasad Aithal[1]. *[1]NIHR Nottingham Biomedical Research Centre, Nottingham University Hospitals NHS Trust and the University of Nottingham, Nottingham, United Kingdom; [2]Sir Peter Mansfield Imaging Centre, School of Physics and Astronomy at the University of Nottingham, Nottingham, United Kingdom; [3]Nottingham University Hospitals NHS Trust, Interventional Radiology, Nottingham, United Kingdom; [4]University Hospitals of Derby and Burton NHS Foundation Trust, Interventional Radiology, Derby, United Kingdom*
Email: guru.aithal@nottingham.ac.uk

Background and aims: The majority of complications in liver cirrhosis arise from portal hypertension. Hepatic Venous Pressure Gradient (HVPG) is the gold standard measure, but is invasive and restricted to a small number of expert centres. We have previously validated MRI as a surrogate measure of HVPG at 1.5T using longitudinal relaxation (T_1) relaxation time and haemodynamic flow. Here, we evaluate quantitative MRI measures at 3T against HVPG in a new cohort.

Method: 43 patients were prospectively recruited (22NAFLD/11ALD/10other, aged 59 (27-83) years, 27 male) after undergoing a HVPG measurement for clinical indications. MRI was performed after a mean of 41 (SD 17) days on a 3 T Philips Ingenia DDAS scanner.

MRI Protocol: T_1 of the liver and spleen was measured with a respiratory triggered inversion recovery fat-suppressed spin-echo EPI scheme (9 axial slices, 10 inversion times 100-1500 ms, 58 ms temporal slice spacing, acquired in ascending/descending, acquisition time ~3 minutes). Phase-contrast (PC)-MRI was used to assess velocity, area and bulk flow in the superior mesenteric artery (SMA).

Data Analysis: T_1 data at each inversion time was motion corrected, and then fit on a voxel-by-voxel basis to generate M_0 and T_1 maps (MATLAB, Mathworks). Histogram analysis assessed the distribution of T_1 within the liver, with the mode of the distribution used to represent tissue T_1 and FWHM to assess heterogeneity. Q-flow software (Philips Medical Systems) was used to analyse the PC-MRI data to compute mean vessel cross sectional area, velocity, and flux over the cardiac cycle.

Statistical Analysis: All data was tested for normality using Shapiro-Wilk's, a Pearson correlation was used for normally distributed data and a Spearman correlation test used for non-parametric data.

Results: 28/43 patients had cirrhosis on biopsy. HVPGs ranged from 2-23 mmHg. 29 patients had HVPG ≥ 6 mmHg, 16 ≥ 10 mmHg and 10 had oesophageal varices. HVPG significantly correlated with SE-EPI T_1 ($R = 0.75$, $p < 0.0001$) and SMA velocity ($R = 0.70$, $p = 0.02$), Figure 1A/B. Splenic T_1 correlated with HVPG ≤ 10mmHg ($R = 0.63$, $p = 0.029$), >10mmHg no significance was observed ($R = 0.07$, $p = 0.868$), Figure 1C.

Conclusion: We have shown that 3T liver tissue T_1 and SMA mean velocity show good correlation with degree of portal hypertension and may be used as a surrogate for HVPG. Splenic Tissue T_1 has strong correlation for portal pressure ≤ 10mmHg but is not accurate in clinically significant portal hypertension.

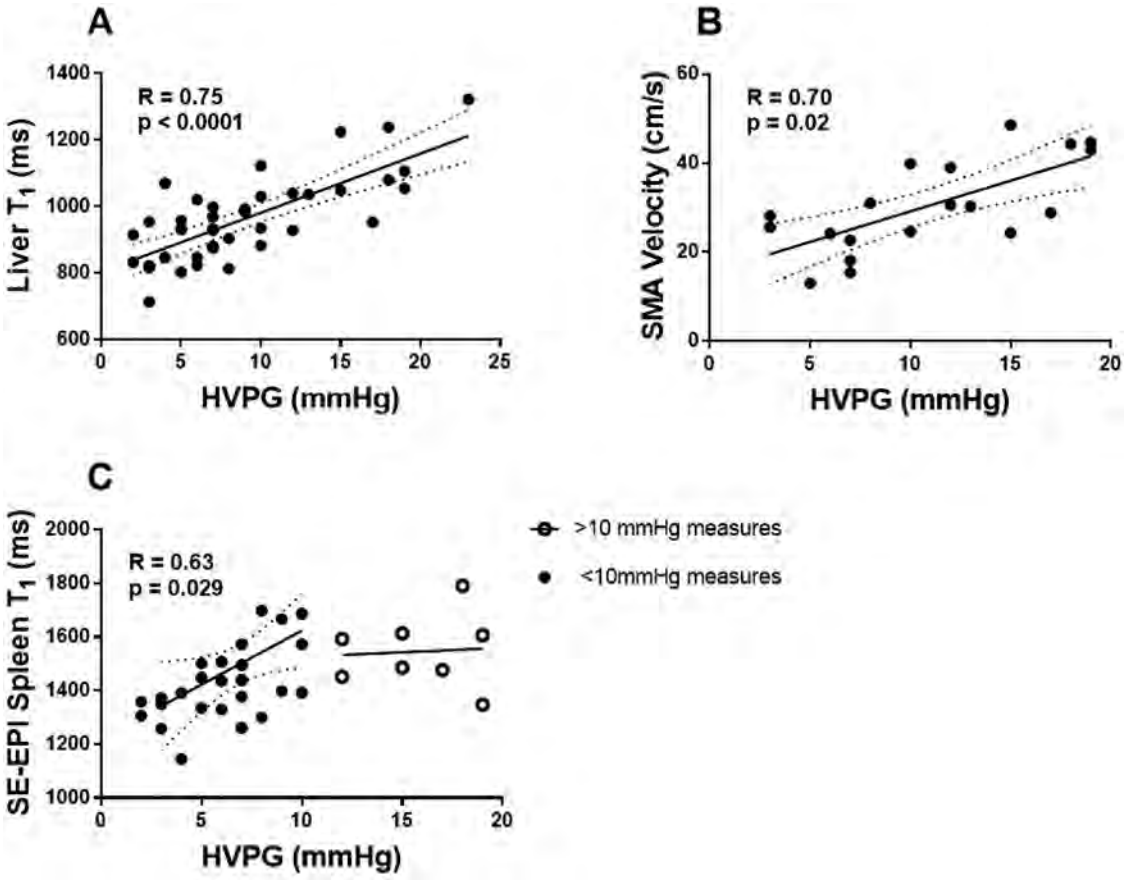


Figure: (abstract: SAT-113)

SAT-114

Impact of farnesoid X receptor polymorphisms on hepatic decompensation and mortality in cirrhotic patients with portal hypertension

Georg Semmler[1,2], Bernhard Scheiner[1,2], Benedikt Simbrunner[1,2], Philipp Schwabl[1,2], Rafael Paternostro[1,2], Theresa Bucsics[1,2], Albert Stättermayer[1], David JM Bauer[1], Matthias Pinter[1,2], Peter Ferenci[1], Michael Trauner[1], Mattias Mandorfer[1,2], Thomas Reiberger[1,2]. [1]*Medical University of Vienna, Department of Internal Medicine III, Division of Gastroenterology and Hepatology, Vienna, Austria;* [2]*Medical University of Vienna, Vienna Hepatic Hemodynamic Laboratory, Vienna, Austria*
Email: georg.semmler@meduniwien.ac.at

Background and aims: The nuclear farnesoid X receptor (FXR) regulates as key bile acid receptor critical pathways of metabolic and biliary homeostasis. FXR is involved in abnormal gut-liver axis signaling in advanced chronic liver disease (ACLD). However, the impact of FXR single nucleotide polymorphisms (SNPs) on portal hypertension-induced complications remains unknown. Thus, we investigated the association of FXR-SNPs with hepatic decompensation and transplant-free mortality in patients with portal hypertension.

Method: Two FXR-SNPs (*rs56163822* G > T, *rs35724* G > C) were genotyped in a cohort of 402 prospectively characterized patients with hepatic venous pressure gradient (HVPG) ≥ 6mmHg.

Results: While only 19 patients (4.7%) harbored a *rs56163822* T-allele, n = 267 (66.4%) patients had at least one minor *rs35724* allele (G/C or C/C). At the time of HVPG-measurement, *rs56163822* T-allele carriers had more pronounced liver disease (Child-Pugh-stage, CPS: 7 ± 2 vs. 6 ± 1 points; p = 0.034) and lower albumin levels (35.9 ± 5.9 vs. 38.9 ± 4.9 g/L; p = 0.026). In contrast, patients harboring at least one *rs35724* C-allele had less pronounced liver disease, as indicated by lower MELD (10 ± 3 vs. 11 ± 4 points, p = 0.016). Other baseline characteristics including the etiology of liver disease and HVPG were similar among FXR-SNP genotypes.

In CPS-A patients, the FXR *rs35724* minor allele was independently protective for the development of ascites (adjusted hazard ratio [aHR]: 0.411, 95% confidence interval (95%CI): 0.191-0.885, p = 0.023) and tended to reduce the risk of any hepatic decompensation (aHR: 0.625, 95%CI:0.374-1.044; p = 0.072) in multivariate analyses. Moreover, carrying the FXR *rs35724* minor allele was associated with reduced transplant-free mortality in CPS-A patients (aHR: 0.488, 95%CI: 0.252-0.946, p = 0.034) as well as in the overall cohort (aHR: 0.658, 95%CI: 0.434-0.998; p = 0.049).

In CPS-A patients, harboring the FXR *rs35724* minor allele tended to decrease transplant-free mortality in CPS-A patients (hazard ratio [HR]: 0.599, 95%CI: 0.319-1.127; p = 0.112; at 5 years: 82% vs. 69%). In female patients, this effect attained statistical significance (HR: 0.376, 95%CI: 0.148-0.959, p = 0.041; at 5 years: 83% vs. 56%).

Conclusion: The FXR *rs35724* C-allele seems to be protective for liver-related mortality in patients with ACLD. Prospective studies are needed to confirm the potential mechanism and independent prognostic value of the FXR *rs35724* genotype for hepatic decompensation and liver-related mortality.

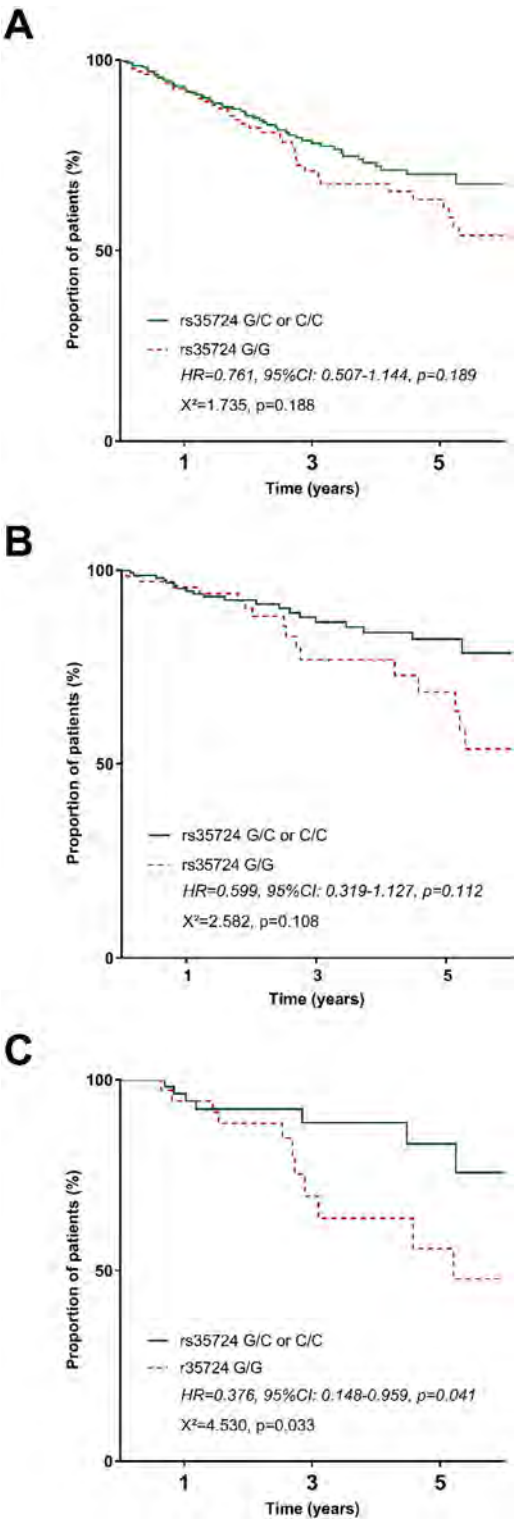

Figure: Kaplan-Meier analyses of transplant-free mortality in patients carrying FXR-SNP *rs35724* wildtype (G/G) or any minor alleles (G/C or C/C) in (**A**) the overall cohort, (**B**) compensated CPS-A patients and (**C**) female patients.

SAT-115

Fondaparinux vs low molecular weight heparin in the treatment of non malignant portal vein thrombosis in patients with cirrhosis

Marco Senzolo[1], Salvatore Piano[2], David Sacerdoti[2], Silvia Tonello[2], Alberto Zanetto[1], Marta Tonon[2], Paolo Simioni[3], Giancarlo Bombonato[2], Patrizia Burra[1], Paolo Angeli[2].
[1]Gastroenterology/Multivisceral Transplant Unit, Padua, Italy; [2]Unit of Internal Medicine and Hepatology, Department of Medicine DIMED, Padova, Italy; [3]Thrombotic Diseases Unit, Department of Medicine (DIMED), Padova, Italy
Email: martatonon11@gmail.com

Background and aims: Nonmalignant portal vein thrombosis (PVT) is a common complication of Cirrhosis. Treatment is advised in particular in liver transplant candidates with anticoagulation as first line option but the optimal anticoagulation's regimen and dose are still to be determined. Until now low molecular weight heparin (LMWH) or warfarin have been reported as treatments describing an efficacy of about 50%. Fondaparinux (FPX) is a factor Xa inhibitor which has been recommended for the treatment of deep vein thrombosis. In spite of its potential advantage due to the absence of induced thrombocytopenia, there are no data regarding the use of FPX in the treatment of nonmalignant PVT in patients with cirrhosis. The aim of our study was to compare FPX versus LMWH in terms of safety and efficacy in the treatment of PVT.
Method: Consecutive patients with non-malignant PVT treated with FPX or LMWH in university Hospital of Padua were retrospectively evaluated. The extension of PVT at baseline as well as its evolution on treatment were evaluated by both Doppler ultrasound and CT scan.
Results: 123 patients (69% male, mean age 59 ± 11 years) with cirrhosis and PVT were included. Main portal vein branch, splenic vein and mesenteric vein were involved in 84%, 13% and 36%, respectively. Forty patients (33%) were treated with FPX and eighty-two (67%) with LMWH. There was no difference between the 2 groups in terms of age, gender, CTP class, platelet count, extension of thrombosis and time occurred from diagnosis of PVT and the start of treatment. Patients treated with FPX had a significantly higher MELD-Na score than patients treated with LMWH (13 ± 4 vs 11 ± 3; p = 0.014). The probability of resolution of PVT at 36 months was significantly higher in patients treated with FPX than patients treated with LMWH (77% vs 51%; P = 0.002). When we adjusted the analysis for age, gender, severity, duration of PVT, and anticoagulant treatment dose (full dose vs prophylactic dose), the treatment with FPX was found to be an independent predictor of PVT resolution (HR = 0.45; P = 0.005) as well as a full anticoagulant dose (HR = 0.53; p = 0.026). There was no difference between the 2 groups in terms of incidence and severity of side effects and/or bleeding episodes. One patient treated with FPX and 3 patients in LMWH had a major bleeding episodes.
Conclusion: FPX seems to be more effective than LMWH in the treatment of PVT with a similar safety profile. Further studies should be performed to confirm these findings, in the meanwhile FPX can be considered among possible treatments of PVT.

SAT-116

Development and validation of a novel model for outcome in patients with cirrhosis and acute variceal bleeding

Gyanranjan Rout[1], Ramesh Kumar[2], Sanchit Sharma[1], Deepak Gunjan[1], Baibaswat Nayak[1], Shalimar[1]. *[1]All India Institute of Medical Sciences, Gastroenterology and Human Nutrition Unit, New Delhi, India; [2]All India Institute of Medical Sciences, Gastroenterology, Patna, India*
Email: drshalimar@yahoo.com

Background and aims: Acute variceal bleeding (AVB) in patients with cirrhosis is associated with high mortality, ranging from 17% to 24% at 6 weeks. The existing prognostic models for AVB lack precision and require further validation. In this prospective study, we developed and validated a new prognostic model for AVB, and compared it with the existing models.
Method: We included 285 patients from March 2017-November 2017 in the derivation cohort and 238 patients from December 2017-June 2018 in the validation cohort. Two prognostic models were developed from derivation cohort by logistic regression analysis. Discrimination was assessed using area under receiver operator characteristic curve (AUROC).
Results: The six week mortality was 22.1% in derivation cohort and 22.3% in validation cohort, P = 0.866. Model for end stage liver disease (MELD) (odds ratio [OR], 1.106) and encephalopathy (E) (OR, 4.658) in one analysis and Child-Pugh score (OR, 1.379) and serum creatinine (OR, 1.474) in another analysis were significantly associated with 6-week mortality. MELD-E model (AUROC 0.792) was superior to Child-creatinine model (AUROC) in terms of discrimination. The MELD-E model had highest AUROC; as compared to other models- MELD score (AUROC 0.751, P = 0.036), Child-Pugh score (AUROC 0.737, P = 0.037), D'Amico model (AUROC 0.716, P = 0.014) and Augustin model (AUROC 0.739, P = 0.018) in derivation cohort. In validation cohort, the discriminatory performance of MELD-E model (AUROC 0.805) was higher as compared to other models including MELD score (AUROC 0.771, P = 0.048), Child-Pugh score (AUROC 0.746, P = 0.011), Augustin model (AUROC 0.753, P = 0.039) and D'Amico model (AUROC 0.736, P = 0.021).
Conclusion: In cirrhotic patients with AVB, the novel MELD-Encephalopathy model predicts 6 weeks mortality with higher accuracy than the existing prognostic models.

SAT-117

Enhanced liver fibrosis score is an accurate non-invasive predictor of clinically significant and high-risk portal hypertension

Benedikt Simbrunner[1,2], Rodrig Marculescu[3], Philipp Schwabl[1,2], Bernhard Scheiner[1,2], Theresa Bucsics[1,2], Matthias Pinter[1,2], Alek Stadlmann[1], David JM Bauer[1,2], Mattias Mandorfer[1,2], Michael Trauner[1], Thomas Reiberger[1,2,4,5]. *[1]Medical University of Vienna, Dpt. of Internal Medicine III, Div. of Gastroenterology and Hepatology, Vienna, Austria; [2]Medical University of Vienna, Vienna Hepatic Hemodynamic Laboratory, Vienna, Austria; [3]Medical University of Vienna, Clinical Department of Laboratory Medicine, Vienna, Austria; [4]Ludwig Boltzmann Institute for Rare and Undiagnosed Diseases (LBI-RUD), Vienna, Austria; [5]Center for Molecular Medicine (CeMM), Austrian Academy of Science, Vienna, Austria*
Email: benedikt.simbrunner@meduniwien.ac.at

Background and aims: Diagnosis of clinically significant portal hypertension (CSPH) depends on invasive measurement of hepatic venous pressure gradient (HVPG). Enhanced liver fibrosis (ELF) score was developed as a non-invasive test for liver fibrosis. Limited data on the correlation of ELF with portal pressure is available. Thus, we investigated (i) the correlation of ELF with HVPG, and the diagnostic accuracy of ELF for (ii) CSPH (i.e. HVPG ≥ 10mmHg) and (iii) high-risk portal hypertension (HRPH, i.e. HVPG ≥ 20mmHg).
Methods: ELF and HVPG were assessed within the prospective VICIS study. Patients with pre- or posthepatic portal hypertension, liver malignancy, previous transplantation, and non-cirrhotic portal hypertension were excluded.
Results: Among 187 patients (mean age 56.3 ± 0.9 years, 66.8% male), alcoholic liver disease (ALD, n = 63, 33.7%)) and viral hepatitis (n = 55, 29.4%) were the main etiologies. Child-Pugh stage (CPS) was CPS-A in 112 (59.9%), CPS-B in 52 (27.8%), and CPS-C in 23 (12.3%) cases.
Mean HVPG was 15.6 ± 0.5 mmHg, CSPH and HRPH were diagnosed in 146 (78.1%) and 57 (30.5%) patients. Median ELF was 11.2 (IQR 10.2-12.4) and 161 (86.1%) patients had ELF ≥ 9.8 indicating advanced fibrosis.
ELF significantly correlated with HVPG in the overall cohort (r = 0.485; p < 0.001). Area Under the Receiver Operating Characteristic Curve (AUROC) of ELF to detect CSPH was 0.76 in the overall cohort, while ELF-AUROC to diagnose CSPH was better in ALD (0.97) than in

patients with viral hepatitis (0.67). Importantly, CSPH could be ruled-out in ALD by ELF < 10.1 (sensitivity 96.6%) and in viral hepatitis by ELF < 9.0 (sensitivity 91.9%).
Among HCV patients who achieved SVR (n = 35), ELF was not able to identify patients with persistence of CSPH after SVR (AUROC: 0.69; p = 0.079).
ELF-AUROC for non-invasive diagnosis of HRPH was 0.73, while ELF-AUROC to diagnose HRPH was better in viral hepatitis (0.77) than in patients with ALD (0.66). HRPH could be ruled-in in ALD by ELF > 14.7 (specificity 97.0%) and in viral hepatitis by ELF > 12.7 (specificity 95.8%).
Conclusions: ELF correlates with HVPG and is an accurate non-invasive screening tool for CSPH in patients with advanced chronic liver disease of different etiologies. CSPH may be ruled-out in ALD patients by ELF < 10.1 and in viral hepatitis by ELF < 9.0. Importantly, ELF > 14.7 in ALD and ELF > 12.7 in viral hepatitis is highly suggestive of HRPH and may be used to triage patients to transjugular intrahepatic portosystemic shunt (TIPS).

SAT-118

Estimating proportion of cirrhosis and hepatocellular carcinoma attributable to hepatitis B and C in clinical centres in Sofia (Bulgaria) and Lisbon (Portugal): Results from a European pilot

Marieta Simonova[1], Otilia Mardh[2], Erika Duffell[2], Chantal Quinten[2], Slava Pavlova[1], Carolina Simões[3], Tanja Hadzhiolova[1], Krum Katzarov[1], Helena Cortez-Pinto[3]. [1]*Military Medical Academy, Department of Gastroenterology, HPB and Transplant Surgery, Sofia, Bulgaria;* [2]*European Centre for Disease Prevention and Control, Stockholm, Sweden;* [3]*Universidade de Lisboa, Departamento de Gastrenterologia, CHLN, Laboratório de Nutrição, Faculdade de Medicina, Lisboa, Portugal*
Email: simonova_m@yahoo.co.uk

Background and aims: WHO set target to reduce mortality attributable to hepatitis B (HBV) and hepatitis C (HCV) by 65% by 2030. While national mortality data from cirrhosis (CIR) and hepatocellular carcinoma (HCC) exist, proportion of cases due to HBV and/or HCV are unknown. A study protocol was developed to calculate the attributable fraction of HBV, HCV and other risk factors for CIR and HCC in a standardised way and piloted in Sofia (Bulgaria) and Lisbon (Portugal).
Method: All patients presenting with CIR and/or HCC at the national reference centre in Sofia during 2016-2017 and the first 100 sequential patients with CIR and 100 with HCC presenting at national reference centre in Lisbon during 2015-2016 were included. Cases with CIR and HCC were identified based on ICD-10 codes in Sofia and on clinical criteria in Lisbon. Patients diagnosed with both CIR and HCC were classified as HCC. HBsAg and anti-HCV positivity were considered markers for chronic HBV and HCV, respectively. When markers for both HBV and HCV were present, HCV-RNA existence defined the case as being attributable to HCV. When viral markers were absent, excessive alcohol consumption (> 30 grs/day) or non-alcoholic-fatty liver disease (NAFLD) were considered main risk factors for CIR or HCC.
Results: Data for 518 CIR, 84 HCC cases were collected in Sofia and 100 CIR and 100 HCC in Lisbon. 70% of CIR and 80% of HCC cases in Sofia and 78% of CIR and 82% of HCC in Lisbon were males. 38% of CIR, 68% of HCC in Sofia and 53% of CIR and 71% of CIR in Lisbon were ≥ 60 years. In both sites, distribution of CIR and HCC cases did not differ by gender ($p_{Sofia} = 0.07$, $p_{Lisbon} = 0.48$) but patients with HCC were significantly older ($p_{Sofia} = 0.00$, $p_{Lisbon} = 0.03$). In Sofia the main risk factors for CIR were: alcohol 46%, HBV 18%, HCV 16% and NAFLD 4% and for HCC: HBV 37%, HCV 25%, alcohol 8%, NAFLD 8%. In Lisbon main risk factors for CIR were: alcohol 56%, HCV 25%, HBV 6%, NAFLD 6% and for HCC: alcohol 46%, HCV 37%, HBV 9%, NAFLD 3%. Considerable overlap between risk factors was observed (Fig1).
Conclusion: Viral hepatitis B and C were important risk factors for liver morbidity in both centres. The pilot demonstrated the feasibility of collecting data on viral hepatitis prevalence that can be used to estimate mortality attributable to HBV and HCV for monitoring elimination. Further consideration should be given to representativeness of samples collected from reference centres, assessment of cases with overlapping risk factors, data collection simplification.

Figure 1. Overlap of positivity for HBsAg,antiHCV and excessive alcohol consumption among cirrhosis and hepatocellular carcinoma cases included in the pilot

SAT-119

Comparison of liver frailty index at admission and 30 days after discharge from hospital in patients with advanced chronic liver disease

Lubomir Skladany[1], Tomáš Koller[2], Janka Vnencakova[1], Zuzana Drotarova[1]. *[1]F.D.Roosevelt University Hospital of Slovak Medical University, HEGITO of Dept Internal Medicine 2, Banská Bystrica, Slovakia; [2]University Hospital Bratislava Ruzinov of Komensky University, Internal Medicine 5, Bratislava, Slovakia*
Email: lubomir.skladany@gmail.com

Background and aims: Liver frailty index (LFI)-objective, reproducible and easy-to-use diagnostic tool for frailty, has been shown to predict (independently of MELD) outcome in outpts awaiting liver transplantation (LTx), and admitted to hospital with ACLD. To date, evolution of LFI after discharge from hospital has not been studied.
Aim: To determine LFI 1 month (M) after discharge in pts admitted to hospital with ACLD.
Method: Frailty-HEGITO-7 is a prospective observational study at the Liver Unit with small-volume LTx program. *Inclusion interval:* June 2017-February 2018. *Inclusion criteria:* admission with ACLD; age > 18y. *Exclusion criteria:* Extrahepatic malignancy, HCC > Milan, LTx or death or lost to follow-up (LFU) < 1M after discharge. Apart from standard evaluations for ACLD, all pts underwent testing for frailty by measuring LFI using internet calculator[3] at admission (LFI-A) and M1 after discharge (LFI-M1); their difference (ΔLFI-M1). At discharge, all pts received structured verbal and written (graphical) nutritional and exercise counselling by dedicated nurse.
Results: Enrolled and measured for baseline LFI were 200 pts, excluded 111 (due to: in-hospital and 1M mortality 14 and 24, LTx < M1 3, and LFU 70, respectively). Of 99 analyzed pts **at baseline**, median age was 58.9 years, females 33%, alcoholic liver disease 77%, MELD 14.5, **LFI 4.25, 34.7% were frail**. **At M1,** MELD was 14.7 (ns), **LFI 4.3 (ns), 24.5% were frail** (p = 0.06). Median **ΔLFI-M1** was –0.7% (p = 0.1). At M1, of 32 frail pts at baseline 15 (48.5%) improved to pre-frail, 17 stayed frail; of 63 prefrail pts at baseline 6 (9.7%) worsened to frail and 57 stayed prefrail; of 4 robust, 1 stayed, 2 became prefrail and 1 frail. Overall, of patients surviving 30 days 16% improved, 13% worsened, and 76% did not change their frailty status, respectively.
Conclusion: One month after discharge from hospital with lifestyle counselling, one in four pts changed frailty status-62.5% (15/24) for the better; LFI improved (albeit not significantly). This pilot study shows that frailty can be improved. Predictive factors, measures needed and prognostic impact of change in frailty status deserve further study.

SAT-120

Influence of previous acute decompensation and organ failure on the long-term prognosis in cirrhotic patients with decompensation

Do Seon Song[1], Tae Yeob Kim[2], Eileen L Yoon[3], Jin Mo Yang[1], Hee Yeon Kim[1], Chang Wook Kim[1], Young Kul Jung[4], Hyung Joon Yim[4], Soung Won Jeong[5], sang gyune kim[5], Jae Young Jang[5], Moon Young Kim[6], Dong Hyun Sinn[7], KI TAE Suk[8], Dong Joon Kim[8]. *[1]The Catholic University of Korea, Seoul, Korea, Rep. of South; [2]Leeheart Medical Clinic, Seoul, Korea, Rep. of South; [3]Inje University Sanggye Paik Hospital, Seoul, Korea, Rep. of South; [4]Korea University Ansan Hospital, Ansan, Korea, Rep. of South; [5]Soonchunhyang University College of Medicine, Seoul, Korea, Rep. of South; [6]Yonsei university, Wonju, Korea, Rep. of South; [7]Samsung Medical Center, Seoul, Korea, Rep. of South; [8]Hallym University, Chuncheon, Korea, Rep. of South*
Email: dsman@catholic.ac.kr

Background and aims: To investigate long-term mortality according to the experience and time of previous acute decompensation (AD) and severity of organ failure in cirrhotic patients with AD
Method: A total of 1252 cirrhotic patients (male 943, alcohol 808, mean age 56.2 years) with AD were prospectively followed up. AD was defined as: acute development of overt ascites, hepatic encephalopathy, gastrointestinal bleeding, and infection. Organ failure was defined according to the chronic liver failure-sequential organ failure assessment (CLIF-SOFA). We determined subgroups using CLIF-SOFA scores as follows: high CLIF-SOFA (≧7) and low CLIF-SOFA (< 7).
Results: During follow-up duration (14.9 ± 10.6 months), long-term survival rate in the high CLIF-SOFA were significantly lower than those in the low CLIF-SOFA (149/319 vs 725/933, P < 0.001). Also, in 1009 patients who survived from for more than 3 months following AD (long-term survivors), the difference in long-term survival rates between groups was significant (p < 0.001). The presence of previous AD negatively affected long-term survival in two groups (low CLIF-SOFA, 82.6% vs 73.0%, P < 0.001; high CLIF-SOFA, 54.6% vs 40.4%, P = 0.041), and these findings also showed significant difference in long-term survivors (low CLIF-SOFA, 85.1% vs 75.1%, P < 0.001; high CLIF-SOFA, 80.5% vs 64.0%, P = 0.004). In total patients, patients with AD within 1 year showed a significantly lower survival rates than those without AD and with AD more than 1 year prior, although no significant difference was seen between patients with AD more than 1 year prior and without AD in two groups (low CLIF-SOFA, 82.6%, 79.0%, 65.9%, P < 0.001; high CLIF-SOFA, 54.6%, 50.7%, 33.0%, P = 0.003). However, in long-term survivors with high CLIF-SOFA, patients with AD within 1 year and with AD more than 1 year prior showed a significantly lower survival rates than those without AD (60.0% and 67.3% vs 80.5%, P = 0.004 vs P = 0.021, respectively)
Conclusion: Long-term prognosis was related to the degree of organ failure and previous AD. Especially, in long-term survivors with AD, previous AD was associated with high mortality regardless of the time of previous AD. It is necessary to decide the proper treatment policy.

SAT-121

Predicting sarcopenia in patients with cirrhosis based on clinical and laboratory parameters using machine learning

Guido Stirnimann[1,2], Maryam Ebady[1], Bret Hoehn[3], Isabela Bertoli De Simone[4], Vera C. Mazurak[4], Russ Greiner[3], Puneeta Tandon[1], Aldo J. Montano-Loza[1]. *[1]University of Alberta Hospital, Division of Gastroenterology and Liver Unit, Edmonton, Canada; [2]University Hospital Inselspital and University of Bern, University Clinic for Visceral Surgery and Medicine, Bern, Switzerland; [3]University of Alberta, Computing Science, Edmonton, Canada; [4]University of Alberta, Nutritional Science, Edmonton, Canada*
Email: guido.stirnimann@insel.ch

Background and aims: In patients with cirrhosis, sarcopenia is associated with further complications and a reduced probability of survival. Gold standard for the diagnosis of sarcopenia is cross-sectional muscularity analysis. However, this requires access to CT or MR imaging technology, a specialized image analysis software and trained staff. The aim of this study was to develop a machine learning (ML) tool to identify patients with cirrhosis who are at risk for sarcopenia prior to radiological work-up.
Method: For the development of the ML tool, we used data of patients with cirrhosis who were assessed for liver transplantation between 2000 and 2014 in a tertiary care University Centre. As part of the transplant assessment, each patient had a routine CT analysis to assess muscularity at the level L3 with SliceOmatic V4.3 (Tomovision, Canada). Within the database, patients are described using the following features: age, aetiology of liver cirrhosis, hepatic encephalopathy (HE), BMI, albumin, bilirubin, INR, WBC, platelets, neutrophils, lymphocytes, platelets-lymphocytes-ratio (PLR), neutrophils-lymphocytes-ratio (NLR), C-reactive protein (CRP), ferritin, testosterone, triglycerides, homocysteine and vitamin D. Features were tested for log-normality and transformed if suitable. We considered various different ML algorithms and evaluated each using 5-fold cross-validation.
Results: Overall, 603 patients were included in this analysis (68% male; mean age 57 ± 8 [SD] years). Our cross-sectional image analysis

found 201 patients were sarcopenic (76% male), and 402 (63% male) were not. Aetiology of liver disease was hepatitis C (40%), followed by NASH (23%), alcohol (22%), autoimmune liver disease (8%) and hepatitis B (6%). Mean MELD score was 14.3 ± 7.7 (SD). The ML model was developed using the following features: BMI, gender, HE, alcoholic liver disease, PLR, NLR and CRP. A logistic regression model with cost-sensitive training (weight 1 for non-sarcopenic patients, weight 2.5 for sarcopenic patients) was identified as the best tool to predict sarcopenia in this patient population. The AUC of the model was 0.772 (95% CI 0.760-0.784), resulting in a sensitivity of 79.6% (95% CI 77.0-82.2) and a specificity of 66.2% (95% CI 61.9-70.5) for sarcopenia detection.
Conclusion: A ML classifier can accurately identify whether patients with cirrhosis have sarcopenia, based only on standard and easily accessible clinical and laboratory features.

SAT-122
Cirrhotic cardiomyopathy: An observational study pre-liver transplant
Mohsan Subhani[1], Katie Ramos[1], Louisa Vine[1], Matthew Cramp[1].
[1]*Derriford Hospital, Plymouth, United Kingdom*
Email: subhani@doctors.org.uk

Background and aims: Cirrhotic cardiomyopathy (CCM) is a form of cardiac dysfunction observed in patients with liver cirrhosis and can arise at any cirrhosis stage. However we still lack data on the prevalence of the problem and its implications pre and post-liver transplant. We conducted a retrospective analytical observational study at a regional pre-transplant assessment centre to explore the burden of disease in our population.
Methods: We reviewed patient records, transthoracic echocardiography results (ECHO), and cardiopulmonary exercise test (CPET) results of all patients who underwent liver transplant for chronic liver disease between 2014–2017. Cirrhotic cardiomyopathy was defined as systolic dysfunction or impaired diastolic relaxation using both Montreal criteria (2005) and British Society of Echocardiography (Echo) guidelines and correlated to CPET findings. Data was collected and analysed by using a tabulated database (Microsoft Excel 14.7.7) and SPSS.
Results: A total of 81 patients were identified (51 male). Mean age was 56 years (median 58, range 23-70). The commonest aetiologies were alcoholic liver disease (27%), HCV with or without HCC (20%) and NASH with or without HCC (15%). On Echo criteria evidence of cirrhotic cardiomyopathy was identified in 34 (42%) patients, including diastolic dysfunction (DDF) in 32 and reduced resting ejection fraction in 2. Other findings included isolated dilated left atrium in 9 (11%), isolated dilated left ventricle in 7 (8%) and intra pulmonary shunting in 4 (5%) patients. All patients underwent CPET with median V02 max of 17.8 (range 8.6-32) and anaerobic threshold (AT) median of 11.3 (range 6.4-21.1). In those with cirrhotic cardiomyopathy the VO2 max and AT were lower than in those without, (median 16 vs 18.5 ($p < 0.01$) and median 11 vs 12 ($p < 0.01$) respectively). We found no significant correlation between severity of liver disease (Child Pugh, MELD) and presence of cirrhotic cardiomyopathy.
Conclusions: Our study demonstrated that a significant proportion of transplanted patients have evidence of cirrhotic cardiomyopathy as assessed by echo. Cirrhotic cardiomyopathy was associated with impaired performance on CPET. This lends further support to the need for detailed study of the impact of cirrhotic cardiomyopathy on patient outcomes, both pre- and post- liver transplant. We also plan to undertake careful repeat analysis (ECHO) of patients post-liver transplant to assess for improvement in this common problem.

SAT-123
Serum Mac-2 binding protein glycosylation isomer and handgrip strength correlate with serum myostatin level in chronic liver disease
Tomoyuki Suehiro[1], Yuki Kugiyama[1], Shigemune Bekki[1], Satoru Hashimoto[1], Akira Saeki[1], Shinya Nagaoka[1], Seigou Abiru[1], Kazumi Yamasaki[1], Atsumasa Komori[1], Hiroshi Yatsuhashi[1]. [1]*Clinical Research Center National Hospital Organization Nagasaki Medical Center, Omura city, Japan*
Email: chuntomo0902@gmail.com

Background and aims: Myostatin belongs to transforming growth factor β (TGF-β) family which has been reported as a key mediator of fibrosis in several organs, and negatively works for differentiation of skeletal muscle cells. In vivo, TGF-β/Myostatin pathway activity associated with muscle fibrosis and atrophy. Furthermore, recent study showed higher myostatin level in liver cirrhosis associated with unfavorable outcome, however, the precise mechanism between high myostatin level and poor prognosis in chronic liver disease is still unknown. The aim of our study is to elucidate the correlation between serum myostatin level and clinical parameters, especially Serum Mac-2 binding protein glycosylation isomer (M2BPGi) which we reported as predictor of liver fibrosis and hepatocellular carcinoma in previous study.
Method: This study was approved by Clinical Research committee in our hospital. 162 patients with chronic liver disease and 20 healthy control were enrolled, and serum myostatin level was calculated by ELISA method (GDF-8/Myostatin Quintikine® ELISA kit). We measured handgrip strength which has been reported to correlate with skeletal muscle function.
Results: 91 female patients and 71 male patients were included with a median age of 66 years. 53 patients were diagnosed liver cirrhosis. Serum myostatin level was 4780 pg/ml (1306-24815) in patient group, 4329 pg/ml (2438-16952) in healthy control group, respectively ($p = 0.2987$). For the female patients serum myostatin level was 4663 pg/ml (1306-22330), on the other hand, 4943 pg/ml (2188-24815) for male patients ($p = 0.9129$).The median myostatin level for Child grade B or C patients ($n = 17$) was 17213 pg/ml (3504-24815), for Child grade A patients ($n = 145$) was 4628 pg/ml (1306-18939) ($p = 0.0041$). Serum myostatin level significantly correlated with body mass index ($r = 0.1845$, $P = 0.0188$), albumin ($r = -0.432$, $P < 0.0001$), prothrombin time ($r = -0.4533$, $P < 0.0001$), total bilirubin ($r = 0.4243$, $P < 0.0001$), platelets ($r = -0.3461$, $P < 0.0001$), Child Pugh score ($r = 0.5464$, $P < 0.0001$), and M2BPGi ($r = 0.615$, $P < 0.0001$). In addition, handgrip strength significantly negatively correlated with myostatin level in female patients ($r = -0.218$, $P = 0.036$). Multiple regression analysis in patients revealed handgrip strength ($p = 0.0187$), body mass index ($p = 0.0265$), Child Pugh score ($p = 0.0281$), and M2BPGi ($p = 0.0019$) were independent factors associated with serum myostatin level.
Conclusion: Increased serum myostatin level reflected deteriorated liver function in previous report, and our study revealed similar results in the relationship between myostatin level and liver function. In addition, we presented M2BPGi and handgrip strength significantly correlated with myostatin level. These interesting results imply high myostatin level in liver disease mirror sarcopenia, severe liver fibrosis and potential of hepatocarcinogenesis.

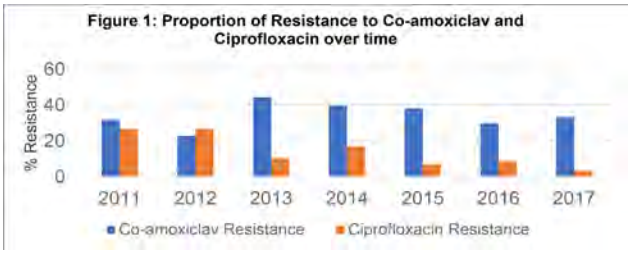
SAT-124
Microbiological culture yield from ascitic fluid and changing antimicrobial sensitivities over time
Rachael Swann[1], Susan Mcfaul[1], Sharon Irvine[1], Diarrmid Sutherland[2], Ewan Forrest[1]. [1]*NHS Greater Glasgow and Clyde, Glasgow, United Kingdom;* [2]*NHS Lanarkshire, Hairmyres Hospital, East Kilbryde, United Kingdom*
Email: rswann@nhs.net

Background and aims: Diagnostic paracentesis is recommended for all ascitic patients to diagnose spontaneous bacterial peritonitis

(SBP). The majority of ascitic fluid cultures do not grow an organism although yield may be improved by inoculating blood culture bottles. Therefore empirical treatment based on fluid white cell count (WCC) is recommended but bacterial resistance to first line antibiotics is a concern. Our aim was to investigate the causative organisms in patients with SBP and antibiotic resistance in our region over a period of seven years.

Method: Microbiology laboratory databases within Greater Glasgow Health Board were searched for all ascitic fluid samples from January 2014 to December 2017. Samples from non-cirrhotic ascites were excluded. These data were combined with an existing database on samples from North Glasgow from January 2011 to December 2013. Data on organisms cultured and proportions of antibiotic resistance when tested were collated and analysed.

Results: In total 9790 ascitic fluid samples were identified. Organisms were cultured in 1249 samples, 302 were identified as commensals leaving 947 of all samples (9.6%) with potentially pathogenic organisms. In those samples where WCC was available, WCC > 250/mm^3 had a sensitivity of 0.5 and specificity of 0.91 for culture positive ascites, whereas WCC > 500/mm^3 gave a sensitivity of 0.41 and specificity of 0.95. The most common pathogens cultured were Gram Negative Bacilli (52.4%; mainly Escherichia coli) followed by Entercoccus sp (12.3%), Streptococcus sp (10.7%) and Staphylococcus sp (8.3%). Resistance to co-amoxiclav was 34.5% (26% for gram negatives), ciprofloxacin 12.4% (12%), Tazocin 8, 2 (8.4%) Amoxicillin and Temocillin 6.4% (3.6%). Co-amoxiclav resistant organisms were also resistant to Tazocin in 24.4%, Ciprofloxacin in 18.9% and Temocillin in 7.8% of cases. Bacterial sensitivities over time are shown (Figure 1).



Conclusion: Only a minority of ascitic fluid samples will culture pathogens. Fluid WCC has high specificity but low sensitivity for pathogenic bacterial culture. Gram Negative Bacilli remain the most common organisms cultured. These show substantial rates of Co-Amoxiclav resistance, consistent over the 7 year period. However, a combination of Amoxicillin and Temocillin has relatively little resistance. Increasing sensitivity to quinolone antibiotics suggest antibiotic stewardship policies may be effective in reducing prevalence of resistant bacteria.

SAT-125

Animal naming test is simple and reliable for diagnosis of minimal hepatic encephalopathy and prediction of development of overt hepatic encephalopathy in patients with cirrhosis

Sunil Taneja[1], Ankit Agarwal[2], madhu chopra[1], Ajay Duseja[1], Radha Krishan Dhiman[1]. [1]*Post Graduate Institute of Medical Education and Research, Chandigarh, Hepatology, Chandigarh, India;* [2]*Post Graduate Institute of Medical Education and Research, Chandigarh, Internal Medicine, Chandigarh, India*
Email: drsuniltaneja@hotmail.com

Background and aims: Minimal hepatic encephalopathy (MHE) is the mildest form in the spectrum of hepatic encephalopathy that impairs health-related quality of life. PHES remains the gold standard for the diagnosis of this condition. Animal naming test (ANT) is reliable and sensitive tool for diagnosis of MHE and can also predict overt episodes of HE. We compared usefulness of PHES and ANT for the diagnosis of MHE and for the prediction of the development of overt episodes of HE.

Method: Between July 2017 to June 2018, one hundred and three consecutive patients with liver cirrhosis without overt HE were subjected to PHES and ANT evaluation. MHE was diagnosed when the PHES was ≤ -5. Receiver-operating characteristic (ROC) curve was used to determine the optimum cut-off of ANT value for the diagnosis of MHE. The best sensitivity and specificity was found at < 14. Patients were followed-up every 3-6 months till October 2018.

Results: Thirty-seven (35.9%) patients had MHE as assessed by altered PHES. ANT (< 14) was present in 36 (34.95%) patients with MHE with sensitivity of 89.19% and specificity of 95.7%, PPV of 91.67%, NPV of 94.03% and diagnostic accuracy of 93.20%. The area under the curve for diagnosis of MHE was 0.978 (95% CI 0.954-1.0). MHE patients had significantly lower ANT as compared to non MHE patients and controls (10.81 ± 0.324 vs 15.27 ± 0.147 vs 15.78 ± 0.192, respectively, $P = 0.01$). MHE patients had lower hand grip strength compared to non-MHE patients and the control group (Males: 26 vs 30 vs 38, Females 25 vs 28 vs 28, p > 0.05). PHES significantly correlated with Child-Pugh (r = -0.421, $P = 0.001$) and model for end-stage liver disease (MELD) (r = -0.345, P = 0.001) scores. ANT correlated with PHES (r = 0.752, P = 0.001) and also with Child-Pugh (r = -0.408, P = 0.001) and MELD (r = -0.318, P = 0.001) scores. During follow-up, 14 patients in MHE group and 4 in non-MHE group developed overt episodes of HE (p = 0.001). Out of 37 patients with abnormal PHES 14 patients developed overt HE on follow-up and out of 36 patients with abnormal ANT 14 patients developed overt HE on follow-up. 33 patients had both PHES and ANT abnormal. 4 patients had PHES abnormal and ANT normal. 3 patients had PHES normal and ANT abnormal.

Conclusion: ANT is a simple and reliable test for the diagnosis of MHE and prediction of overt episodes of HE in patients of cirrhosis as compared to PHES and correlates well with the Child-Pugh and MELD scores.

SAT-126

Minimal hepatic encephalopathy: Proper diagnosis for a better quality of life

Vlad Taru[1], Mina Ignat[1], Madalina Indre[1], Antonella Forgione[1], Oana Nicoara-Farcau[2], Petra Fischer[2], Horia Stefanescu[2], Zeno Sparchez[3], Marcel Tantau[3], Bogdan Procopet[2]. Fodor", 3rd Medical Clinic, Hepatology Department, Cluj-Napoca, Romania*
Email: bogdanprocopet@gmail.com

Background and aims: Minimal hepatic encephalopathy (MHE), may affect up to 80% of cirrhotic patients. Despite the limitations in relation with age and education, currently, MHE is diagnosed using psychometric tests. Other diagnostic tools, as Critical Flicker Frequency (CFF) and STROOP test are promising alternatives to the psychometric tests but lack extensive validation. The aim of this study was to compare CFF with STROOP test in diagnosing MHE and to assess the impact of MHE on the quality of life of patients with liver cirrhosis.

Method: 85 consecutive cirrhotic patients admitted to our centre were included. None of the patients showed clinical signs of overt hepatic encephalopathy at examination. All subjects underwent a battery of five psychometric tests, CFF, STROOP and the chronic liver disease questionnaire (CLDQ). Performances of the diagnostic tests were measured calculating the ROC curves. The diagnosis of MHE was established with PHES score using the Spanish norms (http://www.redeh.org/phesapp/datosE.html). The CLDQ assessed 6 domains and

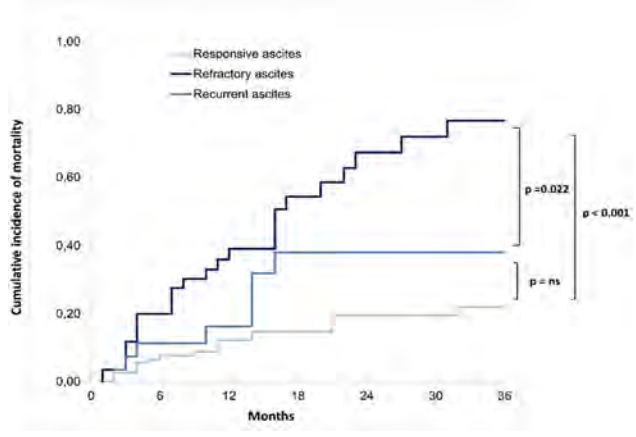
the overall QoL of the patients with a score ranging from 1 (very poor) to 7 (very good).
Results: Out of the 85 cirrhotic patients, 52 (61.2%) were compensated without any previous decompensation (subgroup 1) and 33 (38.8%) with previous or present decompensation, evaluated for TIPS insertion (subgroup 2). Twenty-nine (34.1%) patients presented MHE, of whom 15 (28.8%) in subgroup 1 and 14 (48.3%) in subgroup 2. Overall Stroop test has AUROC of 0.76 (95%CI: 0.65-0.86) ($p < 0.001$) and for CFF of 0.59 (95%CI: 0.45-0.72), $p = 0.2$. Stroop test has the best performance in subgroup 1 achieving 0.87 (95%CI: 0.77-0.96), $p < 0.001$ and the best cut-off value of 240 seconds (Se = 92.3%; Sp = 77.8%). Patients with MHE in comparison with those without MHE had significantly lower CLDQ in the overall score [4.55 (3.55-5.34) vs. 5.24 (4.79-5.93), respectively, $p < 0.01$] and in the following domains: abdominal symptoms [4.33 (2.67-6.67) vs. 6.00 (4.33-6.67), respectively p < 0, 05], systemic symptoms [4.20 (3.80-5.80) vs. 5.40 (4.40-6.00), respectively $p < 0.05$] and activity [4.00 (3.00-6.00) vs 5.67 (4.67-6.67), respectively $p < 0.01$].
Conclusion: Stroop test is superior to CFF in diagnosing MHE in compensated patients with liver cirrhosis. Patients with MHE experience a decrease in the quality of life, signalling the need of proper diagnosis and treatment of this condition.

SAT-127

The clinical course of recurrent versus refractory ascites in outpatients with cirrhosis

Marta Tonon[1], Salvatore Piano[1], Carmine Gambino[1], Eleonora Bertoli[1], Andrea Martini[1], Alessandra Brocca[1], Marco Di Pascoli[1], Silvano Fasolato[1], Patrizia Pontisso[1], Paolo Angeli[1]. [1]*Unit of Internal Medicine and Hepatology (UIMH), Department of Medicine DIMED, Padova, Italy*
Email: martatonon11@gmail.com

Background and aims: Refractory ascites has been defined by the International Club of Ascites (ICA) as an ascites that recurs early (within 4 weeks) after large volume paracentesis (LVP) and that cannot be prevented by medical therapy. Refractory ascites has a well known negative impact on mid-term survival. Recurrent ascites was defined by the ICA as an ascites that recurs at least 3 times within 12-month. However, its impact on survival is still unknown. The aim of the study was to assess the mid term-survival in outpatients with refractory, recurrent or responsive ascites.



Method: 199 consecutive patients with ascites attending our outpatient clinic from March 2008 were included in the study. Refractory ascites was defined according to the ICA criteria. For the purpose of the study, recurrent ascites was defined as above plus the need of at least 3 LVPs within 12 months with a time interval between LVPs > 4 weeks. Patients without refractory or recurrent ascites where defined as patients with responsive ascites. Clinical and laboratory data were collected at inclusion in the study. Patients were followed up until death, liver transplant (LT) or 36 months. LT was considered a competing event for mortality.
Results: Refractory ascites, recurrent ascites and responsive ascites were found in 56 (28%), 28 (14%) and 115 (58%) patients, respectively. No difference was found in MELD score among the 3 groups. During the 36-month follow-up, 52 patients died and 28 were transplanted. The 36-month cumulative incidence of mortality was significantly higher in patients with refractory ascites than in those with recurrent or responsive ascites (76.7%, 38.1% and 22%, respectively; $p < 0.001$ for the comparison between refractory and responsive ascites and $p = 0.02$ for the comparison between refractory and recurrent ascites), while no significant difference was found between those with recurrent ascites and those with responsive ascites. In multivariate analysis, age (sHR = 1.07; $p < 0.001$), MELD score (sHR = 1.17; $p < 0.001$) and refractory ascites (sHR = 3.88; $p < 0.001$) were found to be independent predictors of 36-month mortality.
Conclusion: Patients with refractory ascites have a significant worse prognosis than those with recurrent ascites, which in turns had similar outcomes than those with responsive ascites. These findings have relevant implications in clinical practice, when patients with ascites are considered for invasive procedures for the management of ascites, such as TIPS, or evaluated for priority in the LT waiting list.

SAT-128

The natural history of acute kidney disease in patients with cirrhosis

Marta Tonon[1], Salvatore Piano[1], Silvia Rosi[1], Carmine Gambino[1], Andrea Martini[1], Elia Vettore[1], Sara Mareso[1], Eleonora Bertoli[1], Antonietta Sticca[1], Paolo Angeli[1]. [1]*Unit of Internal Medicine and Hepatology (UIMH), Department of Medicine, University of Padova, Padova, Italy*
Email: martatonon11@gmail.com

Background and aims: The International Club of Ascites (ICA) in its consensus document has adapted the KDIGO criteria for the diagnosis of Acute kidney Injury (AKI) in patients with cirrhosis. AKI was defined as an absolute increase in serum creatinine (sCr) $\geq$ 0.3 mg/dl in 48 hours or an increase of sCr $\geq$ 50% during the last 3 months. As a consequence, the KDIGO criteria for the diagnosis of AKD should be also adapted in these patients by considering only: a) a Glomerular Filtration Rate (GFR) < 60 ml/min or b) a decrease of GFR $\geq$ 35% for less than 3 months. While it is well proven that AKD has an impact on mortality in the general population, there are no data in cirrhotic patients. The aim of the study was to assess the prevalence, the clinical course of AKD and its impact on mortality in patients with cirrhosis.
Method: 324 consecutive patients were included in the study. AKI and AKD were diagnosed according to ICA guidelines while Chronic Kidney disease (CKD) was defined according to KDIGO definition (a GFR < 60 ml/min for $\geq$ 3 months). Clinical and laboratory data were collected at inclusion in the study. Patients were followed up until death, liver transplant or for a maximum period of 5 years.
Results: At inclusion, 53 patients (16.2%) had already developed CKD. During the follow-up, 113 patients (34.9%) developed AKD, 15 among those with previous CKD and 98 among those with normal GFR. AKI preceded AKD in 21.2% of the cases. Twenty-eight patients with AKD (24.8%) developed AKI during or after the resolution of AKD, and 15 of them (53.6%) died. In 13 patients AKD (11.5%) then evolved to CKD (11.5%). In 53% of patients AKD was transient. The 5-year incidence of mortality was significantly higher in patients who developed AKD than in those who did not (61.7% and 15.4%, respectively) (Fig.1A) while no difference was found comparing patients who developed only AKD with those who developed AKD and AKI, CKD or AKD and CKD (Fig. 1B). In multivariate analysis, age (HR = 1.03; $p = 0.002$), GFR at inclusion (HR = 0.98; $p = 0.001$) and sCr $\geq$ 1.5 mg/dl (HR = 5.41; $p = 0.03$) were found to be independent predictors of AKD, while age (HR = 1.05; $p < 0.001$), CTP score (HR = 1.30; $p < 0.001$), and

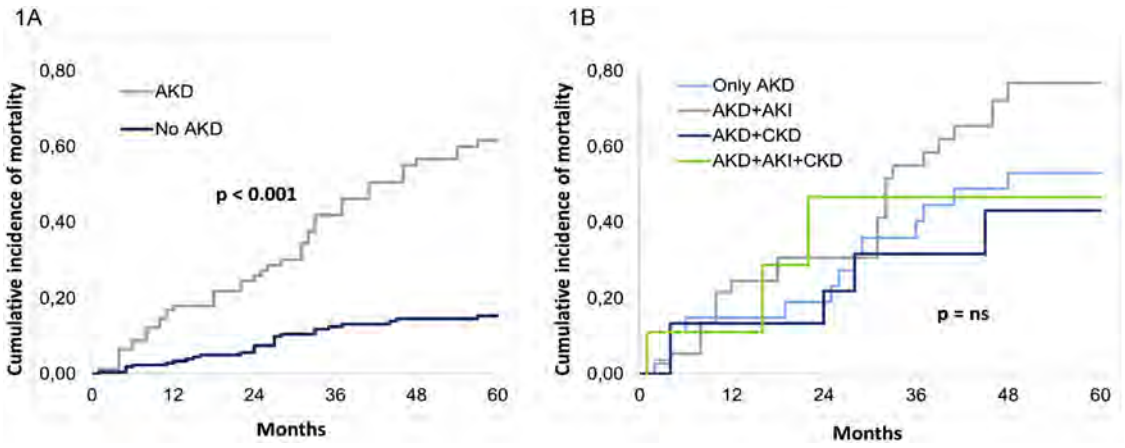


Figure: (abstract: SAT-128)

the development of AKD (HR = 3.27; p < 0.001) were found to be independent predictors of 5-years mortality.
Conclusion: AKD is a common type of renal impairment in patients with cirrhosis. The development of AKD increases the mortality in patients with cirrhosis independently from its clinical evolution.

SAT-129

Type 2 diabetes in patients with liver cirrhosis: prevalence, associated factors and influence on survival

Maria Torner[1], Ana Gomez[1], Carmen Álvarez-Navascués[1], Valle Cadahía-Rodrigo[1], Maria Varela[1], Maria Luisa Gonzalez Dieguez[1], Carlos Rodríguez[1], Manuel Rodríguez[1]. *[1]Hospital Universitario Central De Asturias, Gastroenterology and Hepatology, Oviedo, Spain*
Email: mariatrnrsm@gmail.com

Background and aims: The presence of type 2 diabetes (DM) in patients with cirrhosis is frequent and the relationship between both is complex. Objective: to know the prevalence of DM and the factors associated with its presence in a series of patients with cirrhosis and analyze its influence on survival.
Method: 1456 patients with cirrhosis included in a HCC surveillance program were analysed and followed prospectively. Patients with cirrhosis due to NASH and those with ascites in the initial evaluation were not included. The majority were males (76%), with a median age of 54 years, Child-A (84%), 67% had esophageal varices and 42% had presented a previous episode of decompensation. Etiology: alcohol (49%), HCV (41%), HBV (7%) and autoimmune/cholestasis (3%). The diagnosis of the DM at the inclusion was established based on the presence of two glycemia values ≥ 126 mg/dl or anti-diabetic treatment.
Results: The prevalence of DM was 21.4%. In the univariate analysis, the presence of DM was associated with advanced age (p < 0.001), alcoholic aetiology (p < 0.001), BMI ≥ 30 (p = 0.004), GGT > LSN (p = 0.031), presence of varices (p = 0.027) and previous decompensation (p = 0.003). In the multivariate study, the only variables associated with DM were the age > 60 years (HR, 95% CI: 2.27, 1.57-3.29); BMI ≥ 30 (HR, 95% CI: 1.58, 1.09-2.30) and GGT > LSN (HR, 95% CI: 1.43, 1.02-2.00). During a median follow-up of 48 months (24-96), 546 patients died (406 without DM and 140 with DM). Survival at 5, 10 and 20 years was 78.9%, 43.9% and 31.7% in patients without DM and 74.5%, 36.8% and 20.5% in those with DM (p = 0.11). In the multivariate analysis, the variables that were associated with worse survival were: age > 60 years (HR, 95% CI: 1.83, 1.40-2.38), BMI < 25 (HR, 95% CI: 1.48, 1.14-1.92), AST > LSN (HR, IC95%: 1.54, 1.20-1.98), albumin ≤ 35 g/L (HR, IC95%: 1.46, 1.12-1.91), platelets < 125 × 10^3/mm3 (HR, IC95%: 1.55, 1.24-1.94) and previous decompensation (HR, IC95%: 1.76, 1.35-2.30). In contrast, cirrhosis due to HBV was associated with lower mortality (HR, 95% CI 0.53, 0.33-0.86). After adjustment with other variables, the presence of DM was not associated with higher mortality (HR, 95% CI: 1.11, 0.88-1.39).
Conclusion: 20% of patients with liver cirrhosis have DM in the initial evaluation and their presence is not related to the etiology of the disease. Although in the univariate analysis the presence of DM was associated with more advanced liver disease, the association disappeared after adjustment with other variables. The only variables independently associated with the presence of DM were age, BMI and high GGT. It is possible that the association with elevated GGT is a consequence of the coexistence of a component of NASH in the etiology of cirrhosis. Finally, the presence of DM does not decrease survival in patients with cirrhosis.

SAT-130

Incidence and outcome of portal vein thrombosis in 817 HBV and HCV compensated cirrhotic patients under antiviral treatment: a single center longitudinal study

Giulia Tosetti[1], Alessandro Loglio[1], Elisabetta Degasperi[1], Roberta D'Ambrosio[1], Mauro Viganò[2], Massimo Iavarone[1], Marta Borghi[1], Roberta Soffredini[1], Floriana Facchetti[1], Maria Grazia Rumi[2], Massimo Primignani[1], Pietro Lampertico[1]. *[1]C.R.C. "A.M. and A. Migliavacca Center for Liver Disease Fondazione IRCCS Ca' Granda Maggiore Hospital, University of Milan, Division of Gastroenterology and Hepatology, Milan, Italy; [2]San Giuseppe Hospital, Hepatology, Milan, Italy*
Email: giulia.tosetti@policlinico.mi.it

Background and aims: Long-term NUCs-treatment in HBV and direct-acting antivirals (DAAs) treatment in HCV improve cirrhosis outcomes, however portal vein thrombosis (PVT) risk is still undefined. We evaluated incidence and predictors of PVT in a large cohort of viral cirrhotics treated with antivirals.
Method: 817 cirrhotic patients without PVT were consecutively enrolled in a cohort longitudinal study: 260 caucasian HBV-monoinfected compensated cirrhotics starting TDF or ETV and 557 HCV CPT A-B cirrhotics consecutively receiving DAAs at a single center. Patients underwent regular blood tests, 6-month abdominal imaging and esophageal varices (EV) screening. PVT was graded according to Yerdel classification.
Results: 260 HBV-monoinfected cirrhotics were consecutively enrolled: median age 61 (21-83) years, 81% males, 88% HBeAg negative, PLT 153 (32-304) x10^9/L, spleen diameter 11 (7-20) cm, liver stiffness 8.8 (3-75) kPa, 13% with esophageal varices (EV) and 4 previously decompensated (1.5%), 59% NUCs-experienced. During 103 (16-138) months of study period 9 (3.5%) patients developed non-neoplastic PVT after 58 (23-92) months, with an 8-year cumulative probability of 3%. At multivariable analysis, only previous

decompensation (HR 16, 95%CI 2-113, p = 0.005) and EV at baseline (HR 27, 95%CI 5-136, p < 0.001) predicted PVT. PVT was associated with "de novo" ascites in only one patient and with HCC development in 5 patients (56%), but it did not never display any radiological features of neoplastic thrombosis throughout the entire follow-up.
557 HCV DAA treated cirrhotics were studied: median age 64 (28-87) years, 60% males, 83% CPT A, platelet count (PLT) was 118 (26-753) × 10^3/ml, spleen size 13 (7-24) cm, liver stiffness 17.0 (12.1-75.0) kPa, 32% had baseline EV. During 33 (1-47) months of follow-up, 10 (1.8%) patients developed PVT, with a 3-year cumulative probability of 2%. PVT patients were CPT B (50%), all had EV at baseline (small varices in 2, primary prophylaxis in 5, secondary in 3). PVT were Yerdel grade 1 in 5 patients, grade 2 in 3, grade 3 and 4 in 1 patient each. PVT was associated with HCC development in 2 patients, but none was due to tumor vascular invasion. PVT resulted in de novo or worsening of ascites in 4 (40%) patients, while it was asymptomatic in 6 (60%). At PVT diagnosis, EV worsened compared to baseline in 3 (30%) patients but no GI bleeding occurred. Baseline predictors of PVT reflected disease severity (CPT, MELD, bilirubin, albumin) and portal hypertension (EV, PLT). The 3-year cumulative probability of PVT was 5.2% vs 0% in patients with or without baseline EV, respectively (p = 0.002).
Conclusion: Among HBV NUC-suppressed and HCV treated with DAAs cirrhotics, non-neoplastic PVT is a rare complication, partial in most cases, but strongly associated with severity of liver disease at baseline. In HCV patients, PVT occurrence may cause clinical decompensation.

SAT-131

The impact of sustained virological response on the criteria used to rule out high risk esophageal varices in HCV-related compensated advanced chronic liver disease

Giulia Tosetti[1], Pietro Soru[1], Vincenzo La Mura[1,2], Elisabetta Degasperi[1], Roberta D'Ambrosio[1], Elena Arsie[1], Marta Borghi[1], Roberta Soffredini[1], Massimo Primignani[1], Pietro Lampertico[1]. *[1]C.R.C. "A.M. and A. Migliavacca Center for Liver Disease Fondazione IRCCS Ca' Granda Maggiore Hospital, University of Milan, Division of Gastroenterology and Hepatology, Milan, Italy; [2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Università degli Studi di Milano, Medicina Generale Emostasi e Trombosi, Milan, Italy*
Email: giulia.tosetti@policlinico.mi.it

Background and aims: The Baveno VI criteria [platelet count (plt) > 150 × 10^9/l and liver stiffness measurement (LSM) < 20KPa] to rule out high risk esophageal varices (HRV) in chronic advanced viral-related liver disease (cACLD) perform efficiently in viremic patients. Further refinements of the Baveno VI criteria [Expanded Baveno VI criteria (Plt110/LSM25), or Plt125/LSM25 criteria] maintain high accuracy and spare more endoscopies. The Plt150/MELD6 criteria are less accurate in viremic cACLD patients. How sustained virological response (SVR) achieved by DAAs impacts on such criteria is unknown. We assessed the performance of Expanded Baveno VI, Plt125/LSM25 and PLT150/MELD6 criteria, as compared to the original Baveno VI criteria, to rule out HRV in 192 HCV-related cACLD patients with an SVR to DAAs.
Method: 192 consecutive cACLD patients undergoing regular endoscopic follow-up according to international guidelines (Baveno VI) were retrospectively evaluated. LSM, assessed by transient elastography, and plt closest to the follow-up endoscopy were considered.
Results: Out of 192 cACLD patients with an SVR, 8 (4%) had HRV after a median follow-up of 18 (0-36) from SVR achievement. All of them were identified by the original Baveno VI criteria, with 43 (22%) sparing endoscopies. The Plt125/LSM25 criteria maintained the same accuracy, sparing a significant amount of endoscopies (n = 73, 38%; p < 0.001 compared to Baveno VI). By converse, the Expanded Baveno VI criteria, while sparing 86 (45%) endoscopies, missed one (12.5%) out of 8 HRV patients. The Plt150/MELD6 score correctly identified all 8 SVR patients with HRV, sparing 76 (40%) endoscopies (p < 0.001 compared to Baveno VI criteria).
Conclusion: The Plt125/LSM25 and the Platelet150/MELD 6 score are useful tools to rule out HRV in HCV-related cACLD with an SVR to DAAs, sparing significantly more endoscopies than the original Baveno VI criteria, without losing accuracy. Conversely, the expanded Baveno VI criteria (Plt110/LSM25), although most effective in viremic cACLD patients, are less effective in SVR cACLD patients.

SAT-132

Incidence and prognostic factors of de novo development/worsening of esophageal varices in HCV-related compensated advanced chronic liver disease after sustained virological response achieved by direct antiviral agents

Giulia Tosetti[1], Pietro Soru[1], Vincenzo La Mura[1,2], Elisabetta Degasperi[1], Roberta D'Ambrosio[1], Elena Arsie[1], Roberta Soffredini[1], Marta Borghi[1], Massimo Primignani[1], Pietro Lampertico[1]. *[1]CRC "A.M. and A. Background and aims: The development/worsening of esophageal varices (EV) is reduced but not abolished by sustained virological response (SVR) in HCV-compensated advanced chronic liver disease (cALD). Baveno VI suggest performing endoscopy two- or three-years after SVR in patients with small EV or without EV at baseline but the level of evidence is low. Aim: We retrospectively evaluated incidence and predictive factors of "de novo" development/worsening of EV in 163 consecutive HCV-cACLD patients undergoing EV-surveillance according to Baveno VI.
Method: 258 HCV-related cACLD patients achieving SVR (January 2015- March 2017). Ninety-five were excluded (53 large EV at baseline, 29 incomplete data, 9 non-SVR, 4 lost to follow-up). Overall, 163 patients were evaluated: median age 63 years (39-86), males 57%, median BMI 26 (16-40), obese 15%, previous HCC 10%. Median time between SVR and follow-up endoscopy: 18 months (range:0-36).
Results: Thirty-eight of 163 patients (23%) had small, low-risk at baseline, which progressed to large EV in 6 patients. Among 125 patients without EV at baseline, 17 developed small EV and 108 remained without EV. Overall, 23 patients (14%) had EV appearance/progression and 130 patients (80%) did not change (108 patients without baseline EV and 22 with small EV). Baseline variables associated with EV appearance/progression were obesity, spleen-diameter, platelet, LSPS, albumin and diabetes. Variables at SVR12 associated with EV appearance/progression were ALT, GGT and platelet. Multivariable analysis, performed separately for baseline and SVR12 variables, identified LSPS at baseline (OR 1.207, 95% CI 1.032-1.412, p = 0.019), and GGT (OR 1.026, 95% CI 1.009-1.043, p = 0.003) and platelet-count at SVR12 (OR 1.013, 95% IC 1.002-1.026, p = 0.026) as the variables associated with EV appearance/progression. Finally, we tested an algorithm to rule-out endoscopic surveillance by combining LSPS < 1.326 and GGT < 25 (i.e. the cut-offs with sensitivity > 0.9 at the AUROC). "Low risk" patients for the algorithm were 83 (51%), thus entitling them for avoiding endoscopy. However, 3 patients (1 with small-EV and 2 with large-EV) would have been misclassified (2% of the series) with a 87% sensitivity.
Conclusion: De novo development/worsening of EV occurs in 14% of cACLD patients after SVR. An algorithm including LSPS at baseline and GGT at SVR 12 could halve the number of endoscopies with a misclassification rate for large-EV < 5%.

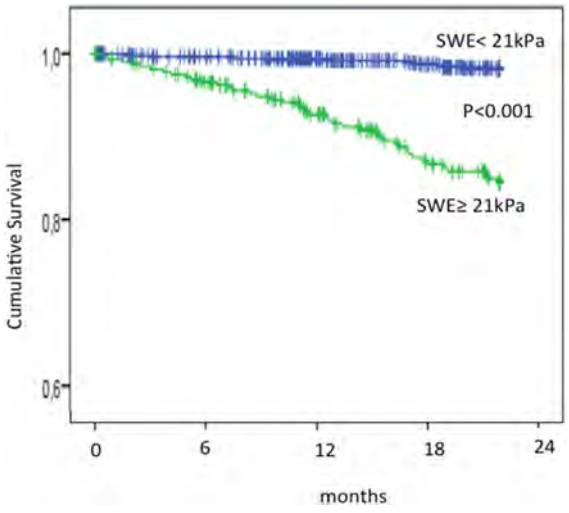
Email: jonel.trebicka@kgu.de

Background and aims: Measurement of liver stiffness is an established technique to assess significant fibrosis in patients with chronic liver disease. Moreover, it might be a useful surrogate marker to diagnose or rule out clinically significant portal hypertension. However, the value of 2-dimensional shear wave elastography (2D-SWE) to predict mortality in cirrhotic patients is unknown. The aim of this multicentre retrospective study was to assess the value of 2D-SWE using Aixplorer to predict mortality in chronic liver disease patients.
Method: Inclusion criteria were presence of chronic liver disease, valid 2D-SWE at baseline, no previous events of decompensation at baseline and at least one year of clinical follow-up after the index 2D-SWE measurement. Clinical and laboratory parameters were assessed at baseline. The primary outcome was overall mortality. For the selection of cutoff values, receiver operating characteristics (ROC) analysis with survival as end point was calculated. Kaplan-Meier curves were used to compare the survival rates of patients using the log-rank test. Univariate time-to-event analysis and multivariate Cox regression analysis was performed to identify independent predictors of survival.



Results: 2062 patients from 16 centres were screened and 1170 patients fulfilled the inclusion criteria and were included in the analysis with a median follow-up of 31.5 months. The median age of the population was 54 (range: 18-83) years, with 63% male patients. The main aetiology was viral hepatitis (38%), while 23% suffered from chronic alcoholic liver disease. The median liver 2D-SWE was 11kPa (range: 1-155). The AUC of SWE for mortality within 24 months was 0.81 (CI: 0.76-0.85) with the best Cut-off of 21 kPa (sensitivity 70%, specificity 80%). In univariate analysis age, MELD, creatinine, bilirubin, albumin, platelets, AST and SWE > 21kPa were significantly associated with overall mortality. In the cox-regression multivariate analysis SWE > 21kPa was independently associated with over all mortality (HR: 3.75 (2.13-6.61)), besides albumin (HR: 0.90 (0.87-0.93)) and age (HR: 1.06 (1.04-1.09).
Conclusion: This study shows for the first time that liver stiffness measured by 2D-SWE predicts mortality in patients with chronic liver disease. 2D-SWE of more than 21kPa might be helpful to stratify risk and guide patient management. NCT03389152

SAT-134

Hypercoagulopathy risk factors in liver cirrhosis due to non-alcoholic steatohepatitis and clinical manifestations of hypercoagulation during 5 years

Nataliya Virstyuk[1], Nataliya Matkovska[2], Iryna Vakalyuk[3], Mykola Bagriy[4], Oleg Virstyuk[5]. *[1]Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine; [2]Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine; [3]Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine; [4]Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine; [5]Ivano-Frankivsk Central Clinical Hospital, Ivano-Frankivsk, Ukraine*
Email: virstyukn@gmail.com

Background and aims: Characteristics and predictive effects of coagulation profile in liver cirrhosis (LC) with non-alcoholic steato-hepatitis (NASH) are now debated. The purpose of the work was to determine the risk factors of hypercoagulation in NASH LC patients and clinical manifestations of hypercoagulation during 5 years of observation.
Method: We analyzed 66 patients (ps) with NASH LC (11 females/55 males; age, 45.8 ± 5.7 yr; body mass index (BMI), 33.5 ± 2.8 kg/m^2): 24 ps with Child-Pugh class A (group I), 22 ps with Child-Pugh class B (group II), 20 ps with Child-Pugh class C (group III). The results were compared with those of 20 healthy volunteers. Biochemical, ultrasound, endoscopic, histological examination and elastography has been carried out. Circulating insulin, tumor necrosis factor alpha (TNFα), factor VIII (FVIII), von Willebrand factor (vWF), antithrombin III (AT III), protein C, platelet-endothelial cell adhesion molecule-1, (PECAM-1), P-selectin, plasminogen activator inhibitor-1 (PAI-1), thrombin activatable fibrinolysis inhibitor (TAFI) were measured by the immuno-assay method.
Results: Hypercoagulopathy was detected in 41.7% of ps in group I, 72.7%-of ps in II group and 80.0%-of ps in group III; hypocoagulopathy-in 4.54% of ps with II group and 20.0% of ps with III group. In ps with NASH LC a statistically significant increase of FVIII (p = 0.009) and vWF (p = 0.003), PECAM-1 (p = 0.002), P-selectin (p = 0.003), PAI-1 (p = 0.001) and TAFI (p = 0.006) and decrease of AT III (p = 0.006), protein C (p = 0.001) vs. group IV were found. The direct correlations between vWF and Child-Pugh score, low density lipoprotein cholesterol (LDLC), TNFα, HOMA-IR, PAI-1, PECAM-1, P-selectin (r = 0, 5643; r = 0, 6438; r = 0, 7251; r = 0, 5924; r = 0, 7903; r = 0, 6257; r = 0, 6588; accordantly; p < 0, 001) and indirect correlations between FVIII and AT III, protein C (r = -0, 7015; r = 0, 8226; accordantly; p < 0, 001) were installed.
During 5 years of follow-up, in group I were clinical manifestations of hypercoagulation: 1 (4.2%) myocardial infarction (MI), 2 (8.3%)-acute coronary syndrome (ACS), 1 (4.2%)-ischemic stroke (IS), 3 (12.5%)-common carotid artery (CCA) stenosis > 50%, 1 (4.2%)- > 70%; group II-1 (4.5%), 3 (13.6%), 3 (13.6%), 5 (22.7%), 2 (9.1%) accordantly, 2 (9.1%)-

died by cardiovascular diseases; group III-2 (8.3%)-ACS, 1 (4.2%)-IS, 7 (35.0%)-died by cardiovascular diseases, 9 (45.0%)-died by decompensation of LC.
Conclusion: In NASH LC ps are mostly hypercoagulopathic; risk factors are an increase of Child-Pugh score, dyslipidemia, inflammation, insulin resistance, an increase in procoagulant and endothelial factors, antifibrinolytic activity and a decrease in AT III, protein C. In NASH LC clinical manifestations of hypercoagulation were MI, ACS, IS and death by cardiovascular diseases.

SAT-135

Splenomegaly status does not impact the efficacy of avatrombopag in increasing platelet counts and reducing platelet transfusions or rescue procedures for bleeding in chronic liver disease patients with thrombocytopenia

Amir Qamar[1], kavita aggarwal[2], Michael Vredenburg[2], Wei Tian[2], Lee F Allen[2]. [1]*Lahey Clinic, Burlington, United States;* [2]*Dova Pharmaceuticals, Durham, United States*
Email: mvredenburg@dova.com

Background and aims: Thrombocytopenia (TCP) is common in patients with CLD, increasing in severity with worsening liver disease. The clinical care of these patients requires multiple invasive procedures each of which carries a bleeding risk. Avatrombopag (**AVA**) is a thrombopoietin receptor agonist FDA-approved as an alternative to platelet transfusions (PT) for patients with TCP and CLD undergoing a procedure. The aim of this study was to assess whether splenomegaly (SM) affected efficacy.
Method: Two randomized, double-blind, placebo (**PBO**)-controlled Phase 3 trials (**ADAPT-1** and **ADAPT-2**) enrolled 435 adults with CLD and platelet counts (PC) < 50 × 10^9/L undergoing a procedure. Patients were divided by Baseline PC into **Cohort 1**- PC < 40 × 10^9/L and **Cohort 2**- PC 40 to < 50 × 10^9/L, and randomized 2:1 to once-daily oral **AVA** (60 mg or 40 mg, respectively) or **PBO** for 5 days, with the procedure done 5 to 8 days after the last dose. The primary efficacy end point in both studies was the proportion of patients not requiring a PT or rescue procedure, and the first secondary end point was the proportion of patients achieving a PC ≥ 50 × 10^9/L on Procedure Day. Patients with SM were identified at Baseline by investigators and designated with a status of 'yes' or 'no'.

	COHORT 1 (< 40 × 10^9/L) N = 251		**COHORT 2** (< 50 × 10^9/L) N = 184	
	AVA 60 mg (N = 160)	PBO (N = 91)	AVA 40 mg (N = 117)	PBO (N = 67)
Proportion of Patients Not Requiring a Platelet Transfusion or Rescue Procedure for Bleeding, %				
Overall	**66.9**	**28.6**	**88.0**	**35.8**
Splenomegaly Status: *No*	67.5 (n = 117)	27.5 (n = 69)	90.0 (n = 90)	42.9 (n = 49)
Splenomegaly Status: *Yes*	65.1 (n = 43)	31.8 (n = 22)	81.5 (n = 27)	16.7 (n = 18)
Proportion of Patients with Platelet Counts ≥ 50 × 10^9/L on Procedure Day, %				
Overall	**68.1**	**5.5**	**90.6**	**29.9**
Splenomegaly Status: *No*	69.2 (n = 117)	4.4 (n = 69)	92.2 (n = 90)	32 (n = 49)
Splenomegaly Status: *Yes*	65.1 (n = 43)	9.1 (n = 22)	85.2 (n = 27)	22.2 (n = 18)

Results: Overall, **AVA** was superior to **PBO** in both cohorts in the proportion of patients not requiring a PT or rescue procedure for bleeding (**Cohort 1**: p < 0.0001; **Cohort 2**: p < 0.0001). Efficacy in meeting the primary end point by SM status was generally similar, with a trend of less placebo-treated patients with SM meeting the primary end point. (**Cohort 1**: *No SM*: **AVA** 67.5%, **PBO** 27.5%; *With SM*: **AVA** 65.1%, **PBO** 31.8%; **Cohort 2**: *No SM*: **AVA** 90.0%, **PBO** 42.9%; With SM: **AVA** 81.5%, **PBO** 16.7%).
Conclusion: **AVA** was superior to **PBO** in increasing PC and reducing both the proportion of patients requiring a PT or rescue procedure for bleeding, and the proportion achieving a PC ≥ 50 × 10^9/L by Procedure Day. Efficacy was similar for both end points regardless of splenomegaly status, supporting the consistent efficacy of **AVA**. For patients with a PC < 40 × 10^9/L, < 1/10 **PBO**-treated patient achieved a PC ≥ 50 × 10^9/L regardless of splenomegaly status compared to ~7/10 **AVA**-treated patients.

SAT-136

Hepatocellular carcinoma does not impact the efficacy of avatrombopag in increasing platelet counts and reducing platelet transfusions or rescue procedures for bleeding in chronic liver disease patients with thrombocytopenia

Naim Alkhouri[1], kavita aggarwal[2], Michael Vredenburg[2], Wei Tian[2], Lee F Allen[2]. [1]*Texas Liver Institute, San Antonio, United States;* [2]*Dova Pharmaceuticals, Durham, United States*
Email: mvredenburg@dova.com

Background and aims: Patients with CLD and hepatocellular carcinoma (HCC) may require invasive procedures such as ablation and embolization. Thrombocytopenia (TCP) is common in patients with CLD and may increase the risk of bleeding with invasive procedures. Avatrombopag (**AVA**) is a thrombopoietin receptor agonist FDA-approved as an alternative to platelet transfusions (PT) for patients with TCP and CLD undergoing a procedure. This analysis assessed whether HCC status affected the efficacy of AVA.
Method: Two randomized, double-blind, placebo (**PBO**)-controlled Phase 3 trials (**ADAPT-1** and **ADAPT-2**) enrolled 435 adults with CLD and platelet counts (PC) < 50 × 10^9/L undergoing a procedure. Patients were divided by Baseline PC into **Cohort 1**- PC < 40 × 10^9/L and **Cohort 2**- PC 40 to < 50 × 10^9/L, and then randomized 2:1 to once-daily oral **AVA** (60 mg or 40 mg, respectively) or **PBO** for 5 days; the procedure was done 5 to 8 days after the last dose. The primary efficacy end point in both studies was the proportion of patients not requiring a PT or rescue procedure, and the first secondary end point was the proportion of patients achieving a PC ≥ 50 × 10^9/L on Procedure Day. Subgroup analyses of efficacy were also conducted based on HCC status.

	COHORT 1 (< 40 × 10^9/L) N = 251		COHORT 2 (40 to < 50 × 10^9/L) N = 184	
	AVA 60 mg (N = 160)	PBO (N = 91)	AVA 40 mg (N = 117)	PBO (N = 67)
Proportion of Patients Not Requiring a Platelet Transfusion or Rescue Procedure for Bleeding, %				
Overall	**66.9**	**28.6**	**88.0**	**35.8**
No HCC	68.4 (n = 117)	34.9 (n = 66)	91.7 (n = 84)	36.7 (n = 49)
HCC	64.3 (n = 42)	12.0 (n = 25)	81.3 (n = 32)	33.3 (n = 18)
Proportion of Patients with Platelet Counts ≥ 50 × 10^9/L on Procedure Day, %				
Overall	**68.1**	**5.5**	**90.6**	**29.9**
No HCC	68.4 (n = 117)	6.1 (n = 66)	91.7 (n = 84)	28.6 (n = 49)
HCC	69.1 (n = 42)	4.0 (n = 25)	90.6 (n = 32)	33.3 (n = 18)

Results: Overall, **AVA** was superior to **PBO** in both cohorts in the proportion of patients not requiring a PT or rescue procedure for bleeding (**Cohort 1**: p < 0.0001; **Cohort 2**: p < 0.0001). Efficacy by HCC status was generally similar between the different treatment groups for the primary end point. **Cohort 1**: *No HCC*: **AVA** 68.4%, **PBO** 34.9%; *HCC:* **AVA** 64.3%, **PBO** 12.0%; **Cohort 2**: *No HCC*: **AVA** 91.7%, **PBO** 36.7%; *HCC*: **AVA** 81.3%, **PBO** 33.3%. Similarly, efficacy results for the secondary end point were also generally comparable regardless of HCC status. **Cohort 1**: *No HCC*: **AVA** 68.4%, **PBO** 6.1%; *HCC*: **AVA** 69.1%, **PBO** 4.0%; **Cohort 2**: *No HCC*: **AVA** 91.7%, **PBO** 28.6%; *HCC*: **AVA** 90.6%, **PBO** 33.3%. Fewer HCC patients in the **Cohort 2** PBO arm reached the

primary end point compared to non-HCC patients though their baseline PC was similar.
Conclusion: **AVA** was superior to **PBO** in increasing PC and reducing both the proportion of patients with CLD who required a PT or rescue procedure for bleeding, and the proportion of patients who achieved a PC $\geq 50 \times 10^9$/L by Procedure Day. Efficacy was similar for both end points regardless of HCC status, supporting the consist efficacy of **AVA**.

SAT-137

Adverse drug reactions in patients with cirrhosis: analysis of spontaneous reports from the Dutch Pharmacovigilance Centre Lareb

Rianne A. Weersink[1,2], Katja Taxis[1], Eugene G. van Puijenbroek[1,3], Sander D. Borgsteede[2,4]. [1]*University of Groningen, Groningen, Netherlands;* [2]*Health Base Foundation, Houten, Netherlands;* [3]*Dutch Pharmacovigilance Centre Lareb, Den Bosch, Netherlands;* [4]*Erasmus University Medical Centre, Rotterdam, Netherlands*
Email: rianne.weersink@healthbase.nl

Background and aims: Patients with cirrhosis are susceptible for certain adverse drug reactions (ADRs), such as renal impairment and hepatic encephalopathy. However, not much is known. To obtain more ADR information, data from pharmacovigilance centers could be useful. We aim to describe the content of ADR reports from a pharmacovigilance center on patients with cirrhosis.
Method: We extracted all reports that mentioned "cirrhosis" from the database of the Dutch Pharmacovigilance Center Lareb. We excluded double reports, reports with cirrhosis as ADR and reports with an uncertain diagnosis of cirrhosis. The content of the included reports was quantitatively described.
Results: We retrieved 50 reports from the Lareb database. Twelve reports were excluded: two were double, in two others cirrhosis was the ADR and eight reports had an uncertain diagnosis of cirrhosis. Of the 38 included reports, 12 (32%) described the severity of cirrhosis of the patient. The reporter expressed this severity in a Child-Pugh class in seven and the other five reports mentioned severity in terms of decompensated or severe cirrhosis. The 38 reports concerned 49 suspected ADRs (median 1; range 1-3). These ADRs most often involved the following organ classes: "skin and subcutaneous tissue disorders" (n = 8; 21%), "nervous system disorders" (n = 6; 16%) and "gastrointestinal disorders" (n = 5; 13%). The most reported individual ADRs were: thrombocytopenia, a rash and an insult (all reported thrice). Two reports involved hepatotoxic events (one cholestatic hepatitis and one acute hepatitis). The pharmacovigilance assessor considered more than half (61%) of ADRs serious. In three, a death was reported. The medicines most frequently suspected for causing the ADR were: pegylated interferon-alpha-2a (n = 3), meropenem and norfloxacin (both n = 2). In one-fifth (21%) of reports the causality was evaluated as "probable" and in the remaining the causality was "possible".
Conclusion: The frequency of ADR reports on patients with cirrhosis is low in the Dutch Pharmacovigilance database. This suggests underreporting or inadequate documentation of cirrhosis as (co) morbidity. To indicate ADR risks in patients with cirrhosis, we advise to use a worldwide pharmacovigilance database.

SAT-138

Cirrhotic cardiomyopathy: A 2-year longitudinal follow-up study using advanced cardiac imaging

Signe Wiese[1], Jens Hove[1], Jens Otto Clemmesen[2], claus l. petersen[1], Flemming Bendtsen[1], Søren Møller[1]. [1]*Copenhagen University Hospital Hvidovre, Copenhagen, Denmark;* [2]*Copenhagen University Rigshospitalet, Copenhagen, Denmark*
Email: signeswiese@gmail.com

Background and aims: Cardiac dysfunction is an established complication in cirrhosis, but the temporal relationship between progression of liver dysfunction, cardiac impairment and survival is unknown. The study aim was to investigate the development of structural and functional cardiac changes over time with the progression of cirrhosis and outcome
Method: In a prospective 2-year longitudinal follow-up study, we included 63 cirrhotic outpatients (Child class: A = 9, B = 46, C = 8) and 14 healthy controls. We assessed advanced cardiac characteristics such as cardiac MRI with extracellular volume (ECV) quantification, speckle tracking echocardiography, ECG and biomarkers at 0/6/12/18/24 months. Patients were followed-up for a median of 30 months with registration of acute decompensations (AD), liver transplantation (LT), and death.
Results: In the 34 patients who remained stable or improved in cirrhosis during the 2-year study period limited cardiac deterioration was seen. Conversely, patients who progressed, underwent LT, or died had more pronounced cardiac dysfunction with structural myocardial changes, and left atrial enlargement. During follow-up 25 patients developed AD, 4 underwent LT, and 20 died. Mean arterial pressure was the only cardiovascular parameter associated with death in a univariate analysis ($p = 0.037$), and the main predictors were MELD and age. However, last visit myocardial ECV was independently associated with the combined end point of LT/death ($p = 0.001$), and in AD patients a low cardiac index was independently associated with death ($p = 0.01$).
Conclusion: Patients with stable cirrhosis have limited progression in cardiac dysfunction over a 2-year period with modest impact on survival. However, cardiac function seems to deteriorate in relation to progression in cirrhosis and may influence survival in AD patients. Our results encourage careful cardiac monitoring in patients with advanced cirrhosis.

Email: florence.wong@utoronto.ca

Background and aims: Acute-on-chronic liver failure (ACLF), irrespective of definition, is often precipitated by an event that disturbs systemic or regional homeostasis, leading to failure of one of more extra-hepatic organs, associated with high morbidity and short-term mortality. The aim of the study was to characterize cirrhotic inpatients with ACLF and to identify admission predictors of development of ACLF, as defined by the North American Consortium for the Study of End-stage Liver Disease (NACSELD) in hospitalized patients with cirrhosis.
Method: NACSELD, a consortium of 14 hepatology centers, prospectively enrolled non-electively admitted cirrhotic inpatients. We compared those who developed ACLF (≥ 2 organ failures) ≥ 48 hours after admission (ACLF+, n = 125) to those who did not (ACLF-, n = 2516). We excluded 416 patients with ACLF within the 1st 48 hrs of

admission. Extra-hepatic organ failures (OFs) were defined as: circulatory = need for vasopressor support; renal = initiation of dialysis; cerebral = Grade III or IV hepatic encephalopathy; respiratory = need for ventilation.

Results: Compared to ACLF- patients, ACLF+ patients were younger (55.5 ± 8.3 vs. 57.4 ± 10.9 years) ($p = 0.045$), but were similar in gender (male: 58 vs. 62%), alcoholic etiology (28 vs. 31%) and diabetes (37 vs. 34%). ACLF+ patients had more cirrhotic complications, more recent hospitalizations [within 6 months (M)], and more were admitted with infection, hence a higher proportion of patients had systemic inflammatory response syndrome (SIRS) compared to the ACLF- group. Regarding OFs, 82, 36 and 7 patients had 2, 3 and 4 OFs respectively in the ACLF+ group, with no significant differences between subgroups, except more OFs increased the rate of dialysis. Mortality in hospital (42% vs. 3%) and at 30 days (50% vs. 7%) was significantly higher in the ACLF+ vs. ACLF- patients ($p < 0.0001$). Independent predictors of ACLF development ≥ 48 hours after admission included admission MELD (OR: 1.14; confidence interval 1.11-1.16), presence of SIRS (OR: 1.96; CI: 1.96-3.01), and hospitalization in ≤ 6 Ms (OR: 2.80; CI: 1.59-4.96).

Conclusion: Cirrhotic patients admitted with higher a MELD score, infection, signs of inflammation and a recent hospitalization are more likely to develop ACLF. This patient subgroup requires intensive monitoring for prompt recognition and management of ACLF.

Table:

Admission parameters	ACLF- (N = 2516)	ACLF + (N = 125)	P value
	% (n) or mean (SD)	% (n) or mean (SD)	
Admitted with infection	25% (625)	38% (48)	0.0008
Ascites	68% (1720)	85% (106)	0.0001
Refractory ascites	32% (800)	49% (61)	< 0.0001
Admission in ≤ 6 Ms	66% (1518)	8% (93)	0.0001
Rifaximin use	35% (853)	50% (61)	0.0006
SIRS	24% (606)	37% (45)	0.0025
Serum creatinine (mg/dL)	1.46 (1.39)	2.33 (1.71)	< 0.0001
MELD	18.76 (7.32)	26.91 (7.77)	< 0.0001

SAT-140

The natural history of stages 2 and 3 acute kidney injury in hospitalized patients with decompensated cirrhosis and ascites

Florence Wong[1], Rajender Reddy[2], Puneeta Tandon[3], Jacqueline O'leary[4], Guadalupe Garcia-Tsao[5], Jennifer Lai[6], Hugo E. Vargas[7], Scott Biggins[8], Benedict Maliakkal[9], Michael Fallon[10], Ram Subramanian[11], Paul J. Thuluvath[12], Patrick S. Kamath[13], Leroy Thacker[14], Jasmohan S Bajaj[15]. *[1]University of Toronto, Medicine, Toronto, Ontario, Canada; [2]University of Pennsylvania, Medicine, Philadelphia, United States; [3]University of Alberta, Medicine, Edmonton, Canada; [4]VA Medical Center, Medicine, Dallas, United States; [5]Yale University of Medicine, Medicine, New Haven, United States; [6]University of California, San Francisco, Medicine, San Francisco, United States; [7]Mayo Clinic Scottsdale, Medicine, Phoenix, United States; [8]University of Washington, Medicine, Seattle, United States; [9]University of Tennessee, Medicine, Memphis, United States; [10]University of Arizona, Medicine, Phoenix, United States; [11]Emory University, Medicine, Atlanta, United States; [12]Mercy Medical Center, Medicine, Baltimore, United States; [13]Mayo Clinic Rochester, Medicine, Rochester, United States; [14]Virginia Commonwealth University, Biostatisitcs, Richmond, United States; [15]Virginia Commonwealth University, Medicine, Richmond, United States*
Email: florence.wong@utoronto.ca

Background and aims: AKI occurs in ≈50% of hospitalized cirrhotic patients, with stage 1 AKI with a peak serum creatinine (SCr) < 1.5 mg/dl having a relatively benign course. Higher stages of AKI have been reported to have significantly worse prognosis in a European cohort. However, the natural history of stages 2 and 3 AKI in cirrhosis in North American patients has not been described. The aim of the study was to assess the prognosis and predictive factors for the development of stages 2 and 3 AKI in the North American Consortium for the Study of Liver Disease (NACSELD) cohort.

Method: Decompensated admitted cirrhotic patients with ascites who developed AKI per the International Ascites Club (IAC) 2015 definition from the NACSELD database were included, comparing patients with stage 1 versus stages 2 and 3 AKI with respect to demographics, laboratory values, AKI treatment response and survival.

Results: 760 of 989 AKI (43% of 2297 total eligible) patients with ascites formed the study cohort. There was no difference between the stage 1 (n = 419) and stages 2 and 3 (n = 341) patients with respect to demographics (males: 63%; mean age: 58 years; cirrhosis etiology (alcohol: 30%). When compared to stage 1 AKI patients, stages 2 and 3 patients were sicker (MELD: 25.9 ± 7.3 vs. 21.9 ± 7.5, $p < 0.0001$), were more likely to be on SBP prophylaxis, had higher white cell counts, were more likely to have SIRS on admission, and more developed a second infection during admission ($p < 0.05$ for all). Significantly more stages 2 and 3 patients were treated for their AKI (albumin: 74% vs. 67%, $p = 0.03$; midodrine/octreotide: 43% vs. 23%, $p < 0.0001$). Despite this, more of them had a progressive course (31% vs. 12%, $p < 0.0001$). AKI progression occurred more frequently in older patients who had hospital contacts in past 6 months. The in-hospital mortality was 20% for stages 2 and 3, vs. 6% for stage 1 ($p < 0.0001$), and was associated with lower 30-day transplant-free survival (56% vs. 81%, $p < 0.001$). Predictors of stages 2 and 3 AKI development were a higher admission MELD ($p < 0.0001$), presence of SIRS on admission ($p = 0.023$), and the development of 2nd infections ($p < 0.0001$).

Table: Outcomes of Stages 2 and 3 AKI

	Transient (*n* = 99)	Persistent (*n* = 130)	Progressive (*n* = 101)	*p value*
Baseline serum creatinine	0.94 (0.34)	1.14 (0.48)	1.25 (0.58)	< 0.0001
Peak Serum creatinine	2.71 (1.18)	3.56 (1.57)	4.73 (1.95)	< 0.0001
Δ Serum creatinine	1.78 (1.03)	2.42 (1.42)	3.49 (1.74)	< 0.0001
Started on dialysis (%, n)	4% (4)	16% (21)	41% (41)	< 0.0001
Admitted to ICU (%, n)	39% (39)	39% (50)	70% (71)	< 0.0001
Length of hospital stay (days)	19.3 (19.7)	21.8 (21.6)	23.2 (15.4)	0.0113

Conclusion: Sicker cirrhotic patients are more likely to develop stages 2 and 3 AKI, especially if there is a 2nd infection while admitted. They tend to have a progressive AKI course, with decreased transplant-free survival. Therefore such patients need careful monitoring and aggressive AKI treatment to improve outcomes.

SAT-141

The diagnosis of hepatorenal syndrome: How much does use of the 2015 revised consensus recommendations affect earlier treatment and serum creatinine at treatment start?

Florence Wong[1], Stephen Pappas[2], Hugo E. Vargas[3], Todd Frederick[4], Arun Sanyal[5], Khurram Jamil[6]. *[1]University of Toronto, Toronto ON, Canada; [2]Orphan Therapeutics, LLC, Lebanon NJ, United States; [3]Mayo Clinic Hospital, Phoenix AZ, United States; [4]California Pacific Medical Center, San Francisco CA, United States; [5]Virginia Commonwealth University, Richmond VA, United States; [6]Mallinckrodt Pharmaceuticals, Bedminister NJ, United States*
Email: spappas1@comcast.net

Background and aims: In 2015, the International Club of Ascites (ICA) published revised consensus recommendations for the diagnosis of acute kidney injury (AKI) and HRS based on a dynamic

change in serum creatinine (SCr) rather than a static level of SCr of 2.5 mg/dL in patients with cirrhosis, in an effort to facilitate earlier treatment of HRS Type 1 (HRS1). The aim of this study was to estimate the effect of using the new ICA-AKI diagnostic criteria on timing of HRS treatment, applying these criteria to subjects ultimately enrolled in a large, prospective, randomized trial of patients with HRS1 treated with terlipressin (REVERSE trial) (Gastroenterology 2016; 150: 1579-1589).

Method: 2015 HRS-AKI criteria were retrospectively applied to individual patient's pre-enrollment serial SCr data from the REVERSE trial. The number of days between meeting current ICA HRS-AKI criteria and old HRS1 criteria were determined to estimate the impact of the new criteria on earlier treatment. SCr at HRS-AKI diagnosis using the new ICA 2015 criteria was compared to SCr at diagnosis of HRS1 using the 2007 diagnostic criteria to estimate the effect of the new criteria on SCr at the potential start of vasoconstrictor therapy

Results: Of 196 patients included in REVERSE, 141 subjects had data available for this analysis. 24/141 subjects (17%) had a decrease or no change in SCr (average –0.5 mg/dL) during interval (average 2.3 days) between meeting HRS-AKI versus HRS1 criteria. 117/141 subjects (83%) had an increase in SCr (average 1.7 mg/dL) during interval (average 4.0 days) between meeting HRS-AKI versus HRS1 criteria Additional results are shown in the Table.

Interval between HRS-AKI and HRS1 N = 141	**3.8** (3.3) days*
SCr at HRS-AKI diagnosis N = 141	**2.7** (1.1) mg/dL*
SCr at HRS1 diagnosis N = 141	**3.7** (1.1) mg/dL*
Fold increase SCr, AKI-HRS to HRS1 criteria	% of subjects (N = 117)
> 1 to < 1.5 fold	**53%**
1.5 to 2.0 fold	**22%**
> 2.0 fold	**25%**

*mean (SD)

Conclusions: Applying the new 2015 ICA AKI-based criteria for HRS is estimated to result in earlier treatment of patients by approximately 4 days, with treatment at a SCr approximately 1 mg/dL lower than when using prior HRS1 diagnostic criteria. A significant number of patients (47%) would receive treatment prior to a further ≥ 1.5 fold increase in SCr. Using the new ICA HRS-AKI diagnostic criteria will provide earlier treatment with potentially better outcomes.

SAT-142

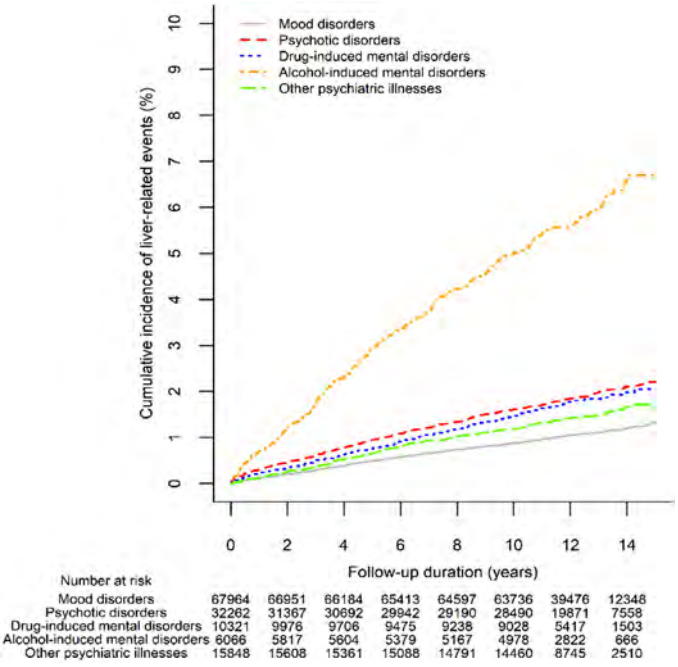
Incidence of hepatocellular carcinoma and cirrhotic complications in patients with psychiatric illness: A territory-wide cohort study

Vincent Wai-Sun Wong[1], Terry CF Yip[1], Yee-Kit Tse[1], Becky Wing-Yan Yuen[1], Hester Wing-Sum Luk[1], Marco Ho-Bun Lam[2], Michael Kin Kong Li[3], Ching Kong Loo[4], Tak Yin Owen Tsang[5], Steven Woon-Choy Tsang[6], Henry Chan[1], Yun Kwok Wing[2], Grace Lai-Hung Wong[1]. *[1]The Chinese University of Hong Kong, Department of Medicine and Therapeutics, Hong Kong, Hong Kong; [2]The Chinese University of Hong Kong, Department of Psychiatry, Hong Kong, Hong Kong; [3]Tuen Mun Hospital, Department of Medicine and Geriatrics, Hong Kong, Hong Kong; [4]Kwong Wah Hospital, Department of Medicine and Geriatrics, Hong Kong, Hong Kong; [5]Princess Margaret Hospital, Department of Medicine and Geriatrics, Hong Kong, Hong Kong; [6]Tseung Kwan O Hospital, Department of Medicine, Hong Kong, Hong Kong*
Email: wongv@cuhk.edu.hk

Background and aims: Because of high-risk behaviours, psychiatric patients are at risk of viral hepatitis and alcohol-related liver disease. Their sedentary lifestyle and side effects of psychiatric medicine are also conducive to obesity and non-alcoholic fatty liver disease. We aim to study the incidence of hepatocellular carcinoma (HCC) and cirrhotic complications in a territory-wide cohort of psychiatric patients in Hong Kong.

Method: We identified patients with psychiatric diagnoses from 2003 to 2007 using the Clinical Data Analysis and Reporting System. This system captures in-patient and out-patient data of all public hospitals and clinics in Hong Kong. The patients were followed for liver-related events (HCC and cirrhotic complications) and deaths until December 2017.

Results: Of 178, 225 psychiatric patients, we included 105, 763 adult patients without prior HCC and cirrhotic complications in the final analysis. During a median follow-up of 12.4 (interquartile range 11.0-13.7) years, 1, 520 (1.4%) patients developed HCC and/or cirrhotic complications (Figure). Compared with the general population, psychiatric patients had increased incidence of HCC (standardized incidence ratio [SIR] 1.70, 95% CI 1.54-1.87). The SIR was highest in patients with alcohol-related (SIR 3.48) and drug-induced mental disorders (SIR 3.34), but was also increased in patients with psychotic disorders (SIR 1.58) and mood disorders (SIR 1.48). Liver disease was the fifth most common cause of death in this population, accounting for 603 of 10, 614 (5.7%) deaths. Chronic hepatitis B (n = 375, 24.7%), chronic hepatitis C (n = 175, 11.5%), alcohol-related liver disease (n = 190, 12.5%) and non-alcoholic fatty liver disease (n = 78, 5.1%) were the leading aetiologies in patients with liver-related events. Importantly, 799 (52.6%) patients were not known to have liver diseases at the time of liver-related events.



Conclusion: HCC, cirrhotic complications and liver-related deaths are common in psychiatric patients, but liver diseases are often undiagnosed. More efforts are needed to identify liver diseases in the psychiatric population so that treatments and screening for HCC and varices can be provided to patients in need.

SAT-143

Albumin-bilirubin as a simple prognostic score for chronic hepatitis B-related liver cirrhosis

Jian Wang[1], Rui Huang[1], Chuanwu Zhu[2], Ming Li[3], Xiaomin Yan[1], Chao Wu[1]. *[1]Nanjing Drum Tower Hospital, The Affiliated Hospital of Nanjing University Medical School, Department of Infectious Diseases,*

Nanjing, China; [2]The Fifth People's Hospital of Suzhou, Department of Hepatology, Nanjing, China; [3]The Fifth People's Hospital of Suzhou, Department of Hepatology, Suzhou, China
Email: dr.wu@nju.edu.cn

Background and aims: The Albumin-Bilirubin (ALBI) score was developed recently to predict the long-term prognosis in patients with hepatocellular carcinoma. We aimed to investigate the performance of ALBI for predicting the severity and long-term prognosis of chronic hepatitis B-related cirrhosis (CHB-LC).
Method: Patients diagnosed with CHB-LC were enrolled from two medical centers between 2011 and 2017. The prognostic performance of ALBI was evaluated and compared with Child-Turcotte-Pugh (CTP) score and model of end-stage liver disease (MELD) score.
Results: This study enrolled 398 CHB-LC patients. The ALBI score increased with the severity of CHB-LC. ALBI was an independent predictor of liver-related mortality by multivariable Cox analysis. The receiver operating characteristic curves (ROCs) analysis revealed that ALBI score (0.756, 0.745, 0.739, 0.767 and 0.765) was superior to MELD score (0.655, 0.629, 0.641, 0.636 and 0.677, $P < 0.05$) and comparable with CTP score (0.785, 0.766, 0.768, 0.772 and 0.793, $P > 0.05$) for predicting 2-year, 3-year, 4-year, 5-year and global mortality. However, no significant differences were observed among three models in predicting 1-year mortality. Over a median follow-up of 33.9 months, patients with lower ALBI grade had a significantly lower mortality than patients with higher ALBI grade ($p < 0.05$). Similar results were observed in the CTP classes A and B subgroup.
Conclusion: ALBI score accurately predicts the severity and long-term prognosis in patients with CHB-LC in China. The prognostic performance of ALBI score was superior to MELD score.

SAT-144

Red blood cell distribution width to albumin ratio as a novel prognostic indicator for patients with chronic hepatitis B-related liver cirrhosis

Rui Huang[1], Jian Wang[1], Linda Henry[2], Zhaoping Zhang[1], Chuanwu Zhu[3], Mindie Nguyen[2], Chao Wu[1]. *[1]Nanjing Drum Tower Hospital, The Affiliated Hospital of Nanjing University Medical School, Department of Infectious Diseases, Nanjing, China; [2]Stanford University Medical Center, Gastroenterology and Hepatology, Palo Alto, United States; [3]The Fifth People's Hospital of Suzhou, Department of Hepatology, Suzhou, China*
Email: dr.wu@nju.edu.cn

Background and aims: Simple, reliable non-invasive indexes to predict prognosis of chronic hepatitis B (CHB)-related liver cirrhosis (LC) are currently lacking. We aimed develop and test a novel index using routine laboratory results to predict the liver-related mortality of CHB-LC.
Method: Patients were enrolled from three medical centers. The derivation cohort contained 398 CHB-LC patients from two medical centers in China. A validation cohort of 198 CHB-LC patients was enrolled from Stanford University Medical Center. Multiple regression was used to identified the predictors. The prognostic value was assessed using Kaplan-Meier analysis.
Results: Red cell distribution width (RDW) and albumin ($p < 0.001$) were independent predictors for CHB-related decompensated cirrhosis (CHB-DCC) in derivation cohort. Thus, RDW to albumin ratio (RAR) was proposed. The receiver operating characteristic curves (ROCs) analysis revealed that RAR (0.771, 0.737 and 0.727) was comparable with CTP score (0.800, 0.743 and 0.746, $P > 0.05$) for

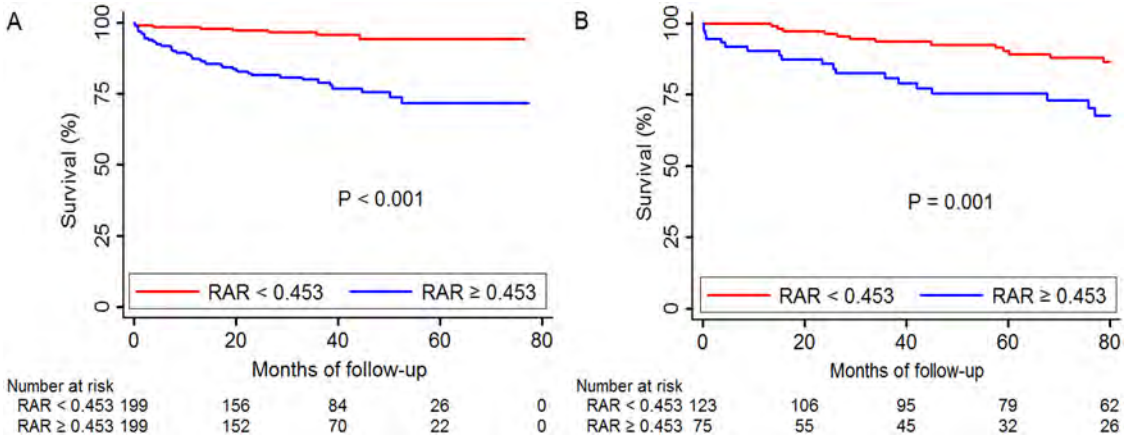

Figure: (abstract: SAT-144)

predicting 1-year, 3-year and 5-year liver-related mortality, and was superior to MELD score (0.624, P = 0.028) for predicting 3-year liver-related mortality, but was comparable with MELD score (0.694 and 0.639, P > 0.05) for predicting 1-year and 5-year liver-related mortality in the derivation cohort. Validation cohort had similar results. Over a median follow-up of 39.8 (IQR 22.8-62.1) months, CHB-LC patients with RAR ≥ 0.453 in both derivation cohort (22.1% vs. 4.0%, P < 0.001) and validation cohort (25.3% vs. 10.6%, P = 0.001) had significantly higher liver-related mortality.
Conclusion: The RAR, a novel easy-to-use index, accurately predicts CHB-LC related mortality in clinical practice.

SAT-145
The prognostic significance of hbeag status on the long-term outcome for chronic hepatitis b-related liver cirrhosis: A propensity score matching analysis
Rui Huang[1], Jian Wang[1], Xiaomin Yan[1], Juan Xia[1], Bei Jia[1], Chuanwu Zhu[2], Chao Wu[1]. *[1]Nanjing Drum Tower Hospital, The Affiliated Hospital of Nanjing University Medical School, Department of Infectious Diseases, Nanjing, China; [2]The Fifth People's Hospital of Suzhou, Department of Hepatology, Nanjing, China*
Email: dr.wu@nju.edu.cn

Background and aims: Serum hepatitis B e antigen (HBeAg) status is a critical predictor of the progression in patients with chronic hepatitis B (CHB). However, there are still lack of evidences whether HBeAg status is related to the long-term outcome of patients with CHB related liver cirrhosis (CHB-LC). We aimed to investigate the prognostic significance of HBeAg status on the long-term outcome for CHB-LC using propensity score matching.
Method: 398 patients with CHB-LC were enrolled from two medical centers (2011-2017). To adjust for the selection bias of patients between HBeAg positive and HBeAg negative, we performed 1:1 match using propensity score matching. The Kaplan-Meier curve and Cox regression analysis was performed for the risk of LC-related death.
Results: After propensity score matching, 77 patients were final included in each group. There were no significant differences of liver related mortality between HBeAg positive CHB-LC patients and HBeAg negative CHB-LC patients before propensity score matching (8.2% vs. 14.9%, P = 0.094). However, after propensity score matching, CHB-LC patients with HBeAg negative (26.0%) exhibited a significantly higher mortality than CHB-LC patients with HBeAg positive (9.1%, p = 0.019) over a median follow-up of 32.1 (IQR, 17.7-50.1) months. Furthermore, after propensity score matching, HBeAg negative status (HR, 2.859; 95% CI 1.207-6.770; P = 0.017) was significantly associated with increased risks of liver related mortality in CHB-LC patients. After adjustment for other prognostic variables in the propensity score matched cohort, HBeAg negative status was still found to be associated with higher mortality (HR, 3.032; 95% CI 1.232-7.460; P = 0.016) in patients with CHB-LC.

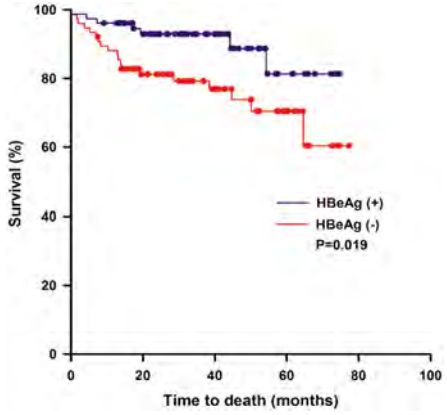

Figure: Survival curves of CHB-LC patients with HBeAg (+) or HBeAg (+) after propensity score matching.

Conclusion: HBeAg negative status appears to be an independently risk predictor of long-term mortality for patients with CHB-LC based on propensity score matching analysis.

SAT-146
Assessing liver function in patients who underwent balloon occluded retrograde transvenous obliteration
Thomas Xu[1], Dr. Sitaram Chivukula[1], Dr. Victor Nguyen[2], Dr. Jordan Tasse[2], Dr. Edie Chan[1]. *[1]Rush University Medical Center, Department of Surgery, Chicago, United States; [2]Rush University Medical Center, Department of Radiology, Chicago, United States*
Email: thomas_xu@rush.edu

Background and aims: Portal hypertension is one of the most fundamental sequelae of liver failure with clinical signs and symptoms representing the major source of morbidity and mortality. One of the effects is the development of portosystemic shunts to help alleviate the pressure from portal hypertension. Treatments have been developed to obliterate portosystemic shunts in order to reverse hepatic encephalopathy. One of these treatment options is balloon occluded retrograde transvenous obliteration (BRTO). There have been minimal studies assessing liver function and how it changes after undergoing BRTO. We aim to assess liver function over time in this cohort of patients.
Method: A retrospective chart review was conducted utilizing the Rush University Medical Center electronic medical record to evaluate patients age eighteen and older who underwent BRTO between 2013 and 2017, yielding data on 21 patients. Cochran's Q, McNemar, and Friedman tests were conducted to assess the changes in paracentesis frequency and amount over time. To examine whether there was a relationship between the change in frequency of paracentesis per patient across time and MELD score, Spearman correlation coefficients were calculated and compared to zero. To look at whether there was a relationship between the change in the number of patients who had paracenteses across time and MELD score, Wilcoxon-Mann-Whitney tests were conducted.
Results: The number, frequency, and amount of fluid removed per paracentesis increased after patients underwent BRTO (Figure 1). When MELD scores were examined as potentially related to a change in paracentesis over time, it was found to be correlated with the change in frequency of paracenteses conducted between pre-BRTO procedure and 90 days post-BRTO procedure with a trend towards significance (r = 0.48; p = 0.06). On average, patients had a higher MELD score 30 days post-BRTO versus at the time of the procedure with a median MELD of 15 at the time of the procedure and a median MELD of 18 thirty days post procedure (p = 0.03). Thirty and ninety day mortality were 9.5% and 14.3%, respectively.

Figure 1: Paracentesis frequency and amount in patients who underwent BRTO

	Pre-BRTO	30 days Post-BRTO	90 days Post-BRTO	p value
Number (%) of patients with paracenteses (38.1%)	2	(9.5%)	6 (28.6%)	8 0.009
Mean (SD) fluid removed from paracentesis (11.0)	0.44	(2.0)	1.7 (5.0)	5.3 0.001
Mean (SD) frequency of paracenteses per patient (3.0)	0.24	(0.9)	0.76 (1.6)	1.6 0.002

Conclusion: In this study, increasing MELD score was found to be associated with increasing frequency of paracenteses after a BRTO procedure. In addition, patients who underwent BRTO had a statistically significant increase in their MELD score. Further research is needed to evaluate the underlying reason for worsening MELD scores in these patients.

SAT-147

Interaction between renal and liver impairment on the risk of lactic acidosis in diabetic patients with chronic hepatitis B-related cirrhosis

Terry CF Yip[1,2], Vincent Wai-Sun Wong[1,2,3], Yee-Kit Tse[1,2], Henry Chan[1,2,3], Grace Lai-Hung Wong[1,2,3]. [1]*The Chinese University of Hong Kong, Medicine and Therapeutics, Hong Kong, Hong Kong;* [2]*The Chinese University of Hong Kong, Institute of Digestive Disease, Hong Kong, Hong Kong;* [3]*The Chinese University of Hong Kong, State Key Laboratory of Digestive Disease, Hong Kong, Hong Kong*
Email: wonglaihung@cuhk.edu.hk

Background and aims: The risk of lactic acidosis across renal and liver function in cirrhotic patients with diabetes mellitus (DM) has not been well-documented. We examined the interaction between severity of renal and liver impairment on the risk of lactic acidosis in DM patients with chronic hepatitis B (CHB)-related cirrhosis.
Method: A territory-wide cohort of DM patients with CHB-related cirrhosis from January 2000 to December 2017 was identified using the Clinical Data Analysis and Reporting System that captures in-patient and out-patient data of all public hospitals and clinics in Hong Kong. Lactic acidosis was defined by diagnosis codes, and/or blood pH ≤ 7.35 with lactate > 5 mmol/L or arterial bicarbonate ≤ 18 mmol/L or venous bicarbonate ≤ 21 mmol/L. Renal and liver function were modelled by time-dependent estimated glomerular filtration rate (eGFR) category and Child-Pugh class. Time-dependent use of medications and comorbidities were included in Fine-Gray model adjusted for competing risk of death. We excluded patients with eGFR < 30 ml/min/1.73 m^2 or renal replacement therapy at baseline.
Results: 4, 627 DM patients with CHB-related cirrhosis were identified. Their mean age was 60.8 ± 10.8 years, 3, 360 (72.6%) were male; 1, 652 (35.7%), 2, 119 (45.8%), 574 (12.4%) and 282 (6.1%) had baseline eGFR ≥ 90, 60-89, 45-59 and 30-44 ml/min/1.73 m^2. 3, 440 (72.2%), 1, 088 (23.5%) and 199 (4.3%) were in Child-Pugh class A, B and C at baseline. At a median (interquartile range) follow-up of 5.3 (2.0-9.6) years, 1, 119 (24.2%) patients developed lactic acidosis. In Child-Pugh class A, the risk of lactic acidosis elevated in eGFR < 45 ml/min/1.73 m^2. The risk of lactic acidosis increased in Child-Pugh class B and C at any eGFR levels. The risk of lactic acidosis increased dramatically in Child-Pugh class C with eGFR < 30 ml/min/1.73 m^2 (Table).
Conclusion: The risk of lactic acidosis increases with renal and liver impairment in DM patients with CHB-related cirrhosis. Child-Pugh class C with eGFR < 30 ml/min/1.73 m^2 is associated with a 102-fold increase in risk of lactic acidosis.

SAT-148

The role of kidney biomarkers in cirrhotic patients with acute kidney injury: interim analysis of multicenter, prospective cohort study

Jeong-Ju Yoo[1], Young Seok Kim[1], sang gyune kim[1], Jung Hyun Kwon[2]. [1]*Soonchunhyang University school of medicine, Bucheon, Korea, Rep. of South;* [2]*Incheon St. Mary's Hospital, The Catholic University of Korea, Department of Internal Medicine, Incheon, Korea, Rep. of South*
Email: mcnulty@schmc.ac.kr

Background and aims: Current AKI criteria using serum creatinine (Cr) has some limitations to predict reversibility of renal function and discriminate renal parenchymal injury in cirrhotic patients. The aim of this study is to evaluate whether urine biomarkers [cystatin C, N-acetyl-β-D-Glucosaminidase (NAG)] can predict survival and response to terlipressin in cirrhotic patients with AKI.
Method: One hundred eleven cirrhotic patients who developed AKI were prospectively enrolled from 11 tertiary medical centers in Korea during 2016 to 2018. AKI was defined as increase in serum Cr (SCr) of 0.3 mg/dL or 50% increase of baseline in SCr with a final value above 1.5 mg/dL. Among them, the patients with SCr ≥ 2.5 mg/dL were diagnosed as hepatorenal syndrome (HRS) and treated with terlipressin. Urine samples were collected for the measurement of urine cystatin C and urine NAG at the diagnosis of AKI and/or HRS.
Results: Of 111 patients, 29 patients had HRS. The mean MELD score was 23.92 ± 8.90, and mean SCr was 2.20 ± 0.79 mg/dL. The baseline urine NAG (AKI stage I, 16.37 ± 16.48 mg/dL; stage II, 27.84 ± 36.70 mg/dL; stage III, 55.69 ± 62.93 mg/dL, P = 0.007) and urine cystatin C (AKI stage I, 0.50 ± 0.78 mg/dL; stage II, 0.67 ± 2.29 mg/dL; stage III, 1.07 ± 2.16, P = 0.558) increased as the baseline AKI stage increased. During median 2.6 months observational period, all-cause mortality was 39.4%. In patients with liver transplantation or death, urine NAG level tended to be higher than in survival group, but not statistically significant (30.56 ± 40.81 mg/dL vs. 20.80 ± 29.22 mg/dL, P = 0.101). However, this urine biomarkers were not yet different depending on the improvement of renal function and survival.
Conclusion: In the interim-analysis of our study, urine NAG and urine cystatin C are strongly associated with severity of AKI in patients with liver cirrhosis and may be helpful to predict transplant-free survival in these patients.

SAT-149

Optimal selection of sedative drug during endoscopy in cirrhotic patients to avoid minimal encephalopathy

Jeong-Ju Yoo[1], sang gyune kim[1], Young Seok Kim[1]. [1]*Soonchunhyang University school of medicine, Bucheon, Korea, Rep. of South*
Email: liverkys@schmc.ac.kr

Background and aims: The indiscriminate use of sedative drug during endoscopy can pose a risk of minimal hepatic encephalopathy (MHE) in patient with liver cirrhosis,. However, it has not been studied yet which drugs are safest and most inviting on these

Table: (abstract: SAT-147)

^ 24, 415 records of Child-Pugh class change were collected in follow-up. aHR = adjusted hazard ratio, CI = confidence interval.

patients. The aim of this study is to evaluate which one among midazolam, propofol, or combination therapy, was the least likely to cause complications including MHE by using Stroop application in cirrhotic patients.

Method: This randomized prospective study included consecutive 60 patients who underwent upper GI endoscopy at tertiary hospitals in Korea. Patients were randomly assigned to one of three groups, midazolam, propofol, or combination group, and underwent Stroop test before endoscopy, and 2 hours after the completion of endoscopy. The vital signs was checked before and after the drug administration and the patient/physician/nurse satisfaction was scored after endoscopy.

Results: Mean age of the patients was 54.0 ± 9.30 years and 81.3% were male. Fifteen patients (46.9%) were child-pugh class A, and 17 (53.1%) were child-pugh class B or C. Alcohol was the most common etiology (21, 65.6%). Patients did not show significant changes in Ontime, Offtime on Stroop test before and after drug administration, and there was no significant difference between the three treatment groups. Also, there was no significant vital sign changes after drug use in all groups. However, with respect to subjective indicators, the satisfaction scores of patient and nursing staff was higher in the combined group than in the other two groups, and time to recovery was shorter in propofol than other groups.

Conclusion: In patients with cirrhosis, sedative endoscopy using midazolam, propofol, or combination therapy is relatively safe, and was not associated with increased risk of MHE. However, since there is subjective satisfaction or recovery time difference among sedative agents, it should be considered according to each individual patient.

Email: noshin@hanyang.ac.kr

Background and aims: Minimal hepatic encephalopathy (mHE) has poor prognosis but hardly drawn attention when patients have no symptoms. We aimed to validate Korean stroop test in the screening of mHE.

Method: Chronic hepatitis B related liver cirrhosis (LC) patients without history of overt hepatic encephalopathy were recruited prospectively from 15 centers for two years. All participants completed Portosystemic encephalopathy syndrome test (PHES) and Korean stroop test. Korean stroop test is consisted of 2 On-states (color, word) and 2 Off-states (inhibition, switching). Correct response rates and response times were measured. Four types of "OnTime+OffTime" have been analyzed (color+inhibition, color +switching, word+inhibition, and word+switching). mHE was diagnosed when PHES scores less than −4. Healthy controls (HC) were also recruited (n = 376).

Results: Among 223 LC patients, 67.3% was male. Mean age was 53 years. Prevalence of mHE was 20.6%. Response times for each states showed negative correlation with PHES scores ($p < 0.001$). Also color +inhibition, color+switching, word+inhibition, and word+switching showed negative correlation with PHES scores, −0.361, −0.310, −0.442, and −0.336, respectively (all $p < 0.001$). The highest AUC in the discrimination of mHE among various "OnTime+OffTime" was word+inhibition (AUC 0.75, 95% C.I 0.67-0.84, $p < 0.001$). Mean values of word+inhibition were significantly different among the three groups, which were 54.6 ± 13.2sec, 63.4 ± 18.2sec, and 83.4 ± 27.8sec in HC, LC without mHE, and LC with mHE, respectively (all $p < 0.001$). Among various factors, time for word+inhibition was the only significant factor (OR 1.04, 95% C.I 1.02-1.06, $p < 0.001$) in multivariate analysis for diagnosis of mHE.

Conclusion: Korean stroop test is simple and valid method for screening of mHE.

SAT-151

What are the predictors of impairment of patient-reported outcome in non-alcoholic steatohepatitis?

Zobair Younossi[1,2], Maria Stepanova[3], Quentin Anstee[4], Vincent Wai-Sun Wong[5], Stephen Harrison[6], Takeshi Okanoue[7], Manuel Romero Gomez[8], Stephen Djedjos[9], Robert Myers[9], Issah Younossi[3], Andrei Racilla[3], Fatema Nader[3]. *[1]Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, United States; [2]Center for Liver Diseases-, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, United States; [3]Center for Outcomes Research in Liver Disease, Washington DC, United States; [4]Institute of Cellular Medicine, Newcastle Univeristy, Newcastle, New Zealand; [5]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, Hong Kong; [6]Pinnacle Clinical Research, San Antonio, United States; [7]Saiseikai Suita Hospital, Suita City, Japan; [8]Hospital Universitarui Virgen del Rocio, Sevilla, Spain; [9]Gilead Sciences, Foster City, United States*
Email: zobair.younossi@inova.org

Background and aims: Patient-reported outcomes (PROs) assess patients' experience with their disease and its treatment. There is a paucity of data related to predictors of PROs in patients with NASH. Aim: To identify demographic and clinical factors associated with PROs in patients with NASH and advanced fibrosis.

Method: NASH patients with bridging fibrosis or compensated cirrhosis were enrolled in two phase 3 STELLAR trials of selonsertib (#NCT03053050, #NCT03053063). The PROs [Short Form-36 (SF-36), Chronic Liver Disease Questionnaire (CLDQ-NASH), EQ-5D, and Work Productivity and Activity Index (WPAI:SHP)] were collected prior to treatment initiation. Independent predictors of PROs were assessed using generalized linear regression models (betas (β; were expressed in % of a PRO range size; $p < 0.01$ was considered significant).

Results: 1, 667 NASH patients with PRO data were enrolled (58 ± 9 years, 40% male, 73% white, 56% from the U.S., 52% had cirrhosis, 69% diabetes). Prior to treatment, physical health-related PRO scores of NASH patients were significantly lower than general population norms ($p < 0.01$). In a series of multivariate analyses, independent predictors of various PRO domain scores included age (β = +0.15% to +0.47% per year), gender (β = -3.0% to -9.1% in female patients), race (β = -16.0% to -8.5% in black and β = +2.3% to +9.9% in Asian patients with reference to whites), the country of enrollment (β = +1.9% to +10.2% for NASH patients enrolled in the U.S.), smoking status (β = -7.5% to -3.1% in current smokers), body mass index (β = -0.99% to -0.18% per kg/m2) and cirrhosis (β = -3.4 to -1.8). In addition, the presence of other comorbidities was found to be independently associated with

lower PROs ($p < 0.01$) (Table). Of those predictors, both musculoskeletal disorders and higher BMI were primarily associated with worse physical health, increased fatigue, and decreased vitality, while having a psychiatric disorder (anxiety, depression, bipolar, sleep disorder) was the only predictor of decreased work productivity ($p < 0.01$).

Predictor of PROs in NASH	Beta (β), % of PRO range size
Diabetes mellitus	−6.1 to − 1.9
Gastrointestinal disorders	−7.3 to − 2.4
Musculoskeletal and connective tissue disorders	−11.8 to − 2.1
Nervous system disorders	−5.5 to − 2.5
Psychiatric disorders	−12.7 to − 2.5

Conclusion: The presence of cirrhosis and comorbidities contributes to impairment of PROs in patients with NASH.

SAT-152

Prediction of nosocomial acute-on-chronic liver failure in patients with cirrhosis admitted to hospital with acute decompensation

Email: paolo.caraceni@unibo.it

Background and aims: Acute-on-Chronic Liver Failure (ACLF) develops during hospitalization in at least 10% of patients with cirrhosis admitted for an acute decompensation (AD) and greatly worsens their prognosis. Aim of the present prospective observational study was the early recognition and stratification of patients at risk for nosocomial ACLF (nACLF) through the identification of rapidly available predictors at hospital admission.
Method: 516 patients with cirrhosis consecutively hospitalized for AD between January 2014 and March 2016 were screened: 106 patients (21%) presented ACLF at admission and were excluded from the analysis; the remaining 410 were enrolled and surveilled during hospitalization for the development of nACLF.
Results: 59 (14%) patients developed nALCF after a median of 7 (IQR 4-18; min 2, max 45) days. At admission, they presented a more severe disease, a higher degree of systemic inflammation, and a higher degree of anemia than those (351; 86%) who remained free from nACLF. Competing risk multivariable regression analysis (considering death, liver transplantation, and discharge as competing events) showed that baseline MELD score (HR = 1.15 [95% CI: 1.10-1.21]; $p < 0.001$), hemoglobin (Hb) level (HR = 0.81 [95% CI: 0.68-0.96]; $p = 0.018$), and leucocyte count (HR = 1.11 [95% CI: 1.06-1.16]; $p < 0.001$) were independent predictors of nACLF. These factors were then categorized according to their optimal cut-off point associated to the highest Youden index (J) at receiver operating characteristic (ROC) curve: 13 points for MELD score, 9.8 g/dl for Hb, and 5.6×10^9/l for leucocyte count. By using these thresholds, the cumulative incidence of nACLF increased with the number of risk factors at admission, being 0, 6, 21 and 59% in patients with 0, 1, 2 or 3 risk factors, respectively ($p < 0.001$). Finally, the development of nosocomial bacterial infection, a well-known precipitating factor of ACLF, significantly increased the risk of nACLF, resulting in a cumulative incidence of 31, 59, and 83% in patients with 1, 2 or 3 risk factors respectively ($p = 0.025$). Interestingly, patients who did not present any of the 3 risk factors at admission did not develop nACLF despite nosocomial infection.
Conclusions: Easily available laboratory parameters, which are related to disease severity, systemic inflammation, and moderate anemia, can be used to identify and stratify at admission patients with AD at increasing risk of developing ACLF during hospitalization.

SAT-153

A systematic review and meta-analysis of the efficacy of magnetic resonance spectroscopy in the diagnosis of hepatic encephalopathy

Georgia Zeng[1,2], Ross Penninkilampi[3], Joga Chaganti[4], Sara Montagnese[5], Bruce Brew[1,6], Mark Danta[1,2]. *[1]St Vincent's Clinical School, Faculty of Medicine, UNSW, Sydney, Australia; [2]Department of Gastroenterology, St Vincent's Hospital, Sydney, Australia; [3]South Western Sydney Clinical School, Faculty of Medicine, UNSW, Sydney, Australia; [4]Department of Medical Imaging, St Vincent's Hospital, Sydney, Australia; [5]Department of Medicine, University of Padua, Padua, Italy; [6]Department of Neurology and Immunology, St Vincent's Hospital, Sydney, Australia*
Email: g.zeng@student.unsw.edu.au

Background and aims: Hepatic encephalopathy (HE) is a neuropsychiatric syndrome occurring in patients with significant liver dysfunction and/or portal-systemic shunting. The pathogenesis of HE is centred around the inter-organ trafficking of ammonia, a neurotoxin of intestinal origin, and exacerbated by infection and inflammatory states. Various imaging modalities have been used to explore pathogenic mechanisms and stratify the severity of HE. The aim of this metanalysis was to assess the value of magnetic resonance spectroscopy (MRS) in assessing patients with HE.
Method: Studies with more than ten cases and reliable HE diagnosis via neuropsychometric testing were identified from the electronic databases PubMed, EMBASE, CINAHL, LILACS and CENTRAL through to 25 July 2018 with no date restriction. Patients were stratified into: healthy controls, NHE (cirrhotic patients without hepatic encephalopathy), MHE (minimal hepatic encephalopathy) and OHE (overt hepatic encephalopathy). Analyses were organized by metabolite studied and brain region examined. Statistical meta-analysis was performed using the metafor package in R (v3.4.1). Pooled standardized mean differences between patient groups were calculated using a random effects model.

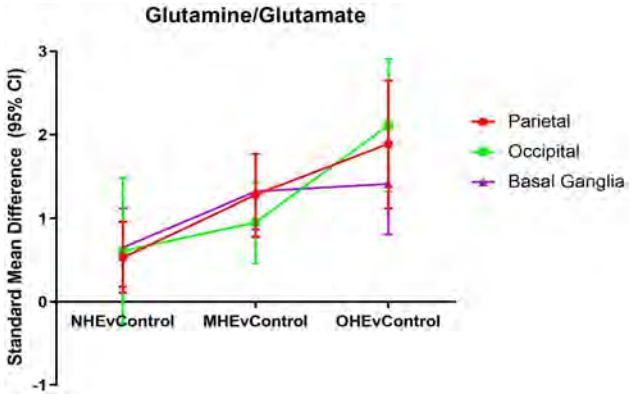

Figure: Glutamate/glutamine results in parietal, occipital and basal ganglia by HE grade. CI: Confidence interval, MHE: minimal hepatic encephalopathy, NHE: cirrhosis without hepatic encephalopathy, OHE: overt hepatic encephalopathy.

Results: From a search of 2198 citations, we identified 298 potentially relevant citations of which 37 studies of MRS imaging in HE met the inclusion criteria. Thirty-one studies (n cases = 1481) included data for Type C (cirrhosis-related) HE. We found the parietal region to be the most reliable in differentiating between patients with and without MHE, with standard mean differences of (+0.82, 95% CI +0.49 to +1.15, $p < 0.0001$, $I^2 = 37.45\%$) for glutamine, (−0.36, 95% CI −0.61 to −0.10, $p = 0.007$, $I^2 = 20.00\%$) for choline, and (−0.77, 95% CI −1.19 to −0.34, $p = 0.0004$, $I^2 = 67.48\%$) for myo-inositol respectively. We also found that glutamine was the metabolite that reliably correlated with HE grade in all brain regions (Figure).
Conclusion: The meta-analysis reveals that MRS changes in glutamine, choline, myo-inositol, particularly in the parietal lobe, correlate with the severity of HE. The vulnerability of the parietal lobe requires further study. MRS may be of value in the diagnosis of HE.

SAT-154

Acute hemodynamic response to I.V propranolol during hepatic hemodynamic study in 26 cirrhotic patients with portal hypertention and nonbleeding esophageal varices. Correlation with esophageal bleeding and survival

Eyal Ashkenazi[1], Yulia Kovalev[1], Alex Haimovich[1], Eli Zuckerman[1].
[1]*Carmel Medical Center, Technion Faculty of Medicine, Liver Unit, Haifa, Israel*
Email: elizuc@clalit.org.il

Background and aims: Bleeding from esophageal varices (EVB) in cirrhosis carries 15-20% mortality. Primary prophylaxis with non-selective beta blockers (NSBB) or esophageal variceal banding reduces bleeding rate from 25% to 15% in 2 years follow-up (2yFU). Hemodynamic response to propranolol is a powerful predictor for EVB. Bleeding rate in responders is lower (5%) during 2 years of follow-up (FU) compared with non-responders (20-25%- almost as "natural history"). Studies indicated that "HVPG (hepatic vein pressure gradient)-guided therapy" may assist in "tailoring" prophylactic treatment for EVB and lower bleeding rates. AIM: To assess HVPG-guided therapy as a tool for to reduce EVB by "tailoring" prophylactic therapy.
Method: 150 hepatic hemodynamic studies (HVPG) were performed in Carmel Medical Center during the last 5 years. Of these, in 26 cirrhotic patients with esophageal nonbleeding varices a hemodynamic response to propranolol was assessed. Responders were treated with propranolol while NR with carvedilol 12.5 mg daily. Baseline clinical, laboratory and hemodynamic data were analyzed. Finally, the rate of bleeding during 2yFU was assessed in the R and NR.
Results: The majority had NASH cirrhosis. 17 of 26 patients (66%) were responders and 9 (33%) were NR. Bleeding rates during 2yFU was lower in the responders compared with the NR (5% vs. 12.5%, respectively, $p = 0.2$). The rate of EVB in all patients during FU was only 8%, supporting the importance of HVPG-guided therapy in avoiding bleeding in NR. However, mortality was similar between the two groups (NR 17% vs. R 22%, p = NS).
Conclusion: HVPG-guided therapy for primary prevention of EVB may be a powerful tool to reduce the risk of EVB in cirrhotic patients. The rate of EVB using HVPG-guided therapy is lower than empiric therapy with NSBB.

Email: mohammad–alkhatib@hotmail.com

Background and aims: A critical role of NS5A in promoting Hepatocellular Carcinoma (HCC) has been recently proposed. Here, we investigated genetic determinants in NS5A associated with HCC.
Methods: This study includes 273 patients (pts) chronically infected with HCV genotype 1b, all DAA-naïve: 50 pts diagnosed with HCC and 223 controls without HCC (154 cirrhotic and 69 No-cirrhotic). NS5A domain-I (aa:1-183) sequences were obtained for all pts, while NS5A domains-II (aa:250-342) and III (aa:356-447) sequences for 27/50 HCC and 65/223 No-HCC pts, by Sanger method from plasma samples. Association of mutations with HCC was assessed by Fisher Exact test. Shannon Entropy (SE) was used to define NS5A residues with significantly higher variability ($SE > 0$) in HCC ($p < 0.05$) compared to No-HCC pts.
Results: HCC and No-HCC pts had comparable median (IQR) log serum HCV-RNA [5.4 (5.2-6.0) vs 5.8 (5.2-6.1) IU/ml] and ALT [64 (37.5-85) vs 62 (41-96) U/L].
Six specific NS5A-I polymorphisms significantly correlated with HCC: H85Y (8.0 vs 1.8%, $p = 0.04$), T122M (8.0% vs 0.9%, $p = 0.01$), M133I (18.0% vs 3.6%, $p < 0.001$), T135I (6.0% vs 0.9%, $p = 0.04$), Q176T (6.0% vs 0%, $p = 0.006$) and Q181E (8.0% vs 0.5%, $p = 0.004$). By SE, three residues were more variable in HCC pts: C13R/S ($SE = 0.272$; $p = 0.01$), N137D/K ($SE = 0.210$; $p = 0.02$) and Q181E/G/H/P ($SE = 0.3$; $p < 0.001$). Mutations at these residues may affect NS5A capability to promote maturation of viral particles, favoring an intracellular accumulation of HCV proteins, a process known to induce cellular stress.
The analysis of NS5A-III domain revealed three specific polymorphisms, with a significantly higher prevalence in HCC: R357K (33.3 vs 10.8%, $p = 0.01$), G381S (22.2% vs 3.1%, $p = 0.003$), P397L (18.5% vs 4.6%, $p = 0.04$). By SE, the residue 390 was characterized by an increased variability in HCC vs no-HCC (S390D/V, $SE = 0.315$; $p = 0.01$). These mutations localize in the NS5A C-terminus, a region known to interact and downregulate p53 activity.
Finally, by SE, three NS5A-II residues appeared more variable in HCC pts: E275A/G ($SE = 0.315$; $p = 0.03$), S328I/P/T ($SE = 0.367$; $p = 0.05$)

and R330D (SE = 0.315; p = 0.04). These mutations reside adjacent to or within NS5A proline-rich domain, known to interact with YB-1 protein, playing a role in neoplastic transformation of hepatocytes.
Conclusions: The association of specific NS5A polymorphisms with HCC provide a focus for further investigations aimed at elucidating the molecular basis of HCV-mediated oncogenesis. These viral signatures, if confirmed in a larger population, could play a crucial role as prognostic markers of HCC, helping to identify patients at higher HCC-risk deserving more intense liver evaluation and/or early treatment.

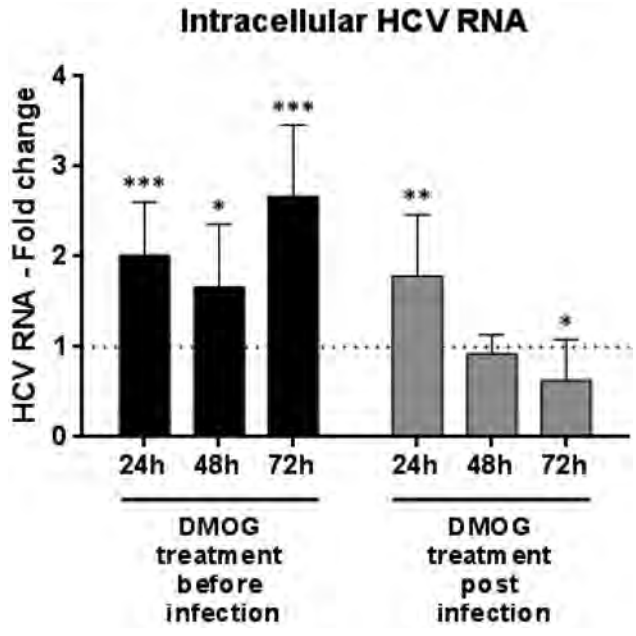
Timing of exposure to dimethyloxalylglycine-mediated hypoxia determines opposite effects in an experimental model of hepatitis C virus infection

Matteo Nazzareno Barbaglia[1], Andrea Magri[2], Rosalba Minisini[1], Mario Pirisi[1]. [1]*Università del Piemonte Orientale, Translational Medicine, NOVARA, Italy;* [2]*University of Oxford, Nuffield Department of Medicine, Oxford, United Kingdom*
Email: rosalba.minisini@med.uniupo.it

Background and aims: A cellular hypoxic state appears to influence hepatitis C virus (HCV) infection and may play a significant role in viral hepatocarcinogenesis. In fact, HCV induces a pseudo-hypoxic state in hepatocytes by stabilizing Hypoxia Inducible Factor-1alpha (HIF-1alpha), thus stimulating the transcription of different hypoxia-related genes (very-low-density lipoprotein receptor, VLDR; vascular endothelium grow factor, VEGF and others). Dimethyloxalylglycine (DMOG), a synthetic analogue of alpha-ketoglutarate, is commonly used to induce HIF signaling and has been shown to directly inhibit mitochondrial function. The aim of our study was to investigate the hypoxia effects mediated by DMOG on HCV infection *in vitro*.
Method: HuH7 cells were treated with DMOG, adding it to culture media either 16 hours before JFH-1 infection (MOI 0.1) or post JFH-1 infection and until the end of experiments. The effects of different DMOG concentrations (64, 320 nM 1.6, 8 and 40 μM) on viral infection were evaluated at 72 hours using the Focus Forming Units (FFU) assay. To verify the influence on intracellular HCV RNA expression, cells were exposed to DMOG (80 μM) at the same time points described above, and viral RNA was quantified at 24, 48 and 72 hours. Data in DMOG treated cells were normalized to those obtained in control infected cells.



Results: In FFU assay, the two higher DMOG concentrations tested showed significant differences (p = 0.013 and p = 0.028, respectively) based on timing in which the treatment is performed (before infection vs post infection). During the time course experiment (Figure), we observed two different kinetics in viral RNA levels. Cells treated before the infection showed a significant up-regulation in intracellular HCV RNA at all time points (2.01 fold at 24h, p = 0.0003; 1.67 fold at 48h, p = 0.017; 2.66 fold at 72h, p < 0.0001). In cells treated post infection, we observed an initial up-regulation at 24 hours (1.78 fold, p = 0.002) and a decrease in HCV RNA at 72 hours compared to control infected cells (0.93 fold at 48h, p = n.s.; 0.63 fold at 72h p = 0.019).
Conclusion: Depending on the timing of exposure, DMOG-mediated hypoxia exerts opposite effects on viral infection. The induction of a hypoxic state shortly before infection significantly favors HCV entry and/or its replication; on the other hand, prolonged hypoxic conditions after the cells have been exposed to the virus impair HCV replication in vitro.

SAT-161

Prevalence of HBV and syphilis co-infection in Ulaanbaatar population, Mongolia

Delgerbat Boldbaatar[1], Uurtsaikh Baatarsuren[2], Purevjargal Bat-Ulzii[1], Oyungerel Lkhagva-Ochir[1], Zolzaya Davaadorj[1], Byambasuren Ochirsum[1], Maral Myanganbayar[2], Khatantuul Boldbaatar[2], Zulkhuu Genden[1], Dahgwahdorj Yagaanbuyant[1], Altankhuu Murdorj[1], Andreas Bungert[1,2], Naranbaatar Dashdorj[1,2], Naranjargal Dashdorj[1,2]. [1]*Liver Center, Ulaanbaatar, Mongolia;* [2]*Onom Foundation, Ulaanbaatar, Mongolia*
Email: b.delgerbat@onomfoundation.org

Background and aims: Mongolia has the highest rate of chronic hepatitis B and D infection in the world. Since currently there are no effective treatment for HBV/HDV infection, it is imperative to prevent further infection. Despite the birth dose HBV vaccination schedule, there are still significant number of acute infections are occurring. Thus, it is important to determine the transmission route of HBV/HDV. Previously it is thought that HBV/HDV is transmitted sexually. In this study, we aim to evaluate prevalence of HBV and syphilis infection pattern in adult population of Ulaanbaatar, Mongolia.
Method: Using the WHO STEP-wise approach, 4515 participants were randomly selected from 8 districts as representative of Ulaanbaatar city population in Mongolia between December 2017 to February 2018. Age and gender matched 552 or 1/8 samples from this random selection were used in the study. All 552 samples were tested for HBsAg by rapid test (CTK Biotech, US) and for syphilis by TPHA (Lorne Laboratories, UK). HBsAg positive samples were tested for anti-HDV by ELISA (Wantai Bio-Pharm, China).
Results: A total of 552 adults, 296 (53.6%) men and 256 (46.4%) women were included in the study. The overall HBsAg prevalence was found to be 51 (9.4%) and the prevalence does not vary significantly among age groups. 68.6% of all HBV infected people tested positive for anti-HDV, which confirm the result (61.0%) of Mongolian general population screening study performed in 2013 (Chen, Oidovsambuu, Hep. 2016). Furthermore, the prevalence of syphilis was determined to be 4.3% in urban adult population. Among syphilis positive subjects, HBsAg and anti-HDV seropositivity were 16.6% (4) and 12.5% (3), while it was 8.9% (47) and 6.1% (32) in syphilis negative group, respectively.

Table 1: HBV, HDV and syphilis prevalence by age groups

Age groups	*20-29*	*30-39*	*40-49*	*50+*	*Percent of sub-group*
Total number of samples (n = 552)	136	144	122	150	
HBsAg (+) (n = 51)	8	11	13	19	
Prevalence (%)	5.9	7.6	10.7	12.7	**9.4**
Anti-HDV (+) (n = 35)	3	5	11	16	
Prevalence (%)	8.5	14.2	31.4	45.7	**68.6**
TPHA (+) (n = 24)	9	6	2	7	
Prevalence (%)	6.6	4.2	1.6	4.7	**4.3**

Conclusion: Prevalence of HBV and syphilis coinfection as well as HDV and syphilis coinfection are high in Mongolian urban population. This result indicates sexual transmission would be one of the main routes of transmission for hepatitis B and B/D in sexual active contingents in Mongolia.

SAT-162

Serum HBV RNA as a predictor of incomplete HBV DNA suppression following initiation of nucleoside therapy in HBV/HIV co-infected individuals

Ruth Byrne[1], Mary Horner[1], Matthew Bruce[1], Jeffrey Gersch[2], Mary Kuhns[2], Gavin Cloherty[2], Kosh Agarwal[1], Ivana Carey[1]. *[1]Kings College Hospital, Institute of Liver Studies, London, United Kingdom; [2]Abbott Laboratories, Chicago, United States*
Email: ruthbyrne@nhs.net

Background and aims: Hepatitis B core-related antigen (HBcrAg) and pre-genomic (pg) HBV RNA are markers of transcriptional cccDNA activity and emerging new biomarkers in the management of chronic HBV. Data on their clinical utility in HBV/HIV co-infection are lacking. A proportion of HBV/HIV co-infected patients, adhering to dual active antiretroviral therapy (ART) with suppressed HIV, have persistent HBV replication. In this pilot study we aimed to measure HBcrAg and HBV RNA concentrations, in chronic HBV/HIV patients at initiation of tenofovir (TDF) based ART, focusing on prediction of incomplete HBV suppression as an end point.
Method: 30 chronic HBV/HIV patients, on TDF based ART, were identified retrospectively and classified into 2 groups: those with fully suppressed HIV (< 50 copies/ml) and HBV (< 20IU/ml) at week 48 of ART (group A, n = 15) and those with persistent HBV replication despite undetectable HIV at week 48 (group B, n = 15). HBcrAg and pgHBV RNA were tested at baseline (initiation of TDF based ART). PgHBV RNA was measured by real-time PCR research assay Abbott Diagnostic (Butler E et al. Hepatology 2018) HBcrAg was measured by CLEIA assay (Fujirebio).
Results: There were no significant differences between groups A and B in sex, age, HBV genotypes, and baseline CD4 and baseline HBV DNA. There was a higher proportion of HBeAg+ patients in group B (87 v 47%, P < 0.05) but more patients in group A (43 v 0%, p < 0.05) achieved HBeAg loss by week 48. At baseline group B patients had higher HBsAg levels (4.53 v 3.99 $\log_{10}$ IU/ml, p < 0.01), HBcrAg levels (7.00 v 5.10 $\log_{10}$ U/ml, p < 0.001) and pgHBV RNA levels (6.23 v 3.82 $\log_{10}$ U/ml, p < 0.05) compared to group A. A baseline HBcrAg cut-off value of 6.85 $\log_{10}$ U/ml had good predictive value for incomplete HBV suppression at 48 weeks (sensitivity 93%, specificity 80%, PPV 82% and NPV 92%) and the area under the ROC curve (AUROC) was good at 0.891 (0.764, 1.000; 95% CI). A baseline pgHBV RNA cut off value of 5.42 $\log_{10}$ U/ml had good predictive value for incomplete HBV suppression at 48 weeks (sensitivity 80%, specificity 80%. PPV 80% and NPV 80%) and the AUROC was good at 0.830 (0.639, 1.000; 95% CI).
Conclusions: In this small HBV/HIV cohort baseline HBcrAg and pgHBV RNA levels were higher in those who failed to suppress HBV DNA despite good adherence to HBV active ART. There may be a role for these biomarkers in risk stratification of co-infected patients warranting closer surveillance and management. A larger cohort is planned to enable evaluation of their combined predictive with the aim to fully establish the clinical utility of HBcrAg and HBV RNA in this group.

SAT-163

HBeAg-negative chronic infection: more complex and conserved quasispecies in Hepatitis B X gene

Carolina González[1], Maria Francesca Cortese[1,2], Josep Gregori[2,3,4], Mar Riveiro Barciela[4,5], Rosario Casillas[1,2], Marçall Yll[1,2], Cristina Godoy[1,2], Sara Sopena[1,4], Josep Quer[2,4], Ariadna Rando[1], Rosa Lopez-Martinez[1], Rafael Esteban-Mur[4,5], Maria Buti[4,5], David Tabernero[1,4], Francisco Rodríguez-Frías[1,4]. *[1]Vall D'hebron University Hospital, Biochemistry and Microbiology/Liver Pathology Unit, Barcelona, Spain; [2]Vall D'hebron Research Institute, Liver Unit, Barcelona, Spain; [3]Roche Diagnostics SL, Sant Cugat del Vallès, Spain; [4]Ciberehd, Instituto De Salud Carlos III, Madrid, Spain; [5]Vall D'hebron University Hospital, Department of Internal Medicine/Liver Unit, Barcelona, Spain*
Email: maria.cortese@vhir.org

Background and aims: Patients with HBeAg-ve chronic infection (CI) usually have a favourable prognosis, however a small but relevant percentage are at risk for Hepatocellular Carcinoma (HCC). HBV X protein (encoded by *HBX* gene) plays a key role in viral replication and HCC development. The aim of this study is to analyse the complexity and conservation of the CIs viral quasispecies (QS) at the 5 'end of *HBX* and compare them with other clinical stages.
Method: Samples from 54 HBeAg-ve patients were included: 16 CI, 15 chronic hepatitis B (CHB), 6 liver cirrhosis (LC) and 17 HCC. All were treatment-naïve, with HBV-DNA > 1000 IU/ml, and infected with A-H viral genotypes. A region between nucleotides (nt) 1255 and 1611 was analyzed by Next Generation Sequencing (NGS). QS complexity was defined by Shannon entropy and Gini-Simpson indices, frequency of mutations (Mf) and nucleotide diversity (Pi). Conservation was studied by calculating the information content (IC) of each nt or aminoacid (aa) position. Intergroup variability was studied by calculating the groups' IC deviation from the general mean. The presence of aa mutations between groups was identified by aligning the haplotypes to the genotype consensus.
Results: CI patients showed higher Mf (median [IQR] = 17.5 [9.5-35.6]) and Pi (median [IQR] = 0.03 [0.02-0.04]) than CHB and HCC (Mf median [IQR] = 3.1[2.7-11.6] and 3.6[1.6-8.0]; Pi median [IQR] = 0.005 [0.004-0.02] and 0.005 [0.003-0.013] for respectively CHB and HCC). Four hyper-conserved regions were highlighted at nt level (1255-1286, 1411-1435, 1519-1543, 1575-1605), and one at aa level (63-72). A similar trend of conservation was observed between the groups, although the CIs were more conserved, mainly related to the CHBs (nt 1300-1375 and aa 20-50, p value < 0.05). A genotype D-specific pattern of mutations (A12S/P33S/T36D-G/P46S) was found in CI (median frequency of 81.7%).
Conclusion: HBeAg-ve CI patients presented more complex and conserved QS than the other groups, thus suggesting the presence in viral population of more haplotypes at low frequency with a higher mutational rate. The identified pattern of mutations in genotype D could indicate a genotype-specific evolution and may explain the low HBV replication rate in CIs. The observed hyper-conserved regions could be efficient targets for directed gene-therapy.

Characterization of HBV kinetics during infection and treatment in primary human hepatocytes

Yuji Ishida[1,2], Preeti Dubey[3], Masataka Tsuge[2,3], Mikaru Yamao[1], Chise Tateno[1,2], Susan Uprichard[3], Harel Dahari[3], Kazuaki Chayama[2]. *[1]PhoenixBio Co., Ltd, Higashi-Hiroshima, Japan; [2]Hiroshima University, Hiroshima, Japan; [3]Loyola University Medical Center, Maywood, United States*
Email: harel.dahari@gmail.com

Background and aims: Detailed characterization of HBV kinetics during infection and treatment in primary human hepatocytes (PHH) is lacking. Thus, we characterized HBV kinetics in cultured PHH.
Method: Fresh PHH isolated from chimeric mice with humanized livers (PXB-cells, PhoenixBio, Co., Ltd), were inoculated with HBV in the presence of PEG8000 for 1 day (AB246341; genotype C) as described (Am J Pathol 2015;185:1275-85). Extra- and intracellular HBV DNA, extracellular HBsAg and cccDNA were measured at days 1, 2, 3, 5, 7, 10 and 12 post-inoculation (pi). Entecavir, ETV (10μM) and HBV entry inhibitor Myr-preS1 (6.25μg/ml) were initiated at inoculation and 24 h pi, respectively.
Results: Extra- and intracellular HBV DNA at day 1 pi were 6.78 and 4.39 $\log_{10}$ cp/well, respectively. Four kinetic phases of HBV infection initiation were identified for both extra- and intracellular HBV DNA. An expected 1st phase decline from day 1-3 of ~1.62 logs (half-life, $t_{1/2}$ = 9 h) and from day 1-2 of ~0.3 logs ($t_{1/2}$ = 24 h), respectively, followed by a 2 and 3 day plateau/eclipse phase, respectively. Thereafter, extra- and intracellular HBV DNA increased (doubling time, t_2 = 17h and t_2 = 24 h) (phase 3), followed by a slower increase (t_2 = 56 h and 77 h) from day 7 (phase 4). In contrast, HBsAg exhibited 2 kinetic phases: 1st phase decline of ~2.19 logs ($t_{1/2}$ = 7h) from an initial 1.65 cp/well, followed by a 2nd phase increase (t_2 = 47 h) from day 3 pi. A biphasic cccDNA amplification was observed with 1st phase rapid increase (t_2 = 7 h) between day 1 and 2, followed by a slower 2nd phase increase (t_2 = 137 h). Myr-preS1 had no effect on extra/intracellular HBV DNA or HBsAg. A similar 1st phase decline in extra/intracellular HBV DNA and HBsAg was seen ± ETV, but no subsequent increase was observed under ETV in contrast to untreated PHH. Interestingly, under ETV, cccDNA 1st phase increase was slower (t_2 = 31 h) and longer followed by a plateau.
Conclusion: A multiphasic HBV infection kinetics was observed in PHH. As anticipated, when initiated at the time of inoculation, ETV does not prevent infection, but does prevent intra/extracellular HBV DNA increase as well as 2nd phase accumulation of cccDNA. As expected, Myr-preS1 treatment 24 h pi did not prevent infection, but the lack of effect on subsequent intra/extracellular HBV DNA and HBsAg kinetics indicates nonsignificant HBV spread during this 12 day infection.

SAT-165

Identification of chromatin-accessible domains on the host genome and hepatitis B virus mini-chromosome in infected primary human hepatocytes

Oceane Floriot[1], Giuseppe Rubens Pascucci[2], Matteo Pallocca[3], Francesca de Nicola[4], Michel Rivoire[5], Marie-Laure Plissonnier[1], Mirjam Zeisel[1], Massimo Levrero[1,2], Francesca Guerrieri[1,2]. *[1]Cancer Research Center of Lyon (CRCL), INSERM U1052, Lyon, France; [2]Istituto Italiano di Tecnologia, Center for Life Nano Science, rome, Italy; [3]Regina Elena National Cancer Institute, UOSD SAFU, rome, Italy; [4]Regina Elena National Cancer Institute, Oncogenomic and Epigenetic Unit, rome, Italy; [5]Centre de lutte contre le cancer Léon Bérard (CLB), Lyon, France*
Email: massimo.levrero@gmail.com

Background and aims: HBV remains a major health problem worldwide with 250 million people chronically infected and at risk to develop liver cirrhosis and hepatocellular carcinoma (HCC). A complex host-virus interaction is responsible for both the dysfunction of HBV-specific B/T cells and the persistence of the viral cccDNA mini-chromosome, the two key challenges for HBV cure. The extent of HBV impact on the cellular transcriptome remains controversial. Transcriptional activation in eukaryotic cells has been tightly linked with disruption of nucleosome organization at open or accessible genomic sites of remodeled chromatin. We used ATAC-seq (assay for transposase-accessible chromatin followed by high throughput sequencing) to probe open chromatin and detect early changes in chromatin accessibility in HBV-infected PHHs.
Methods: ATAC-seq is based on the ability of hyperactive Tn5 transposase to fragment DNA and integrate into active regulatory regions in vivo. Nuclei from HBV infected (2h/24h/72h) PHHs were used for the Tn5 tagmentation and the subsequent library preparation. mRNA libraries were prepared in parallel using the TruSeq® Stranded RNA HT (w/Ribo-Zero™). Both ATAC-Seq and RNA-Seq libraries were sequenced (75×2 cycles) on a NextSeq 500 Illumina.
Results: After HBV infection an increasing number of genomic sites (including proximal extended promoter regions, distal intragenic and intergenic regions) change their chromatin accessibility over time (278 at 2h, 350 at 24h and 1095 at 72h), with a prevalence of more open, potentially transcriptionally active regions. About 30% of the impacted genes were non-coding RNAs (ncRNAs). RNA-seq analysis performed at the same times post infection showed an increasing number of differentially expressed genes (DEGs). Accessible chromatin regions are enriched for the binding motifs of the transcription factors SMADs, STAT3, TP53 and Suz12, a partner of Ezh2 in the PRC2 complex, and an enrichment in genes/ncRNAs involved in viral replication and the establishment of a pre-neoplastic state. The alignment of ATAC-seq and RNA-seq reads to the HBV genome allowed us to correlate the evolution of cccDNA chromatin accessibility with cccDNA transcription at the different times post-infection.
Conclusion: Altogether these results challenge the commonly accepted concept of HBV being a "stealth" virus and show that HBV infection impacts on host cell chromatin landscape and transcription.

Hepatitis C virus-based experimental models in the study of liver-driven altered glucose homeostasis

Diana Gomes[1], Giacomo Gastaldi[2], Cyril Sobolewski[3], Nicolas Goossens[4], Michelangelo Foti[3], Sophie Clément-Leboube[5], Francesco Negro[4]. *[1]University of Geneva, Department of Pathology and Immunology, Geneva, Switzerland; [2]Geneva University Hospital, Division of Endocrinology, Geneva, Switzerland; [3]University of Geneva, Department of Cell Physiology and Metabolism, Geneva, Switzerland; [4]Geneva University Hospital, Division of Gastroenterology and Hepatology, Geneva, Switzerland; [5]Geneva University Hospital, Division of Clinical Pathology, Geneva, Switzerland*
Email: diana.gomes@unige.ch

Background and aims: Infection with hepatitis C virus (HCV) has been associated with insulin resistance. Although hepatitis C is now an easy-to-treat disease, the study of HCV physiopathology can still be useful as a model of altered glucose homeostasis. We have recently shown a significant improvement of peripheral insulin sensitivity upon viral replication suppression, in a cohort of 12 non-diabetic, lean patients infected with HCV genotype 3a treated with an interferon-free regimen. Concomitantly, the levels of some of circulating factors relevant in glucose homeostasis were significantly modified by treatment, suggesting the presence of liver-to-peripheral organ crosstalk (Gomes et al, AASLD 2018). We now aim to further investigate the role of the liver in the control of glucose homeostasis, by using HCV-based experimental models.
Method: Insulin-stimulated glucose uptake was assessed in human primary adipocytes treated either with sera from HCV-infected or non-infected subjects. C57BL/6J mice overexpressing the HCV-3a core protein in hepatocytes were subjected to glucose and insulin tolerance tests (ITT). Hepatic lipid accumulation was evaluated by oil-red-O staining. Phosphorylation level of Akt and AS160 was assessed by immunoblotting. Hepatokine expression levels were evaluated in the liver of HCV-3a core mouse model, and further

assessed in human and mice models of non-alcoholic fatty liver diseases (NAFLD).
Results: Insulin-stimulated glucose uptake was reduced in adipocytes treated with sera from HCV-infected patients as compared to non-infected controls. Overexpression of the HCV-3a core protein in the mouse liver led to the development of steatosis. Insulin sensitivity of mice was reduced, as shown by ITT and by decreased insulin-induced Akt-S473 phosphorylation in both liver and skeletal muscle. In mice livers, the expression of some hepatokines, previously found to be altered in treated patients of our cohort (i.e. Fetuin-A, Igfbp7, Angptl6 and Rbp4), positively correlated with the level of HCV core expression. Moreover, Igfbp7 mRNA expression was increased also in livers of high-sucrose, high-fat diet mice. In a human transcriptome meta-analysis of NAFLD patients, *IGFBP7* upregulation was associated with an advanced severity of the disease.
Conclusion: Taken together, these data indicate that HCV infection affects the hepatokine secretion profile to induce peripheral insulin resistance, providing a model of hepatogenous diabetes.

Email: gundlach@bnitm.de

Background and aims: Characterization of viral RNA-genomes seems to be still challenging. The lack of proof-reading-function of the RNA-dependent RNA-polymerase causes high variability-and in case of Hepatitis E it encourages development of quasispecies. High variability is linked to high pathogenicity, virulence and therapeutic resistance. Some mutations of Hepatitis E are associated with therapeutic failure of Ribavirin. Our aim was to establish a cost-efficient method for routine-diagnostic approaches to determine specific mutations and monitor quasispecies evolution to adapt individual therapy.
Method: We designed 203 of biotinylated 120mer-RNA-probes to prove all genotype 1 and 3 Hepatitis E viruses via BaitFisher method. Since 2016 blood-donors are tested to Hepatitis E-infections at Universitätsklinikum Hamburg-Eppendorf. Positive donors participated at this study. Additionally, we collected samples from a chronically infected patient-cohort. Plasma-samples of both cohorts were used for our investigations. Concentrated RNA-extracts were transcribed to cDNA, which was fragmentated via sonification (Diagenode Bioruptor®) to 200-500 bp fragments, adapter-sequences ligated and amplified. Biotinylated probes were hybridized to viral sequences and isolated via streptavidin-beads. Remaining content of viral origin was amplificated, following by a paired-end 2×250 bp-sequencing in Illumina MiSeq®.
Results: HEV-genomes could be enriched 10^4 fold. We obtained wide genome sequences from patients with viral loads > 10^3 copies/ml and found quasispecies in samples with viral loads > 10^4 copies/ml.
Conclusion: Using Capture Probe Targeting we succeed sequencing HEV-genomes from blood-samples via NGS. Reducing the number of probes lowered costs to 300-400 € per sample depending to depth of sequencing to determinate variants. This method allows to determinate quasispecies and viral evolution.

SAT-168

HBV splice DNA forms detected in serum in majority of patients with chronic HBV infection

Charlotte Hedskog[1], Silvia Chang[1], Bandita Parhy[1], Dara Burdette[1], Ondrej Podlaha[1], Wan-Long Chuang[2], Kosh Agarwal[3], Edward Gane[4], Anuj Gaggar[1], Simon Fletcher[1], Hongmei Mo[1], Evguenia S Svarovskaia[1].
[1]Gilead Sciences, Inc, Foster City, United States; [2]Kaohsiung Medical University Hospital, Kaohsiung Medical University, Department of Internal Medicine, Kaohsiung, Taiwan; [3]Institute of Liver Studies, King's College Hospital, London, United Kingdom; [4]New Zealand Liver Transplant Unit, Auckland City Hospital, Auckland, New Zealand
Email: charlotte.hedskog@gilead.com

Background and aims: Splicing of the HBV genome has been extensively described in the literature. However, to-date HBV spliced forms have not been comprehensively characterized in large cohorts of patients with chronic hepatitis B (CHB). Here, the presence of HBV DNA spliced forms were investigated in > 1600 serum samples from CHB patients.
Method: Full HBV DNA genome deep sequencing data of 1622 CHB serum samples from clinical trials was analyzed using custom software. The presence of 23 previously described HBV spliced forms was investigated. In addition, qPCR analysis was used for quantification and validation of two major slice junctions. Associations of spliced forms with disease characteristics were also performed.
Results: Overall, HBV DNA spliced forms using a 1% cutoff were detected in 67% (74/112), 94% (308/328), 77% (605/783) and 66% (262/399) patients serum samples with genotypes A, B, C and D HBV infection, respectively. The most commonly observed splice junction, observed in 1070 patients, had donor and acceptor site at nucleotide position 2447 and 489 with intra-patient frequency of 1% to < 5%, 5% to < 10%, 10% to < 20% and ≥ 20% in 37%, 26%, 23% and 17% of patients, respectively. Detection of spliced forms were confirmed by quantitative PCR analysis of the two most common splice junctions in GTD with donor and acceptor site at nucleotide position 2447-489 and 2067-489. By qPCR the frequency of DNA spliced form was slightly lower compared to deep sequencing, in line with known amplification bias towards short amplicons. The presence of spliced forms > 1% was associated with HBeAg positive status across genotype A to D and independent of viral load (p value < 0.001). In addition, for GTC patients with HBsAg-loss or seroconversion all patients (6/6) had spliced forms > 1% with donor and acceptor site at nucleotide position 458 and 1385 respectively, whereas the overall prevalence of this splice junction in GTC was 8.9% (70/783). Nucleotide sequence of splice donor and acceptor sites and the subsequently generated open reading frames were highly conserved across genotypes (> 95%). The number of different putative proteins from splice variants is 34 with 11 of them containing a novel amino acid sequence.
Conclusion: There is a high prevalence of HBV spliced DNA forms observed by deep sequencing across GTA-D patient serum samples with potential relevance to disease characteristics and treatment outcomes.

SAT-169

Prevalence of resistance associated substitutions and phylogeographic analysis of HCV infection in Russia

Vasily Isakov[1], Charlotte Hedskog[2], Joel Wertheim[3], Anuj Gaggar[2], Hongmei Mo[2], Natalia Geivandova[4], Morozov Viacheslav[5], Elena Bessonova[6], Natalya Gankina[7], Evguenia S Svarovskaia[2], Konstantin Zhdanov[8].

Prevention, Krasnoyarsk, Russian Federation; [8]Department of Infectious Diseases of Kirov Military Medical Academy, St. Petersburg, Russian Federation
Email: charlotte.hedskog@gilead.com

Background and aims: The prevalence of HCV infections in Russia is estimated to be 3-5% of the population with 1b and 3a subtypes being predominant. However due to limited HCV sequence availability the prevalence of resistance associated substitutions (RASs) in Russia is largely unknown. Here the prevalence of RASs as well as genetic similarity of Russian HCV strains to other countries was investigated.
Method: Resistance and phylogeographic analysis were performed on deep sequencing data of NS3, NS5A and NS5B from baseline patient samples with genotype (GT)1a, 1b and 3a HCV infection from Russia (n = 375), Asia (n = 1222), Europe (n = 2014) and North America (n = 4756).
Results: Differences in prevalence of RASs in Russia was observed compared to other regions (Table). For example, the prevalence of Y93H in 1b was slightly lower in Russia (6%) compared to 20% in Asia. Moreover, the prevalence of L159F in NS5B was comparable to specific countries in Europe, i.e. Estonia, Austria, Italy and Spain (26%-39%) but lower in Asia and North America. Of note, in Estonia 25% of population is ethnically Russian, who migrated to the country after WWII. In agreement, phylogeographic analysis revealed that L159F in GT 1b was originating 80-90 years ago in France with multiple subsequent introductions into Spain, Italy and Russia. In addition, GT 1b had four major introductions from USA and Western Europe into Russia whereas the origin of GT 3a in Russian linages was not as apparent.

		RAS	Russia	Asia	Europe	North America
GT1b	NS3	Any	113/245 (46%)	107/438 (24%)	95/255 (37%)	95/376 (25%)
		Y56F	103/245 (42%)	64/438 (15%)	82/255 (32%)	62/376 (17%)
	NS5A	Any	47/247 (19%)	376/1091 (35%)	138/593 (23%)	215/892 24%)
		L31M	7/247 (3%)	53/1091 (5%)	34/593 (6%)	51/892 (6%)
		Y93H	14/247 (6%)	219/1091 (20%)	63/593 (11%)	73/892 (8%)
	NS5B	Any	91/248 (37%)	29/1103 (3%)	121/552 (22%)	51/877 (6%)
		L159F	88/248 (36%)	13/1103 (1%)	113/552 (20%)	43/877 (5%)
GT3a	NS3	Any	1/82 (1%)	NA	2/434 (0.5%)	5/496 (1%)
	NS5A	Any	20/101 (20%)	4/70 (6%)	128/741 (17%)	126/902 (14%)
		L30S	10/101 (10%)	0/70 (0%)	24/741 (3%)	14/902 (2%)
		Y93H	2/101 (2%)	2/70 (3%)	35/741 (5%)	55/902 (6%)
	NS5B	Any	1/107 (0.9%)	0/70 (0%)	16/835 (2%)	25/937 (3%)

Conclusion: Prevalence of RASs as well as migration patterns showed that HCV in Russia were more similar to strains from Western Europe and North America than Asia. Information on migration patterns and prevalence RASs in Russia may provide information for treatment management as well as for planning HCV elimination.

SAT-170

A phenotypic resistance assay for clinical HCV isolates could help rationalise DAA therapy in individuals experiencing recurrent virologic failure

Christopher R. Jones[1], Dr. Ana Maria Ortega-Prieto[1], Graham Cooke[1], Marcus Dorner[1]. [1]*Imperial College London, Division of Infectious Diseases, London, United Kingdom*
Email: c.jones@imperial.ac.uk

Background and aims: Resistance-associated substitutions (RAS), particularly those that confer resistance to non-structural protein 5A (NS5A) inhibitors, can complicate the treatment of hepatitis C virus (HCV) infection. Current resistance assays use either JFH1-based HCV containing the RAS of interest or subgenomic replicons with an individual's subcloned NS5A region. However, a more life-like model would allow variants to be interpreted in the context of the individual's quasispecies pool. It was recently identified that over-expression of SEC14L2 in Huh7.5 cells allowed infection with clinical HCV isolates. Herein we present this system as a phenotypic resistance assay.
Method: SEC14L2 is a cytosolic lipid-binding protein that supports replication of clinical HCV isolates in Huh7.5 cells. We performed infection assays using this cell culture system and confirmed susceptibility to infection with clinical isolates. Next, we optimised cell culture conditions in order to enhance levels of infection. Finally, we performed phenotypic resistance assays using 100-fold dilutions of Ledipasvir. HCV-infected plasma was acquired from a local tissue bank or leftover plasma from the clinical viral sequencing service. All procedures were conducted in accordance with the principles of the Declaration of Helsinki.
Results: Over-expression of SEC14L2 in Huh7.5 cells enables pangenotypic replication of clinical HCV isolates. The serum-free William's E medium supplemented with hepatocyte maintenance supplements and dexamethasone enhances levels of infection relative to standard cell culture media. This may be explained by an alpha-tocopherol dose-dependent enhancement of infection. Testing of genotype 1a clinical isolates found EC50 values comparable to that reported in replicon assays (range < 1pM-15.4pM). Testing of a genotype 1a clinical isolate containing the Y93H RAS (> 20% cut off) found an EC50 value 3-4x higher than wild-type (relative to G1a replicon assay); this is markedly lower than the > 1000x fold reported in the literature.
Conclusion: The SEC14L2 cell culture systems allows phenotypic resistance susceptibility testing in a manner that accounts for the quasispecies pool. Individuals with multiple failures to DAA combination therapy may benefit from a personalised approach to re-treatment and data from this assay can support the rationalisation of therapy.

SAT-171

HEV seroprevalence in blood donors in Turkey: Comparison of two commercial anti-HEV total Ab ELISA kit

Osman Yaşar[1], Güniz Cengiz[1], Ersin Karatayli[1], Mehtap Kizilpinar[1], Esra Yurdcu[1], Rabia Albayrak[2], Aysel Güven[3], Önder Arslan[4], Zeynep Ceren Karahan[5], Baris Otlu[6], Huseyin Guducuoglu[7], Selma Gökahmetoglu[8], Elife Berk[8], Özlem Gitmisoglu[9], Rüchan Sertöz[10], Cihan Yurdaydin[1], MITHAT Bozdayi[1], Senem Ceren Karatayli[1]. [1]*Ankara University, Hepatology Institute, Ankara, Turkey;* [2]*Ankara University, Department of Biometry Genetics, Ankara, Turkey;* [3]*Baskent University, Ankara, Turkey;* [4]*Ankara University, Faculty of Medicine, Department of Hematology, Ankara, Turkey;* [5]*Ankara University, Faculty of Medicine, Microbiology Department, Ankara, Turkey;* [6]*Inönü University, Faculty of Medicine, Department of Medical Microbiology, Malatya, Turkey;* [7]*Yuzuncu Yıl University, Department of Medical Microbiology, Faculty of Medicine, Van, Turkey;* [8]*Erciyes University, Microbiology Department, Medical Faculty, Kayseri,*

Turkey; [9]Public Hospitals Administration of Turkey, Kahramanmaras, Turkey; [10]Ege University, Faculty of Medicine, Department of Medical Microbiology, Izmir, Turkey
Email: senemceren@gmail.com

Background and aims: Previous Hepatitis E virus (HEV) seroprevalance studies have shown high variabilities in Turkey, leading to conflicting results. We aimed to re-evaluate HEV seroprevalance in blood donors by the sensitive Wantai and the widely used Dia.pro HEV total antibody (Ab) ELISA assays in Turkey and compare their performances.
Method: A total of 2011 blood samples, (807 from Ankara, 243 from Kayseri, 284 from İzmir, 200 from Malatya, 200 from Kahramanmaraş, and 277 from Van) were collected from volunteer blood donors. Each serum sample was tested for serum immunoglobulin G and M anti-HEV (total Ab) both by Wantai (Beijing, China) and Dia.pro (Milan, Italy) EIA kits. Serum samples with an absorbance greater than the cutoff value were considered as positive. Serial dilutions of the WHO anti-HEV reference serum were used to determine the concentration of anti-HEV antibody at the cut-off for each ELISA kits. For statistical analysis, $\chi 2$ test was performed and $p < 0.05$ was considered significant.
Results: The country-wide HEV seroprevalence was calculated as 11.3% (Dia.Pro) and 12.1% (Wantai) with seropositivity rates as 12.0%-12.5% in Ankara, 7.0%-7.8% in Kayseri, 14.5%-15.6% in Malatya, 8.1%-9.7% in İzmir, 14.5%-15.5% in Kahramanmaraş and 11.9%-13% in Van by Dia.Pro and Wantai kits, respectively. Among 2011 samples, 22 samples, which were negative with Wantai assay, were detected as anti-HEV positive by Dia.Pro assay, while 37 samples were anti-HEV positive with Wantai assay which were negative with Dia.pro indicating variability between the assays. Anti-HEV total Ab positivity was consistently detected with both assays in 206 (10.6%) samples. The lowest detectable antibody concentrations were 0.16 and 0.14 WHO units/ml, for Dia.Pro and Wantai assays, respectively.
Conclusion: Compared to the previous studies, HEV was shown to have a higher overall seroprevalance in Turkey as reflected by the results from the cities included in the study. Although not significant, the calculated seroprevalances demonstrated that Wantai kit has found higher rates of HEV positivity for all cities compared to Dia.pro kit. Despite the fact that similar results from both kits indicated a reliable accuracy for the calculated HEV prevalence, the observed variability in assay performances might be explained by the differences in HEV antigens used in each assay suggesting that the interpretation of the HEV serology results should be done with caution.

SAT-172

Novel mathematical modeling of HBsAg kinetics during long-term antiviral treatment: A pilot study

Hwi Young Kim[1], Tae Soo Jang[2], Hee-Dae Kwon[2], Joo Ho Lee[3]. *[1]Ewha Womans University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South; [2]Inha University, Department of Mathematics, Incheon, Korea, Rep. of South; [3]CHA Bundang Medical Center, Department of Internal Medicine, Seongnam, Korea, Rep. of South*
Email: hwiyoung@gmail.com

Background and aims: The kinetics of serum hepatitis B surface antigen (HBsAg) levels during nucleos (t)ide analog (NA) treatment needs to be elucidated for the prediction of off-treatment durability of response in patients with chronic hepatitis B (CHB). The aim was to develop a novel method of mathematical modeling for HBsAg kinetics under long-term NA treatment.
Method: In this pilot study, we reviewed viral decay patterns and HBsAg kinetics in 184 CHB patients from a tertiary hospital in Korea who were treated with entecavir or tenofovir as their initial NAs, without evidence of antiviral resistance. HBsAg and immune effectors were added as new compartments in the model equations for hepatitis B viral dynamics. Parameter estimation was performed using the non-linear least square minimization method and non-linear Kalman filter algorithm.
Results: Mean age was 52.1 ± 10.9 years, and 112 patients (60.9%) were male. Patients received either entecavir (93, 50.5%) or tenofovir (91, 49.5%). Median follow-up duration was 72.5 months. At baseline, 70 patients (38.0%) were HBeAg-positive. Baseline liver stiffness by transient elastography was 6.9 kPa (median; interquartile range [IQR], 4.6-11.1), and alanine aminotransferase (ALT) was 81.0 IU/L (IQR, 39.3-161.8). Baseline HBV DNA and HBsAg titers were 6.26 Log_{10}IU/ml (IQR, 5.34-7.54) and 2420.50 IU/ml (IQR, 1083.25-

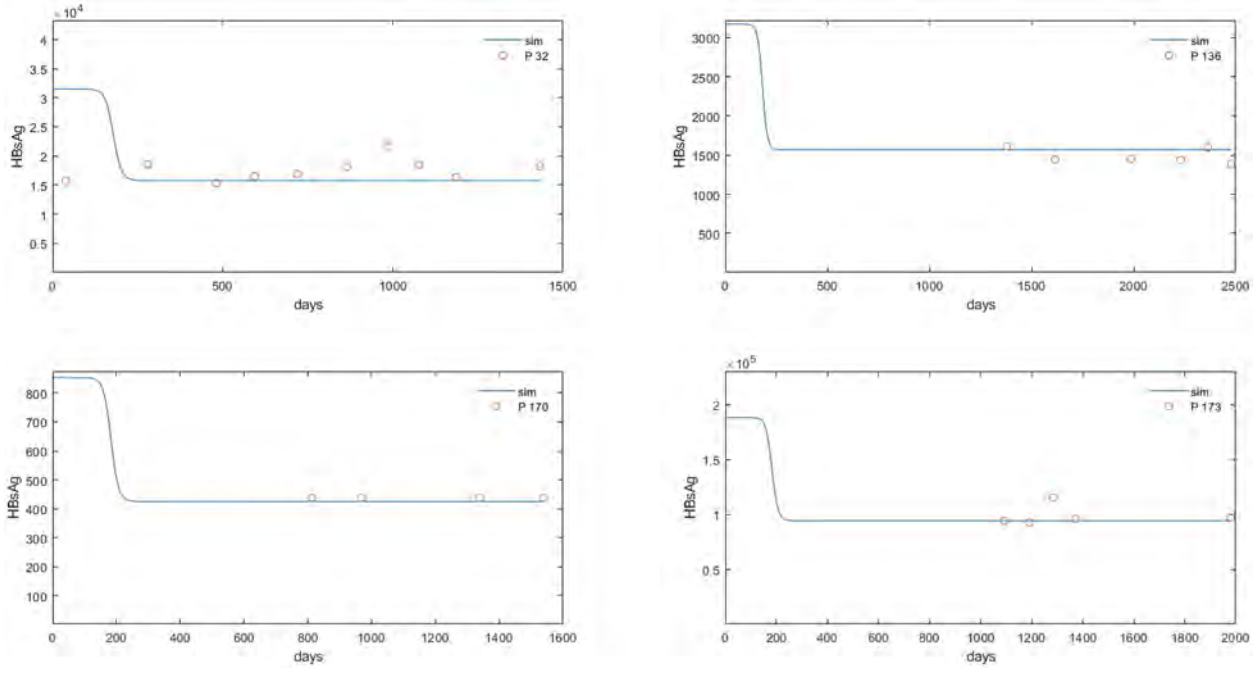

Figure: (abstract: SAT-172)

5342.12), respectively. The model equations for viral and HBsAg dynamics during antiviral treatment were developed as follows, considering i) both cytolytic and non-cytolytic clearance of infected cells, and ii) cccDNA and integrated HBV DNA in the host genome as dual sources of HBsAg:

$dT_1/dt = S\text{-}d_{T1} * T_1 - (1-\eta)\, b * V * T_1$

$dT_2/dt = \alpha * f * I * E\text{-}d_{T2} * T_2 - (1-\eta)\, b * V * T_2 + m_2 * T_2$

$dI/dt = ((1-\eta)\, b * V\, (T_1 + T_2) + m_1 * I\text{-}d_I * I\text{-}\alpha * I * E$

$dV/dt = (1-\varepsilon)\, p * d_I * I\text{-}c * V$

$dE/dt = S_E + b_E * I * E/\, (I + k_E)\text{-}d_E * E$

$sAg = \gamma * T_2/\, (T_2 + k_T) + \delta * I/\, (I + k_I)$

(NOTE. T, target cell; I, infected cells; V, virus; E, immune effectors; sAg, HBsAg; d, death rate; η, treatment efficacy of inhibiting de novo infection; b, de novo infection rate of T; f, calibration coefficient of α for T; m, mitotic production rate of I; α, E-induced clearance rate of I; ε, treatment efficacy of inhibiting viral production; p, viral production rate by I; c, clearance rate of free virions; S_E, production rate of E; b_E, maximum birth rate for E; k_E, Michaelis-Menten type coefficient for E)

Figure 1 demonstrates sample visualization of the HBsAg kinetics with fitted curves using the model equations.

Conclusion: Our novel mathematical model for hepatitis B viral dynamics showed promising results in terms of long-term fitting of HBsAg kinetics. These results need further validation in various clinical settings including discontinuation of NAs.

SAT-173

Global patterns of HBV genotype E epidemic dispersal from Africa determined using a full-genome phylogenetic and phylogeographic approach

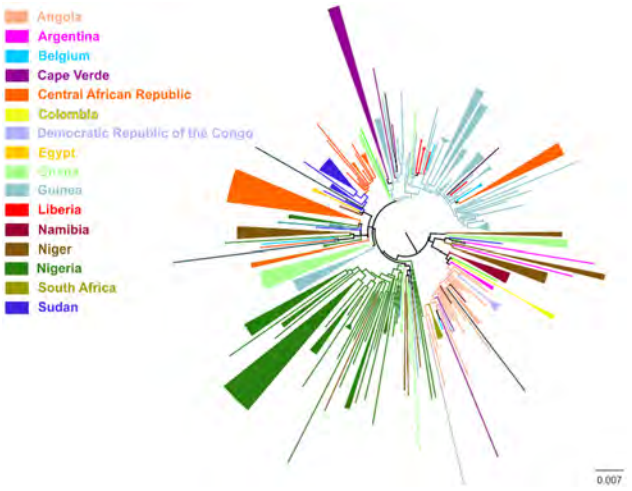
Evangelia-Georgia Kostaki[1], Louizer Ingasia[2], Dimitrios Paraskevis[1], Anna Kramvis[2]. [1]*Medical School, National and Kapodistrian University of Athens, Department of Hygiene, Epidemiology and Medical Statistics, Athens, Greece;* [2]*Hepatitis Virus Diversity Research Unit, University of the Witwatersrand, Department of Internal Medicine, Johannesburg, South Africa*

Email: ekostakh@med.uoa.gr

Background and aims: The Hepatitis B virus (HBV) (sub)genotypes circulating in Africa include A1, D3 and E, with E prevailing in W. Africa where HBV is hyperendemic. Unlike subgenotype A1, genotype E is rarely found outside Africa. Despite the wide geographical distribution in Africa, genotype E has a very low genetic diversity. Genotype E has a unique serological subtype ayw4 and a 3-nucleotide deletion in the preS1 region. Our aim was to estimate the levels of regional dispersal of genotype E, in order to shed light on how the virus has been disseminated within different geographic areas.

Method: We analyzed 271 full-length HBV/E sequences available on the HBV database. The number of sequences per geographic region was: W. Africa: 172, C. Africa: 50, E. Africa: 18, America: 9, S. Africa: 8, Europe: 8, N. Africa/Middle East: 5 and Asia: 1. Phylogeny reconstruction was conducted by the maximum likelihood method. We defined as regional dispersal the sequences found within highly supported (bootstrap value > 70%) monophyletic clusters, within which 70% of HBV/E strains share the same geographic area of sampling. Phylogeographic analysis was conducted by the criterion of parsimony.

Results: Analysis revealed that 55% (N = 149) of the HBV/E sequences were found within monophyletic clusters. Country-wise analysis showed that HBV/E sequences form regional clusters at different percentages according to their geographic origin. Specifically, 100% of the sequences from Democratic Republic of the Congo form a single monophyletic cluster. The same pattern was observed for Argentina, Colombia, Egypt and South Africa. High levels of regional dispersal were found for Ghana (79%), Niger (75%), the Central African Republic (71%), Liberia (67%), Namibia (67%) and Sudan (67%). A high number of sequences from Guinea (60%) and Nigeria (54%) were found within 14 and 9 monophyletic clusters, respectively. Sequences from Cape Verde (43%), Belgium (33%) and Angola (11%) revealed the lowest regional dispersal. In addition, we found that sequences from W. Africa were located close to the root of the tree.



Conclusion: Our analysis suggests considerable differences in the patterns of HBV genotype E regional dispersal. Genotype E showed a strong pattern of regional dispersal suggesting that the population movements associated with cross-border transmissions were limited. Genotype E epidemic probably originated in W. Africa and expanded to other regions inside and outside of Africa.

SAT-174

Formation of the occult chronic hepatitis B during antiviral therapy in patients with HIV + HBV + HDV + HCV infection: Clinical cases

Konstantin Zhdanov[1], Ilnur Gabdrakhmanov[1], Yulia Ostankova[2], Konstantin Kozlov[1], Vitalii Sukachev[1], Denis Gusev[3], Aleksandr Semenov[2], Svetlana Romanova[3], Svetlana Kizhlo[3], Sergey Ignat'ev[3], Dmitrii Schakhmanov[1]. [1]*Military Medical Academy, Saint-Petersburg, Russian Federation;* [2]*Saint-Petersburg Pasteur institute, Saint-Petersburg, Russian Federation;* [3]*Saint-Petersburg Center for Prevention and Control of AIDS and Infectious Diseases, Saint-Petersburg, Russian Federation*

Email: ilnur87rahmanov@yandex.ru

Background and aims: Occult HBV infection can develop in patients after acute hepatitis B, in patients with chronic HBV-infection who have eliminated HBsAg and in seronegative patients infected with small amounts of the virus, insufficient to form an immune response. We observed patients with HIV + HBV + HDV + HCV infection, one of whom (F4 fibrosis stage, HBeAg-negatif) underwent HBsAg seroconversion after the end of therapy with pegylated interferon alpha-2a 180 μg and ribavirin 1200 mg and continued the antiretroviral (HAART) therapy with tenofovir DF 300 mg + lamivudine 300 mg + atazanavir 300 mg/ritonavir 100 mg once daily (OD). In the second patient (F4 fibrosis stage, HBeAg-negatif) seroconversion of HBsAg occurred 6 years after the administration of pegylated interferon alfa-2b and ribavirin 1000 mg with continuing the HAART using lamivudine 300 mg OD till now. Both patients have achieved SVR after treatment of HCV (genotype 1b). In both patients, HBV cccDNA was detected in the liver tissue after HBsAg seroconversion.

Method: The concentration of HBV DNA, HDV RNA, HCV RNA, HIV RNA in blood serum and HBV cccDNA concentration in liver biopsy specimens of two men aged 40 and 49 years was evaluated. There was also performed the qualitative determination of HBsAg, anti-HCV and anti-HDV in blood serum of these patients. The detection of HBV cccDNA in the liver tissue was performed according to Pollicino T. et al., using TaqMan probes for real-time PCR.

Results: Case 1*: Pegylated interferon alpha-2a 180 μg for 96 weeks.

Time period Indicators	Baseline	End of treatment with PIFN	12 Month follow-up	48 Month follow-up
HBsAg	**Posit.**	Neg.	Neg.	**Neg.**
ALT (IU/ml)	53	62	25	15
HBV DNA	**Posit.**	Neg.	Neg.	**Neg.**
cccDNA (copies/ cell)	-	-	-	**0.737**

*Patient is continuing HAART with tenofovir DF 300 mg + lamivudine 300 mg + atazanavir 300 mg/ritonavir 100 mg OD

Case 2*: Pegylated interferon alpha-2b 180 μg for 48 weeks.

Time period Indicators	Baseline	End of treatment with PIFN	12 Month follow-up	72 Month follow-up
HBsAg	**Posit.**	Posit.	Posit.	**Neg.**
ALT (IU/ml)	34	28	11	13
HBV DNA	**Neg.**	Neg.	Neg.	**Neg.**
cccDNA (copies/ cell)	-	-	-	**0.865**

*Patient is continuing HAART with lamivudine 300 mg OD

Conclusion: Seroconversion of HBsAg in these patients is probably the result of effective antiviral therapy. However, the presence of cccDNA in hepatocytes testifies to the formation of occult HBV infection, which requires further careful monitoring of immunological and virological indicators, in view of the possible activation of the infectious process.

SAT-175

Recruitment of HBx on HBV DNA depends on FXR and is inhibited by FXR agonist

Benoît Lacombe[1], Camille Ménard[1], Vincent Lotteau[1], Patrice Andre[1], Christophe Ramière[1]. [1]*INSERM U1111-CNRS UMR5308-Université Lyon 1 and ENS de Lyon, CIRI, Lyon, France*
Email: patrice.andre@inserm.fr

Background and aims: HBV infection and bile acids metabolism are interdependent. HBV infection increases expression of the BA nuclear receptor FXR in infected patients. Reciprocally, FXR is a proviral factor for HBV whose activity is inhibited by FXR agonists, in vitro and in vivo. Presence of FXR favors cccDNA completion as well as viral mRNAs transcription, likely through its binding to two HBV genome sites (FXRE). Since FXR and HBx interact, we aimed at deciphering the respective role of HBx and FXR, and ligand, in controlling HBV transcription.
Method: Expression of FXR was studied in HBV-permissive differentiated HepaRG (dHepaRG) and in hepatocarcinoma cell line Huh7. dHepaRG were infected HBV WT or ΔHBx-HBV. ChIP were realized in Huh7 transfected with Enh2/Cp regulatory region of HBV containing the two FXRE. FXR KO Huh7 cell line was generated through FXR-shRNA to study the impact of HBx on FXR fixation at FXRE. FXR agonist GW4064 (GW) was used at 10μM.
Results: HBV infection with either wild type or ΔHBx-HBV increased FXR expression at the protein level in agreement with in vivo observations, when treatment with FXR agonist decreased this expression. Down regulation of FXR by agonists renders difficult studying the effect of that molecule on FXR binding to FXRE in dHepaRG. On the opposite, agonist increased FXR protein expression and/or stabilization in Huh7. We thus took advantage of this particular FXR expression regulation to perform FXR and HBx-ChIP in Huh7 transfected with Enh2/Cp promoter. FXR-ChIP revealed FXR presence in the Enh2/cp in a dose dependent manner. GW treatment decreased FXR presence at the viral promoter in contrast to FXR stabilization at the BSEP promoter. RXR was also recruited at the Enh2/Cp and released after GW treatment, again at odds with the stabilization at the BSEP promoter. When HBx was cotransfected in Huh7 or shFXR-Huh7 cells with Enh2/Cp region, HBx was recruited to the viral promoter but not in the shFXR-Huh7 cells or in presence of agonist.
Conclusion: Altogether, data suggest that FXR proviral activity depends on its binding to the viral genome at the Enh2/Cp region. Presence of FXR might recruit cellular factors for cccDNA completion and HBx for efficient transcription. Inhibition of FXR proviral activity by agonist might result from repression of FXR expression and of the release of FXR from its viral targets. This later effect seems to be DNA sequence dependent since agonist stabilize FXR on cellular promoter.

SAT-176

The effect of HBV and HCV infection on pregnancy status

Julita Nikolajuk-Stasiuk[1], Anna Parfieniuk-Kowerda[1], Tadeusz, Wojciech Lapinski[1], Robert Flisiak[1]. [1]*Medical University of Bialystok, Department of Infectious Diseases and Hepatology, Bialystok, Poland*
Email: twlapinski@wp.pl

Background: HBV and HCV infections affect 1-7% and 0.2-2.4% pregnant women in Europe. The assessment of impact of these infections on pregnancy is still uncertain.
The aim of study was to assess the course of pregnancy and the condition of a children born by pregnant women infected with HBV or HCV.
Methods: The study included 148 women infected with HBV and 46 with HCV. The control group consisted of 330 healthy pregnant women living in the same region.
Results: All pregnant women infected with HBV were HBeAg negative. HCV infection was caused in 67% by genotype 1b, 20%-3a and 13%-4. Increase of HBV DNA between 6 and 32 week of pregnancy was found in 46%, decrease in 15%, and in 39% remained unchanged. Among both HCV and HBV infected, the incidence of miscarriages was significantly higher than in healthy women (8.6% and 4.1% vs. 1.8%; $p < 0, 05$). In 4 patients infected with HBV who had a miscarriage, HBV viremia was 4.0 log IU/ml and 2 was undetectable. Significantly more frequent premature deliveries were in HCV and HBV infected than in the control group (2.2% and 3.4% vs. 0.6% $p < 0.05$). The duration of pregnancy was shorter, the birthweight of the children was lower and APGAR score was lower among those infected with HCV and HBV compared to children born to healthy mothers. Among newborns born by HCV and HBV infected, the cyanosis (23.9% and 10.8% vs. 6.4%;) and breathing disorders (8.7% and 4, 1% v. 0, 9%; $p < 0.05$) were more frequent.
Conclusions: HCV and HBV infection in pregnancy increase the probability of miscarriages affecting more frequent occurrence of cyanosis, respiratory disorders and lower birth weight of newborns compared to children born by healthy women.

SAT-177

Loss of HBsAg by patients with high levels of HBV-DNA during treatment with nucleoside or nucleotide analogues

Tadeusz, Wojciech Lapinski[1], Monika Pazgan-Simon[2], Simon Krzysztof[1], Robert Flisiak[1]. [1]*Medical University of Bialystok, Department of Infectious Diseases and Hepatology, Bialystok, Poland;* [2]*Wroclaw Medical University, Department of Infectious Diseases and Hepatology, Wroclaw, Poland*
Email: twlapinski@wp.pl

Background: Treatment with pegylated interferon (PEG IFN) in patients with chronic HBV infection and high HBV DNA levels is not recommended. Such patients are usually treated with nucleoside or nucleotide analogues (NUCs).
The aim of this study is to find the factors conducive to the loss of HBsAg during therapy with NUCs among patients chronically infected with high viral load.

Methods: Analysis of patients who cleared HBsAg was carried out among 470 treated with NUCs in two hepatologic centers between 2010 and 2018.
Results: The loss of HBsAg was found in 19 patients, more often in men then women (63% vs. 37%). The time of infection ranged from 1 to 28 years and no relationship between the time of infection and HBsAg clearance was found. In 3 cases HBeAg was present. The mean age of patients was 63 years and only one was below 45 years. The mean viral load before start of therapy was 7 Log IU/ml. No patient was previously treated with PEG IFN, 63% patients received more than one NUCs, and 37% were treated with only one NUC. Elimination of HBsAg was most frequently observed after treatment with Entecavir (58%, mean treatment duration 63 months) less often after Tenofovir (16%, mean treatment duration 44 months) or Lamivudine (16%, mean treatment duration 113 months). In 74% patients anti-HBs antibodies appeared after HBsAg clearance and in 21% after liver transplantation. The advancement of hepatic fibrosis did not affect chance of HBsAg elimination.
Conclusions. Age over 45 years as well as male gender predispose to a more frequent elimination of HBsAg in patients treated with NUCs. The elimination of HBsAg among patients with high levels of HBV-DNA is the most likely during treatment with entecavir. Liver transplantation promotes elimination of HBsAg.

SAT-178

Identification of Hepatitis B virus events in liver and peripheral blood mononuclear cells in individuals with chronic hepatitis B infection

Keith Lau[1], Shan Gao[1], Mei Liu[2], Guido van Marle[1], Norah Terrault[3], Kelly Burak[1], Carla Coffin[1]. [1]*University of Calgary, Cumming School of Medicine, Calgary, Canada;* [2]*Capital Medical University, Beijing, China;* [3]*University of California San Francisco, San Francisco, United States*
Email: kcklau@ucalgary.ca

Background and aims: The Hepatitis B Virus (HBV) can integrate into host genomes with implications towards hepatocellular carcinoma (HCC) development. HBV genomes are found within circulating peripheral mononuclear blood cells (PBMCs), but viral integration and subsequent genetic alterations within the PBMC compartment is unknown. We aim to characterize viral integration in the liver and PBMC of chronic hepatitis B (CHB) carriers with and without HBV-related HCC.
Method: Plasma and PBMC was collected from 16 CHB carriers diagnosed with HBV-related HCC (11 M, median age 62, 14 Asian; 2 African, 13 on nucleos/tide analog therapy [NAT]) in parallel to 14 non-HCC CHB carriers (8 M, median age 48, 10 Asian; 2 African; 2 Caucasian, 9 on NAT). Explant liver tissue from 10 additional cases of end-stage HBV-related HCC (8 M, median age 57, 10 Asian, 9 on NAT) were also collected. HBV-specific regions were amplified from phenol chloroform extracted total DNA derived from liver or plasma and PBMC tissues by nested PCR. Viral-host integration sites in liver and PBMC DNA were identified with AluPCR followed by clonal sequencing of amplicons. Sequences were analysed with MEGA 7 and NCBI blast.
Results: HBV DNA was detected in all patient plasma, PBMC, and liver samples by HBV-specific nested PCR. In the PBMC of the non-HCC and the CHB + HCC cohorts, 44 and 48 HBV-host integration sites were detected, respectively. 13/44 and 17/48 of these sites were present within known coding genes. 110 integration sites were detected in the liver tissues, of which 16 are within known coding genes. HBV integration in genes potentially implicated in oncogenesis, such as SCAI, NECTIN2, and CDKN3, was identified in all cohorts.
Conclusion: Despite long-term NAT, CHB carriers ± HCC show persistent HBV genomes in plasma, PBMC, and liver. Viral integration in known coding genes were identified in both liver and PBMC-derived DNA. Many of these genes have recognized and/or suspected roles in cancer or are components in key signalling pathways which may have oncogenic implications when disrupted.

SAT-179

Human liver organoids culture as a novel in vitro model of HBV infection

Chuan Kok Lim[1], Bang M Tran[2,3], Byron Shue[4], Nicholas Eyre[4], Dustin Flanagan[2,3], Elizabeth Vincan[2,3], Danni Colledge[2,3], Stephen Locarnini[2,3], Erin McCartney[5], Edmund Tse[5], Andrew Ruszkiewicz[6], Michael Beard[4]. [1]*Research Centre for Infectious Diseases, The University of Adelaide, Adelaide, Australia;* [2]*The Peter Doherty Institute for Infection and Immunity, Melbourne, Australia;* [3]*Victorian infectious Diseases Reference Laboratory, Melbourne, Melbourne, Australia;* [4]*Research Centre for Infectious Diseases, The University of Adelaide, Adelaide, Australia;* [5]*Royal Adelaide Hospital, Department of Gastroenterology and Hepatology, Adelaide, Australia;* [6]*SA Pathology, Surgical Pathology, Adelaide, Australia*
Email: chuankok.lim@adelaide.edu.au

Background and aims: The use of primary hepatocytes as a model of HBV infection is limiting due to rapid dedifferentiation and short lifespan. In an effort to develop a physiological human model of HBV replication we used the method developed by *Huch* to isolate 3D human liver organoids that demonstrate mature hepatocyte function, genetic stability, long-term expansion and importantly they retain the genomic background of the tissue of origin. Our aim was to assess liver organoid culture as a novel *in vitro* model for characterisation of the HBV life-cycle, cellular response and antiviral susceptibility testing.
Method: Human liver organoids were generated following isolation of LGR5+ ductal stem cells from liver resection followed by expansion and differentiation into 3D culture. Hepatocyte differentiation markers (albumin, CYP3A4) and NTCP (bile acid transporter and high affinity HBV receptor) expression were evaluated using qRT-PCR and confocal microscopy. Infection of organoids was performed using HepAD38 cell culture derived HBV (genotype D) at 1000 GE/cell and HBV total RNA harvested and quantified by qRT-PCR at 12 dpi while HBV infected cells (HBsAg, HBcAg) were visualised by immunofluorescence detection.
Results: Differentiation of organoids was confirmed by expression of albumin and CYP3A4 and loss of LGR5 (qRT-PCR and confocal microscopy) and hepatocyte polarisation as assessed by the redistribution of Zona occludens-1 to tight junctions (confocal microscopy). Undifferentiated organoids did not express the HBV receptor, NTCP, while differentiated organoids expressed NTCP at the mRNA level with concomitant expression at the cell surface. Differentiated organoids were successfully infected with HBV as confirmed by an increase in HBV RNA over time and immunostaining for HBcAg and HBsAg by confocal microscopy. No adverse effects on cell or overall organoid viability were noted following infection.
Conclusion: We have successfully generated liver organoid cultures that retain a hepatocyte phenotype that express the NTCP receptor and are permissive to HBV infection. These findings accentuate the utility of human liver organoids as a HBV infection model, with the potential to further dissect HBV replication and the cellular response in a model system that more accurately reflects human HBV infection. Liver organoids also show promise as a personalised antiviral testing platform to guide future HBV cure therapy and to study resistance.

Email: online-marc@mx.de

Background and aims: Hepatitis D Virus (HDV) is a single strand circular RNA virus which is classified into eight genotypes. HDV-3 is known to cause severe hepatitis, while patients infected with HDV-1 can develop a wide range of severity. Moreover, it is not known whether sequence and protein diversity between genotype 1 and 3 may allow coinfection and productive replication of both viruses at single cell level. In this study we aimed to investigate the kinetics of coinfection and superinfection of HDV-1 and HDV-3 in vivo both intrahepatically and at single cell level.
Method: Human-liver chimeric mice stably infected with HBV infected were (A) co-infected with HDV-1 and HDV-3 or (B) first infected with HDV-1 and after 9 weeks superinfected with HDV-3 or vice versa. All mice were sacrificed 9 weeks after the last infection. Virological parameters were determined by strain specific qRT-PCR (serum and liver) and using strain specific RNA in situ hybridization (ISH) and immunofluorescence staining of HDAg.
Results: Mice co-infected with HDV-1 and HDV-3 developed viremia for both genotypes; however, HDV-3 was the dominant strain in serum (> 2 log difference) and in the liver, both at RNA and protein levels. Interestingly, ISH revealed the lack of co-existence of anti-genomic HDV1 and HDV3 RNA at single cell level, suggesting strong viral interference. Moreover, the step-wise infection experiments, where stably HDV1 infected mice were superinfected with HDV3, showed that HDV-3 remained below detection in serum. Similarly, dominance of the first virus was determined also when HBV/HDV-3-infected mice were superinfected with HDV-1.
Conclusion: Although HDV3 spread more efficiently and hence appeared dominant, co-infection of HDV1 and HDV3 in the same liver could be detected. However, double infection was never observed at single cell level, indicating that superinfection exclusion in vivo does exist, at last between HDV3 and HDV1. Such coinfection exclusion may allow HDV to evade excessive recombination by incoming viruses. Further studies are needed to analyze whether the inability of delta protein to support replication of distant HDV genotypes is responsible for the observed phenomenon.

SAT-181

Efficacy and safety of glecaprevir/pibrentasvir in patients with severe renal impairment in Japan: A prospective, multicenter study (KTK 49 Liver Study Group)

Masanori Atsukawa[1], Makoto Nakamuta[2], Takashi Kumada[3], Hidenori Toyoda[3], Koichi Takaguchi[4], Tsunamasa Watanabe[5], Hiroki Ikeda[5], Akito Nozaki[6], Atsushi Hiraoka[7], Kojiro Michitaka[7], Hiroshi Abe[8], Keizo Kato[8], Noritomo Shimada[9], Toru Asano[10], Haruki Uojima[11], Chikara Ogawa[12], Shinya Fukunishi[13], Akira Asai[13], Takuya Genda[14], Shigeru Mikami[15], Tadashi Ikegami[16], Akihito Tsubota[17], Yoshio Aizawa[18], Naoki Hotta[19], Shinichi Fujioka[20], Hironao Okubo[21], Norio Itokawa[22], Taeang Arai[22], Chisa Kondo[1], Etsuko Iio[23], Yasuhito Tanaka[23], Katsuhiko Iwakiri[1]. *[1]Nippon Medical School, Tokyo, Japan; [2]National Hospital Organization Kyushu Medical Center, Fukuoka, Japan; [3]Ogaki Municipal Hospital, Ogaki, Japan; [4]Kagawa Prefectural Central Hospital, Takamatsu, Japan; [5]St. Marianna University School of Medicine, Kawasaki, Japan; [6]Yokohma City University Medical Center, Yokohama, Japan; [7]Ehime Prefectural Central Hospital, Matsuyama, Japan; [8]Shinmatusdo Central General Hospital, Matsudo, Japan; [9]Otakanomori Hospital, Kashiwa, Japan; [10]Tokyo Metropolitan Bokutoh Hospital, Tokyo, Japan; [11]Kitasato University School of Medicine, Sagakihara, Japan; [12]Takamatsu Red Cross Hospital, Takamatsu, Japan; [13]Osaka Medical College, Osaka, Japan; [14]Juntendo University Shizuoka Hospital, Shizuoka, Japan; [15]Kikkoman General Hospital, Noda, Japan; [16]Tokyo Medical University Ibaraki Medical Center, Ibaraki, Japan; [17]The Jikei University School of Medicine, Tokyo, Japan; [18]Joban Hospital, Iwaki, Japan; [19]Mashiko Memorial Hospital, Nagoya, Japan; [20]Okayama Saiseikai General Hospital, Okayama, Japan; [21]Juntendo Nerima Hospital, Tokyo, Japan; [22]Nippon Medical School Chiba Hokusoh Hospital, Inzai, Japan; [23]Nagoya City University, Nagoya, Japan*
Email: momogachi@yahoo.co.jp

Background and aims: In the present analysis of a multicenter study, we evaluated the efficacy and safety of Glecaprevir/Pibrentasvir for chronic hepatitis C Japanese patients with severe renal impairment.
Method: Chronic hepatitis C Japanese patients treated with Glecaprevir/Pibrentasvir between November 2017 and June 2018 were subjected to the present analysis. Patients received Glecaprevir/Pibrentasvir for 8 or 12 weeks according to patient's characteristics. For patients with liver cirrhosis, genotype 3 and patients who failed to achieve SVR with prior DAAs IFN-free treatment, patients were treated with Glecaprevir/Pibrentasvir for 12 weeks. For the remaining patients, the patients such as DAAs naïve, genotype1 and 2, and non-cirrhosis were treated with Glecaprevir/Pibrentasvir for 8 weeks.
Results: Of 1, 003 chronic hepatitis C patients, 142 had CKD stage 4, 5. The patients comprised 107 males and 35 females. The median age was 68 years (range, 38-89 years). Patients with genotype 1b, 2a, 2b and 3 were 30, 59, 28 and 1, respectively. The median eGFR level at baseline was 6.3 ml/min/1.73 m^2; 19.7% (28/142) had CKD stage 4, 80.3% (114/77) had CKD stage 5. Of these, 73.2% (104/142) were undergoing hemodialysis or hemodiafiltration. Of all the patients, 4.2% (6/142) had previously received IFN-free DAAs treatment. The overall SVR rate was 99.3% (141/142). SVR rates in the patients with 8 weeks and 12 weeks were 98.6% (72/73) and 100% (36/36), respectively. Among the 6 patients who failed to achieve SVR with IFN-free DAAs treatment, the SVR rate was 100%. All of the patients with cirrhosis achieved SVR. The SVR rates as per the CKD stage were 100% (24/24) in stage 4, 98.8% (84/85) in stage 5. Almost of all patients undergoing hemodialysis achieved SVR (79/80). Time-course changes in eGFR levels were analyzed in the patients with CKD 4 and 5 without hemodialysis. The most common adverse event was pruritus. In particular, it was frequently observed in patients CKD 5. Multiple logistic regression analysis was performed to clarify the factors associated to the appearance of pruritus. Hemodialysis therapy and hypoalbuminemia were extracted as statistically significant independent factors related to pruritus.
Conclusion: The present analyses of a multicenter, prospective study demonstrated that Glecaprevir/Pibrentasvir is highly effective and safe for chronic hepatitis C Japanese patients with severe renal impairment.

SAT-182

Full length deep sequencing of South African hepatitis B virus isolates reveals increased viral diversity and X-gene deletions in hepatocellular carcinoma patients

Tongai G Maponga[1], Anna Mcnaughton[2], Mariateresa de Cesare[3], M Azim Ansari[2], Camilla LC Ip[3], Richard Glashoff[4], Wolfgang Preiser[1], David Bonsall[2,5,6], Monique I Andersson[1,5], Philippa Matthews[2,5,7]. *[1]Stellenbosch University, Division of Medical Virology, Cape Town, South Africa; [2]University of Oxford, Nuffield Department of Medicine, Oxford, United Kingdom; [3]University of Oxford, Wellcome Centre for Human Genetics, Oxford, United Kingdom; [4]Stellenbosch University, Division of Medical Microbiology and Immunology, Oxford, South Africa; [5]Oxford University Hospitals NHS Foundation Trust, Department of Infectious Diseases and Microbiology, Oxford, United Kingdom; [6]University of Oxford, Big Data Institute, Oxford, United Kingdom; [7]Oxford University Hospitals NHS Foundation Trust, NIHR Oxford Biomedical Research Centre, Oxford, United Kingdom*
Email: anna.mcnaughton@ndm.ox.ac.uk

Background and aims: More than 60% of hepatocellular carcinoma (HCC) cases in South Africa are associated with chronic HBV infection. Mutations within the HBV genome have been associated with an elevated risk of HCC development. The aim of this study was to describe the differences in genetic diversity of HBV among South

African adults with HCC and those with chronic HBV infection (CHB) without HCC using deep sequencing.
Method: Blood was collected from 10 patients diagnosed with HBV-associated HCC and 10 patients with CHB. Patients with HIV co-infection and HBeAg positivity were present in both groups. HBV DNA was extracted from plasma and the viral load was quantified by qPCR. Libraries were prepared using a Nextera kit, pooled and then underwent target enrichment with custom-designed pangenotypic HBV probes. Libraries were sequenced on an Illumina Mi-Seq platform and data analysed using a bespoke pipeline.
Results: HBV viral loads were significantly higher in HCC patients ($p = 0.001$). 10/10 HBV HCC and 9/10 CHB samples were successfully sequenced, generating medians of 82196 reads/sample and coverage of 3536 reads/site after deduplication. HBV genotypes A, D and E were identified in both HCC and CHB groups. Resistance mutations L180I and M204I, associated with Lamivudine resistance, were identified at the consensus level in one HCC individual.
Two peaks of diversity were evident within both the HCC and CHB patients, spanning the regions at the end and start of polymerase where only a single gene is encoded. Median within-host viral diversity was significantly higher amongst patients with HCC ($p = 0.03$). X-gene deletions of 8-21 nucleotides (nt) and core deletions of 24-48 nt were identified in the consensus sequences in 3 and 2 HCC patients, respectively, but not in any CHB patients. There was no associations between viral diversity and HIV status, HBeAg positivity or nucleoside analogue therapy.
Conclusion: An unbiased deep sequencing approach specifically enriching for HBV was successfully applied to look for viral differences in HCC vs CHB patients of African origin. Well-described deletions in Core and X-gene were observed in HCC patients infected with genotypes A and E. Continued application of such methods with larger African cohorts will facilitate improved insights into the aetiology of HCC in HBV-infected individuals in the region.

SAT-183

High resolution insight into hepatitis B virus infection and immunity in Africa to inform on intervention strategies

Anna Mcnaughton[1], José Lourenço[2], Phillip Armand Bester[3], Jolynne Mokaya[1], Sheila F Lumley[1,4], Donall Forde[5], Tongai G Maponga[6], Kenneth R Katumba[7], Dominique Goedhals[3], Sunetra Gupta[2], Janet Seeley[7,8], Robert Newton[9], Ponsiano Ocama[10], Philippa C Matthews[1,4]. *[1]University of Oxford, Nuffield Department of Medicine, Oxford, United Kingdom; [2]University of Oxford, Department of Zoology, Oxford, United Kingdom; [3]University of the Free State and National Health Laboratory Service, Division of Virology, Bloemfontein, South Africa; [4]Oxford University Hospitals NHS Foundation Trust, Department of Infectious Diseases and Microbiology, Oxford, United Kingdom; [5]University of Oxford, Nuffield Department of Medicine, Oxford, United Kingdom; [6]University of Stellenbosch, Division of Medical Virology, Cape Town, South Africa; [7]Medical Research Council/Uganda Virus Research Institute and London School of Hygiene and Tropical Medicine Uganda Research Unit, Entebbe, Uganda; [8]London School of Hygiene and Tropical Medicine, Department of Global Health and Development, London, United Kingdom; [9]University of York, Department of Health Sciences, York, United Kingdom; [10]Makerere University College of Health Sciences, Kampala, Uganda*
Email: anna.mcnaughton@ndm.ox.ac.uk

Background and aims: "Catch-up" HBV vaccination in adults is sometimes employed in working towards the UN 2030 elimination targets. Epidemiological studies and informed interventions for HBV typically only examine the prevalence of hepatitis B surface antigen (HBsAg), a biomarker of active infection. Given the high rates of natural clearance (> 90% in healthy adults), the background of immunity should also inform intervention strategies. We examined the relationship between HBV exposure and active infection in Africa.
Method: We undertook a systematic search of multiple databases in June 2018, using PRISMA criteria to identify studies from adult African populations including data for both anti-HBc and HBsAg prevalence. We used the United Nations geoscheme for Africa to define a list of countries and to sub-divide the region into North (NA), Southern (SA), West (WA), East and Central Africa (CA). Immunity to HBV was defined as HBV core antibody (anti-HBc) positive and HBsAg negative.
Results: We identified 89 studies spanning 37 countries. Across Africa, HBsAg prevalence is positively correlated with total anti-HBc, $p < 0{\cdot}0001$. The prevalence of both HBsAg and anti-HBc positivity are highest in WA, with the lowest exposure and infection rates in NA. There were notable differences in HBsAg prevalence between NA and SA ($p = 0.04$) without any corresponding difference in anti-HBc prevalence ($p = 0.99$). For any given anti-HBc prevalence, the observed HBsAg prevalence in SA was typically two-fold greater than in NA (Fig 1A).
Population exposure to HBV positively correlated with HBsAg prevalence in all regions except CA, where there was no association between HBsAg and anti-HBc ($p = 0.99$, Fig 1B). There were no significant differences in HBsAg or anti-HBc prevalence between HIV positive cohorts ($N = 26$) and other cohorts ($p = 0{\cdot}16$ and $p = 0{\cdot}42$, respectively).

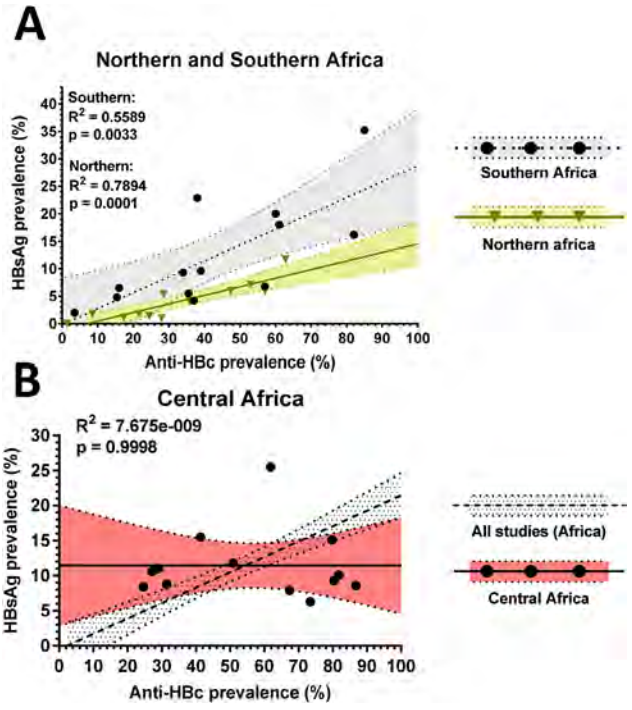

Figure 1: Relationship between anti-HBc (exposure) and HBsAg (active infection) with linear regression analysis in (A) Northern and Southern Africa and (B) Central Africa and all African studies.

Conclusion: We identified distinct regional associations between chronic HBV infection and exposure in Africa. Numerous factors are likely to influence these differences including age at exposure, transmission routes, host genetics and viral genotype.
Population exposure to HBV was ≥ 70% in 24% studies indicating that adult vaccination would benefit < 30% adults, many of whom would clear the infection naturally if exposed. Alternative interventions targeting adults, incorporating diagnosis and treatment, will have considerably more impact in highly endemic populations.

SAT-184

Approximation of the genotype distribution within global chronic hepatitis B virus infections

Stoyan Velkov[1], Ulrike Protzer[1,2], Thomas Michler[1,2]. [1]*Institute of Virology, Technical University of Munich/Helmholtz Zentrum München, Munich, Germany;* [2]*German Center for Infection research (DZIF), Munich partner site, Munich, Germany*
Email: thomas.michler@tum.de

Background and aims: Hepatitis B Virus (HBV) is genetically diverse and divided into nine genotypes, A to I, that differ in their primary transmission route, chronicity rate, development of liver cirrhosis and hepatocellular carcinoma and treatment response to Interferon-α. So far, it is not known how many of the 250 million chronic HBV infections are caused by which genotype. This knowledge, however, could assist to specify the HBV disease burden, plan health policies, optimize diagnostic tests, and develop new broadly active antiviral therapies.
Method: We performed a comprehensive literature research on studies reporting HBV genotyping data throughout the world. Over 800 publications were assessed and genotyping data extracted from 194 sources covering 127 countries. Using previously published HBsAg country-estimates and UN population data, we estimated the number of infections with each HBV genotype per country and world-region and the genotype distribution within global chronic HBV infections.
Results: Distinct differences in the genotype distribution between world regions were confirmed in our study. The drastic differences in HBV endemicity and population levels between world-regions strongly influenced the world-wide genotype distribution. Genotypes with frequent appearances in high-endemic areas such as Sub-Saharan Africa and Eastern Asia were found to cause a majority of global HBV infections. We estimated that approximately 96% of global HBV infections are caused by only five (A-E) of the nine genotypes: Genotype C was found to cause most infections (26%), followed by genotype D (22%), E (17%), A (17%) and B (14%). The four remaining genotypes F-I were estimated to cause together less than 2% of global HBV infections.
Conclusion: While alluding to major biases inherent in such studies, our work provides an up to date review of world-wide genotyping results and an initial approach to estimate the genotype distribution within global HBV infections. It furthermore reveals world areas with poor genotyping data which should be addressed in future studies. Besides clinical implications of the HBV genotype distribution, our study highlights the need to expand HBV cell culture and animal models to at least include genotypes A-E to represent the fast majority of global HBV infections.

SAT-185

Is the performance of ultra-sensitive HBsAg Fujirebio assay consistent across HBV genotypes (comparison between CLEIA HBsAg HQ Fujirebio and Abbott Architect assays)

Christiana Moigboi[1], Matthew Bruce[1], Mary Horner[1], Geoffrey Dusheiko[1], Kosh Agarwal[1], Ivana Carey[1]. [1]*Institute of Liver Studies, King's College Hospital, London, United Kingdom*
Email: christiana.moigboi@nhs.net

Background and aims: HBsAg quantification plays an important role in the management of chronic hepatitis B infection. Several testing platform are available, but there is limited data about the assays performance across HBV genotypes in patients with low HBsAg levels. In this pilot study we aimed to compare HBsAg levels tested on using Abbott Architect™ assay (standard of care) vs. Fujirebio an ultra-sensitive chemiluminescent enzyme immunoassay (CLEIA) HBsAg HQ on Fujirebio Lumipulse G600II platform in chronic hepatitis B patients with low HBsAg levels (0-150 IU/ml) across the different HBV genotypes.
Method: Frozen serum samples collected between 2017 and 2018 from 203 chronic hepatitis B (CHB) patients, all HBeAg negative with known level of HBsAg (0.1-150 IU/ml) tested on Abbott Architect were tested using CLEIA HBsAg-HQ assay (Fujirebio). HBV DNA levels were measured by TaqMan (Roche). HBV genotypes were determined by in-house direct sequencing. Bi-variate non-parametric correlations and rank tests were used to compare both assays.
Results: 197 patients (57% males, median age 49 yrs) had HBsAg levels below detection limit of 150 IU/ml of Fujirebio and based on the initial HBsAg levels were stratified into 3 groups: HBsAg 0.1-10IU/ml (n = 72), HBsAg 10-100IU/ml (n = 98) and HBsAg 100-1000 IU/ml (n = 27). There was the following genotypes distribution in our cohort: A (15%), B (23%), C (14%), D (21%), E (26%) and G (1%). 112 patients had not detected HBV DNA at time of this test. Median HBsAg levels were similar between Abbott (18.6, range 0.1-164) and Fujirebio (17.7, 0.1-150IU/ml) and there was a strong bi-variate correlation ($r = 0.977$, $p < 0.001$). When the comparison was made between the individual genotypes the strongest correlation was noted for genotypes E ($r = 0.985$), B ($r = 0.98$) and A ($r = 0.974$) in contrast to genotypes ($r = 0.952$) and D ($r = 0.969$). The assessment according to HBsAg levels revealed strong correlation between tests at levels 0.1-10IU/ml ($r = 0.967$) with gradual decline with increasing HBsAg levels (10-100 IU/ml, $r = 0.86$ and for 100-1000 IU/ml, $r = 0.545$). Median levels differed significantly between Abbott and Fujirebio in genotype C (50.5 vs 68.4IU/ml, $p < 0.01$) and E (17.2 vs. 22.6 IU/ml, $p < 0.01$) patients and patients with HBsAg levels between 10 and 100 IU/ml (27.2 vs. 28.3 IU/ml, $p < 0.05$).
Conclusion: Despite a very strong correlation between HBsAg levels tested by Abbott Architect and Fujirebio CLEIA HQ assay, there are differences in assay performance across HBV genotypes and HBsAg levels. These findings warrant further evaluations in larger cohorts of patients across HBV genotypes and HBV variants.

SAT-186

Pathophysiological impact of HCV on mitochondrial composition and functions

Léa Monnier[1], Sarah Duponchel[1], Jennifer Molle[1], Jennifer Rieusset[2], Michel Ovize[2], Fabien Zoulim[1], Birke Bartosch[1]. [1]*INSERM U1052, CRCL, Lyon, France;* [2]*INSERM UMR 1060, CARMEN Laboratory, Lyon, France*
Email: lea.monnier@inserm.fr

Background and aims: Hepatitis C virus (HCV) is known to perturb hepatic glucose and lipid metabolism with major patho-physiological consequences including an acceleration of the disease towards liver cancer. However, on the molecular level these processes remain obscure. Mitochondria play a key role in cellular homeostasis. In response to a variety of heterogeneous, external and internal signals such as for example innate immunity, metabolic status and ER/oxidative stress, they adapt cellular metabolism and energy production, activate inflammatory processes or induce apoptosis. This study aims to understand mitochondrial morphological and functional alterations in response to HCV infection and their implication in HCV pathophysiology.
Method: The hepatoma cell line Huh7.5 infected with the HCV JFH1 strain and liver biopsies were used in this study. In order to explore the interactions of HCV with mitochondria and the resulting impact on mitochondrial functions, biochemical fractionation, proximity ligation assays and various functional assays such as mitochondrial respiration, membrane potential, Ca2+ transfer and ROS production were assessed.
Results: Biochemical fractionation revealed the presence of viral proteins at MAMs (Mitochondrial Associated Membranes), the sites of contact between mitochondria and ER, that control metabolic homeostasis, calcium signaling as well as apoptosis. We also observed a modulation in the composition and quantity of MAM resident proteins in HCV infected cells. Genetic ablation by CRISP/Cas9 technology and overexpression of these MAM resident factors in Huh7.5 cells demonstrated that they play pivotal roles in HCV infection and concomitantly impact glucose homeostasis, the central carbon metabolism and respiratory functions in mitochondria.

Finally, we have explored the impact of HCV on mitochondrial functions in more detail, and show that the virus specifically alters activity of respiratory complex 1, with maintained Ca2+ levels in mitochondria albeit the presence of profound ER stress.
Conclusion: Our study advanced our current understanding of the HCV-host interactions. Our data show that HCV associates with mitochondria and MAM, and that infection is associated with changes in mitochondrial functions including increased complex 1 activity, increased superoxide production and maintenance of mitochondrial Ca2+ signaling. These changes may play major role in disease progression. Given that MAM alterations were previously shown to contribute to altered metabolism in liver cancer, our results may also unravel a role of MAM as a driver for HCV-induced liver hepatocarcinogenesis.

SAT-187

Characterization of hepatitis e infection in israel: identification of HEV-7 in camels and high seroprevalence in specific human populations

Orna Mor[1,2], Rachel Shirazi[1], ravit bassal[3], Tamar Shohat[2,3], Marina Wax[1], Yael Gozlan[1], dan cohen[2], Dan David[4], Saif Abu-Mouch[5], ella mendelson[1,2], Ziv Ben Ari[6]. *[1]Ministry of Health, Central Virology Laboratory, Ramat Gan, Israel; [2]Tel Aviv University, Sackler Shool of Medicine, Tel Aviv, Israel; [3]Ministry of Health, Israel Center for Disease Control, Ramat Gan, Israel; [4]Kimron Veterimary Institute, Virology, Beit Dagan, Israel; [5]Hillel yaffe Medical Center, Liver unit, Hadera, Israel; [6]Chaim Sheba Medical Center, Liver Disease Center, Ramat Gan, Israel*
Email: orna.mor@sheba.health.gov.il

Background and aims: Hepatitis E virus (HEV), mainly genotype 1 (HEV-1) and genotype 3 (HEV-3), is a major cause of viral hepatitis worldwide. HEV seroprevalence is ubiquitously age dependent, and is associated with specific population groups. Previously, we have shown that in Israel, HEV-3 is endemic in swine and circulates in sewage however all clinical cases reported were of HEV-1. Recently HEV-7 was shown to infect dromedary camels and cause viral hepatitis in humans. Here, we studied HEV in dromedary camels and in specific populations (Bedouins living in the vicinity of camels, Arabs Muslims, none-Bedouins and Jews), assessed factors associated with anti-HEV seropositivity and determined HEV genotype in camels found to be HEV RNA positive.
Method: Randomly selected serum samples from > 20 years old, Israeli-born Bedouins (n = 305), non-Bedouins Muslim Arabs (n = 320) and Jews (n = 195) collected between 2009 and 2016 were serologically assessed. In addition, serum samples from different age groups dromedary camels (n = 234), collected between 2015 and 2018 were serologically (n = 86) and molecularly (n = 234) assessed. HEV seroprevalence was determined using Wantai IgG ELISA assay and HEV RNA (in camel samples) with Altona real-time PCR assay. HEV ORF2 amplified from HEV RNA positive samples was used for phylogenetic analysis.
Results: Bedouins and non-Bedouin Arabs had significantly higher prevalence of HEV antibodies (21.6% of 305 samples and 15.0% of 320 samples obtained from Bedouins and non-Bedouin Arabs, respectively) compared to Jews (3.1% of 195 samples, p value < 0.05). Seropositivity increased significantly with age in all human populations, reaching 47.6% and 34.8% among ≥ 40 years old, in Bedouins and non-Bedouin Arabs, respectively. 69.8% of the camel serum samples were anti-HEV positive; seropasvity increased with age. Three of 234 camel serum samples (from < 3 years old camels) were HEV RNA positive. Sequencing revealed infection with HEV-7 (Figure 1).
Conclusion: It is possible that HEV-7 is responsible for the high HEV seropositivity in Bedouins. The seropositivty in Muslims, none-Bedouins may result from the endemicity of HEV-3 in Israel. All patients with viral hepatitis should be thoroughly assessed for the possibility of HEV infection.

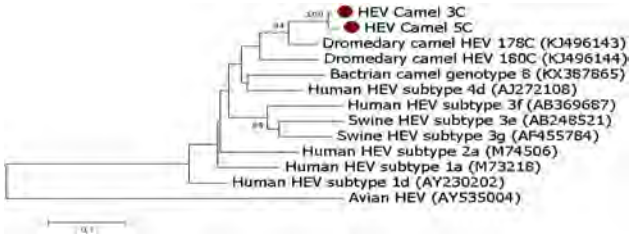

Figure 1: Phylogenetic analysis of partial ORF-2 (180 bp) sequences of HEV genotypes 1-4, 7 and 8.

SAT-188

Expansion and genetic modification of primary hepatocytes to study long-term hepatitis B virus infection

Eleftherios Michailidis[1], Paul Park[1,2], Mohammad Kabbani[1], Liliana Mancio Silva[3], Yingpu Yu[1], William M. Schneider[1], Linda Andrus[1], Chenhui Zou[1,4], Koen Vercauteren[1], Cyprien Jahan[1], Brandon Razooky[1], Corrine Quirk[1], Amir Shlomai[5], Sangeeta Bhatia[3], Charles Rice[1], Ype P. de Jong[1,4]. *[1]The Rockefeller University, New York, United States; [2]University Hospital Heidelberg, Heidelberg, Germany; [3]MIT, Boston, United States; [4]Weill Cornell Medicine, New York, United States; [5]Beilinson Hospital and Tel Aviv University, Tel Aviv, Israel*
Email: yjong@mail.rockefeller.edu

Background and aims: Primary human hepatocytes (PHHs) are the most physiologically relevant cells for studying HBV infection *in vitro*. Unlike hepatoma cells, they have intact innate immune pathways and maintain important hepatocyte functions. However, working with PHHs also has several challenges: their quantities are limited, they readily de-differentiate and lose hepatocyte functions in culture, and cells from different donors vary with respect to viability, susceptibility to HBV infection, and ability to engraft in liver chimeric mice. In addition, genetic manipulation of PHHs is less efficient than in hepatoma cell lines. Our aim here was to develop a robust primary hepatocyte system for HBV infection studies.
Results: Here we report an HBV infection system based on PHHs freshly isolated and *in vivo* passaged in human liver chimeric mice. This system has several benefits over cryopreserved PHHs. First, expansion in the mouse liver results in ~100 fold more viable hepatocytes that can be used in culture. And in contrast to large donor to donor variability with cryopreserved PHH, human hepatocytes freshly isolated from mice reliably form *ex vivo* cultures that are stable for up to eight weeks. These allow for long-term studies into HBV biology. In addition, *ex vivo* cultures are amenable to gene-specific manipulations, including > 95% lentivirus-based transduction. And finally, lentivirus transduced cultures can be re-transplanted into new chimeric mice to study gene manipulations in the context of HBV infection *in vivo*.
Conclusion: *Ex vivo* human hepatocyte cultures are a flexible system to study hepatocyte biology and long-term HBV infections *in vitro* and genetically altered human grafts in chimeric mice.

SAT-189

GCAC1809-1812TTCT a novel viral quadruple mutation is strongly associated with basal core promotor double mutation and viral load in Hepatitis B e antigen negative chronic hepatitis B virus infected patients

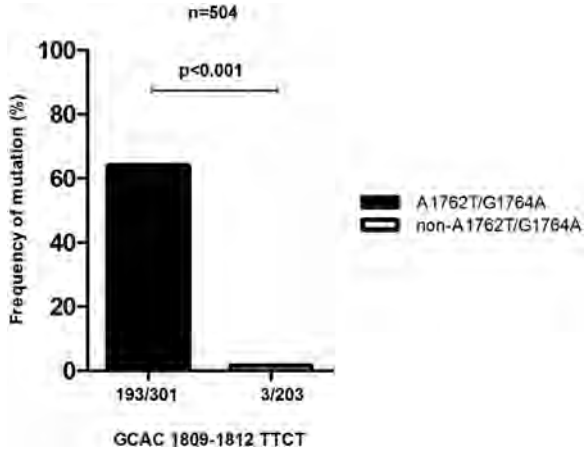
Kai-Henrik Peiffer[1,2], Lisa Kuhnhenn[1], Catrina Spengler[2], Bingfu Jiang[2], Michael Basic[1], Johannes Vermehren[1], Viola Knop[1], Stefan Zeuzem[1], Christoph Sarrazin[1,3], Eberhard Hildt[2]. *[1]University Hospital Frankfurt, Medizinische Klinik 1, Frankfurt am Main, Germany; [2]Paul Ehrlich Institute, Division of Virology, Langen, Germany; [3]St. Josefs Hospital, Department of Gastroenterology, Wiesbaden, Germany*
Email: kai-henrik.peiffer@kgu.de

Background and aims: The double mutation A1762T/G1764A in Hepatitis B virus (HBV) basal core promotor (BCP) is associated with

HBeAg negativity and has been described as a prognostic marker for disease progression and disease-related complications of chronic HBV infection. Although an enhancing effect on replication was observed in *in vitro* studies, we observed recently an association of this mutation with lower viral loads in a large European cohort of Hepatitis B e antigen (HBeAg) negative chronic HBV infected patients. In this study, we aimed to identify additional factors related to this observation.

Method: Sera of 504 patients with HBeAg negative chronic HBV infection from the European Albatros trial were analyzed. Parts of the region encoding the core promotor were amplified by nested PCR in two rounds and directly sequenced. A sensitivity level of about 15-20% was assumed.

Results: Overall BCP double mutation was detected in 60% (301/504) of the samples in a genotype specific pattern as recently described. In addition, a novel quadruple mutation (GCAC1809-1812TTCT) in the Kozak sequence preceding the precore start codon was found in 39% of the samples (196/504). Presence of this novel mutation was highly significantly associated with the coexistence of A1762T/G1764A ($p < 0.001$) independent of the HBV genotype (A-E). While this novel mutation was found in samples with A1762T/G1764A in 64% (193/301), in samples without A1762T/G1764A the GCAC1809-1812TTCT was detected only in 1% (3/203). While, GCAC1809-1812TTCT was significantly associated with lower viral loads (2.5 log IU/ml vs. 3.0 log IU/ml; $p < 0.001$), A1762T/G1764A without GCAC1809-1812TTCT was not associated with differences in the viral load. Neither GCAC1809-1812TTCT nor A1762T/G1764A was associated with changes in quantitative HB surface antigen (HBsAg) levels.



Conclusion: In our study the novel quadruple mutation GCAC1809-1812TTCT in the Kozak sequence preceding the precore start codon was found with a high prevalence of 39% in patients with HBeAg negative chronic HBV infection living in Europe. This mutation occurs almost exclusively in coexistence with BCP double mutation A1762T/G1764A (64% in patients with and 1% in patients without A1762T/G1764A) and is associated with lower viral loads. Therefore, our recent observation that A1762T/G1764A is associated with lower viral loads can be explained by the high prevalence of GCAC1809-1812TTCT in patients with A1762T/G1764A.

SAT-190

Specific genetic elements in HBsAg C-terminus profoundly affect HBsAg levels in vivo, hamper HBsAg secretion in vitro and alter HBsAg structural stability in HBeAg-negative chronic HBV genotype D infection

Email: piermatteolorenzo@gmail.com

Background and aims: In eAg-negative chronic infection, HBV genotype D is characterized by lower HBsAg levels. Here, we aim at investigating the correlation of specific mutations in HBsAg C-terminus (critical for a proper HBsAg release) with HBsAg levels *in vivo*, their impact on HBsAg secretion in vitro and on structural stability.

Method: This study includes 228 drug-naïve eAg-negative patients (all genotype D), stratified in HBsAg ≤ 1, 000IU/ml (N = 130) and HBsAg > 1, 000IU/ml (N = 98). Association of mutations with HBsAg ≤ 1, 000IU/ml is assessed by Fisher Exact Test. Association among mutations in C-terminus is assessed by binomial correlation coefficient (phi). The impact of mutations on HBsAg secretion is analyzed by transfecting HepG2 cells with a plasmid encoding wt and mutated HBsAg, linked to a streptavidin-tag (strep-tag). The strep-tagged HBsAg amount in supernatants is quantified by an ELISA recognizing the Strep-tag, not affected by HBsAg antigenicity and thus, capable to identify a defect in HBsAg secretion. I-Tasser is used to predict HBsAg 3-D structures and their stability ($\Delta\Delta G$[wt-mutated] < 0 indicating reduced stability in presence of mutations [Quan, 2016].

Results: Specific mutations in HBsAg C-terminus tightly correlate with HBsAg ≤ 1, 000IU/ml: S204N (33.7% vs 12.1% in HBsAg < 1, 000 vs > 1, 000 IU/ml, P < 0.001), Y206F (16.9% vs 3.3%, P = 0.001) and S210N (6.5% vs 1.3%, P = 0.04).

These mutations lie on divergent pathways involving other mutations in HBsAg C-terminus: S204N with L205P (Phi = 0.36), Y206F with M197T (Phi = 0.32) and S210N with F220L (Phi = 0.40) (p = 0.006-0.002). Notably, each of these pairs of mutations drastically decreases HBsAg titer compared to wt (S204N + L205P: 226[123-394]IU/ml, Y206F + M197T: 284[52-563]IU/ml and S210N + F220L: 335[209-417]IU/ml vs wt: 2791 [1009-8212]IU/ml, P = 0.003-0.02).

In vitro, S204N + L205P determines an 85% decrease in extracellular HBsAg (p < 0.001), while Y206F + M197T and S210N + F220L cause a 32% and 20% decrease compared to wt (p < 0.001).

By structural analysis, these pairs of mutations determine a relevant reduction in the stability of HBsAg C-terminus (ΔΔG[mut-wt] = -1.8 for S204N + L205P, −1.6 for Y206F + M197T and −1.0 for S210N + F220L) and a profound rearrangement of this domain.
Conclusion: Specific clusters of mutations in HBsAg C-terminus correlate with lower HBsAg levels in vivo, hamper HBsAg release in vitro and affect HBsAg structural stability, supporting their detrimental role on HBsAg secretion. Such mutations should be considered for a proper clinical interpretation of HBsAg levels in HBV genotype D chronic infection.

SAT-191

Host genome integration of hepatitis B is prolific and is the primary contributor to viral HBs antigen gene expression

Ondrej Podlaha[1], George Wu[1], Bryan Downie[1], Raghuraman Raghuraman Ramamurthy[1], Anuj Gaggar[1], Mani Subramanian[1], Zhishen Ye[1], Zhaoshi Jiang[1]. [1]*Gilead Sciences, Inc., Foster City, United States*
Email: ondrej.podlaha@gilead.com

Background and aims: Genomic integration of Hepatitis B (HBV) promotes liver carcinogenesis, yet the prevalence of viral integration events at single-cell level remains unknown. Our goal was to interrogate the human liver cancer genome data and estimate the number of viral integrations per cell in the liver of chronic HBV infected patients.
Method: We analyzed both whole genome and transcriptome paired-end sequencing data of 192 DNAseq samples (120 tumor and 72 adjacent non-tumor) and 59 non-tumor RNAseq samples from HBV positive hepatocellular carcinoma (HCC) patients (Fujimoto et al. 2016, Sung et al. 2012). Paired-end reads were mapped to the human (GRCh38) and HBV reference genomes. Viral integrations into the human genome were quantified via dual-clustering strategy of chimeric reads accounting for strand polarity as well as viral and human genome coordinates. The viral integration prevalence per cell was calculated by dividing the number of viral integrations by the scaled depth coverage of the genome.
Results: Genome analysis of HBV infected liver tissue revealed 3496 and 1356 viral integrations across 120 and 72 tumor and non-tumor DNA HCC samples, respectively. Although the integrated virus had a preference for fusion breakpoint near the DR1 locus of the viral genome (~23% of total), the integration sites in the human genome were scattered across all chromosomes (Fig 1A). Given the stochastic nature of sequence library preparation, the genome depth coverage can serve as a reasonable surrogate for the number of cells sampled. Following this rationale, we estimated that there are on average 0.86 HBV integrations per diploid cell (median = 0.69, min = 0.044, max = 5.34, Fig 1B). In addition, integrated virus has the potential to be transcribed and possibly obscure the interpretation of clinical biomarker measurements. We used integration-specific genomic feature to quantify the extent of transcripts originating from integrated HBV and found that 82.8% of HBV transcript originated from integrated HBV DNA.
Conclusion: Our data indicate high frequency of HBV integration (avg = 0.86 per cell) in HBV infected HCC patients. This integration frequency is expected to be a conservative estimate for hepatocytes given the cellular heterogeneity in liver tumor tissue samples. To generalize these findings comparative examination of large number of chronic HBV liver samples, particularly via single-hepatocyte sequencing, is warranted.

Targeting the HBx-DDB1-Cullin complex inhibits transcription from HBV covalently closed circular DNA in susceptible hepatoma cells

Bingqian Qu[1], Mila Leuthold[1], Jessica Sonnabend[1], Stephan Urban[1,2]. [1]*University Hospital Heidelberg, Department of Infectious Diseases, Molecular Virology, Heidelberg, Germany;* [2]*German Centre for Infection Research, Heidelberg, Germany*
Email: qubingqian@gmail.com

Background and aims: More than 200 million people worldwide are suffering from chronic Hepatitis B (HBV) infection without a curative therapeutic regimen available so far. One approach to control HBV replication is silencing transcription from covalently closed circular DNA (cccDNA). Efficient transcription requires the X protein (HBx) as a transcriptional activator, which binds to DNA-damage binding protein 1 (DDB1) and Cullin 4 and induces degradation of the host restriction factor SMC5/6. Therefore, therapeutic interfering with this pathway may silence transcription from cccDNA.
Method: Wild-type (WT), HBx-minus virus that does not encode HBx and an R96E mutant expressing HBx but is deficient in binding DDB1 were generated and tested for infectivity. Lentiviral trans-complementation was established to complement HBx *in trans* in HBx-minus virus infections. Established clones of DDB1 stable knockdown cells were infected. Two stable HepG2-NTCP-HBx (WT) and (R96E) cells supported the study of HBx-DDB1 interaction.

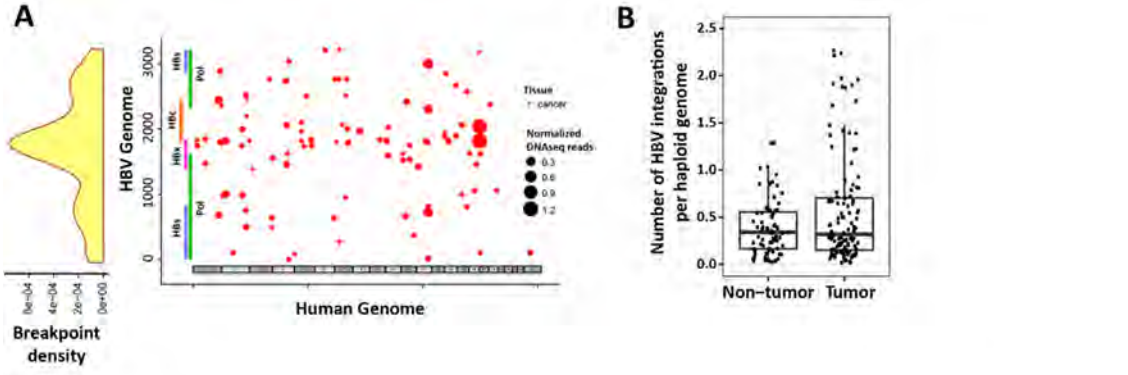

Figure 1
A. Viral-human chimeric paired-end reads were clustered to define viral integration. Each dot represents an independent viral integration event. Size of dot represents number of reads supporting the integration call. Each integration was plotted against the human genomic location (x-axis) and the HBV genome (y-axis). Viral-human fusion breakpoints have a strong preference for the viral region near DR1 but integration spreads out on all human chromosomes. **B.** Estimated viral integration frequency per haploid genome, where each dot represents a sequenced tumor or non-tumor HCC sample.

Figure: (abstract: SAT-191)

Results: Both HBx-minus and R96E viruses expressing DDB1-binding deficient HBx showed lower transcription levels compared to WT virus in infected HepaRG- and HepG2-NTCP cells. Consistently, stable shRNA-mediated knockdown of DDB1 in HepG2-NTCP cells led to reduced transcription from cccDNA. Furthermore, we observed that the reduction degree of HBV transcription is inversely dependent on the level of DDB1 expression.
Besides knockout of HBx and knockdown of DDB1, we identified a small molecule preventing activation of Cullin 4 by prevention of neddylation. Remarkably, this molecule showed inhibitory effects on transcription from cccDNA in all *in vitro* infection models, although it targeted Cullin 4 without affecting HBx expression directly or HBx-DDB1 interaction. We verified that this inhibitor selectively eliminated the enhanced transcription induced by lentiviral HBx transduction in the infection of HBx-minus virus, suggesting dependency on HBx.
Conclusion: Our findings support that the HBx-DDB1-Cullin complex is functionally required for efficient cccDNA transcription and might be targeted using a small molecule to shut down HBV gene expression. To achieve this aim, either depleting HBx, interfering with HBx-DDB1 association, or blocking the function of Cullin 4 result in remarkable inhibition at the transcriptional level.

SAT-193

Evolutionary relationship among hepatitis B virus genotype D in Latin America and Europe

Bibiane Godoy[1], Michele Gomes[2], Romina Salpini[3], Valentina Svicher[3], Francesca Ceccherini Silberstein[3], Carlo Federico Perno[3], João Renato Rebello Pinho[2,4], Nelson Fagundes[1]. [1]*Federal University of Rio Grande do Sul, Department of Genetics, Porto Alegre, RS, Brazil;* [2]*Institute of Tropical Medicine of São Paulo, University of São Paulo School of Medicine, LIM 07, Department of Gastroenterology, São Paulo, SP, Brazil;* [3]*University of Rome Tor Vergata, Department of Experimental Medicine and Surgery, Rome, Italy;* [4]*Hospital Israelita Albert Einstein, Clinical Pathology, São Paulo, SP, Brazil*
Email: jrrpinho@usp.br

Background and aims: Hepatitis B Virus (HBV) infects 7 to 12 million people in Latin America. HBV genotype D (HBV/D) has a worldwide distribution and, in Latin America, is associated to European and Middle Eastern migrations. Indeed, some Latin America regions where HBV/D reach higher frequencies, such as Southern Brazil, had received an important flow of Italian migrants in the late 19th century.
Method: In this study, we used phylogenetic and population genetics approaches to compare HBV/D isolates from Latin America, Europe and Middle East and establish evolutionary relationships between viral distribution and historical events associated to HBV spread. Sequences were aligned using the ClustalW algorithm implemented in MEGA v.7. A maximum likelihood (ML) HBV phylogeny was estimated with RAxML v8.2.10 using ten independent searches, and 1, 000 bootstrap replicates to evaluate clade support. We used the fixation index (Φ_{ST}) to quantify the genetic structure among populations. Variation of effective population size through time was estimated using the Bayesian Skyline method.
Results: Our results showed a predominance of HBV/D3 towards southern South America with subgenotype distributions mirroring those present in Italy. On the other hand, the Caribbean and Northeastern Brazil showed a distinct subgenotype distribution, with HBV/D4 reaching high frequencies. At the subgenotypic level, HBV/D3 was more related to Italian migration in Southeast Brazil (BR-SE), and evidenced an older population expansion shared by both populations, which may suggest that BR-SE acted as a source population in Latin America. In addition, we found similarities between Germany and Poland HBV/D3 and other Latin America populations, and also between Germany, Poland and BR-SE for HBV/D2. HBV/D1 showed that while Brazilian populations (BR-S, BR-SE) were closest to NLD, ARG and CUB were closest to LIB + TUR. Finally, HBV/D4 showed a specific population dynamics, with marked genetic differences among localities.
Conclusion: This study highlighted a complex history for HBV/D dispersal across Latin America, in which multiple sources populations contributed to the current HBV/D gene pool in this region.

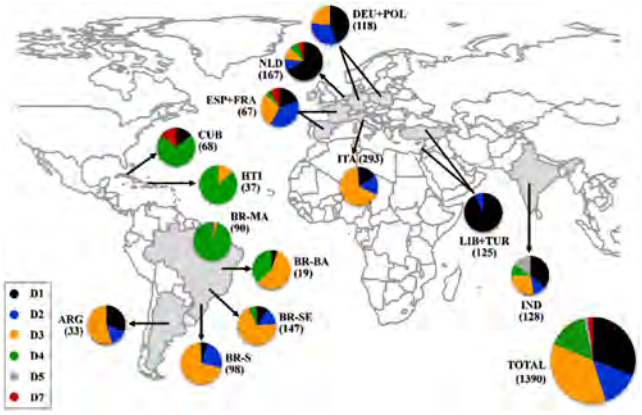

Figure: Geographical distribution of the 1390 HBV sequences belonging to D genotype that were included in this study. Colors indicate the different HBV/D subgenotypes (D1-D5, D7). ARG, Argentina; BR-BA, Brazilian state of Bahia; BR-MA, Brazilian state of Maranhão; BR-S, Southern Brazil; BR-SE, Southeastern Brazil; CUB, Cuba; DEU + POL, Germany and Poland; ESP + FRA, Spain and France; D1, HBV subgenotype D1; D2, HBV subgenotype D2; D3, HBV subgenotype D3; D4, HBV subgenotype D4; HTI, Haiti; IND, India; ITA, Italia; LIB + TUR, Lebanon and Turkey; NLD, Netherlands.

SAT-194

The utility of monomeric HBV genomes for interrogating the HBV cccDNA minichromosome, using in vitro and in vivo models of HBV replication

Thao Huynh[1], Michelle Clark[2], Liana Mackiewicz[2], Vitini Sozzi[1], Hugh Mason[1], Marc Pellegrini[2], Greg Ebert[2], Hans J Netter[1], Peter Revill[1]. [1]*VIDRL, Royal Melbourne Hospital, Peter Doherty Institute of Infection and Immunity, Melbourne, Australia;* [2]*Walter and Eliza Hall Institute of Medical Research, Infection and Immunity Division, Parkville, Australia*
Email: peter.revill@mh.org.au

Background and aims: The Hepatitis B Virus (HBV) exists as nine distinct genotypes (A-I) which are differentiated by more than 8% difference in the complete nucleotide sequence. These different genotypes generally affect particular demographic groups in discrete geographic regions, with varying severity and treatment response. Differences in their replication efficiencies have also been identified and characterized, but molecular analyses have been hindered by lack of suitable models permitting thorough analysis of the complete replication cycle of HBV, particularly the viral cccDNA nuclear reservoir which is a major source of viral persistence.
Method: Using complete genome PCR, we generated full-length Hepatitis B Virus genomes ("1-mers", genotypes A, C and D), transfection of which induced the complete HBV replication cycle, including establishment of a cccDNA-like intermediate, *in vitro*. We next introduced these plasmid-free monomeric HBV genomes into mice via hydrodynamic tail-vein injection, to investigate their utilization as a novel *in vivo* replication model.
Results: Characterization of HBV replication using cell lysates and murine liver tissue demonstrated production of cccDNA-like episomes via Southern blot, as well as detection of major viral RNA transcripts by northern blot. This was achieved for multiple HBV genotypes.
Conclusion: We have demonstrated the utility of the HBV 1 mer model for the production of a cccDNA like molecule in both *in vitro* and *in vivo* models of HBV replication, across HBV genotypes. This model system will next be used to investigate interactions between

HBV cccDNA and viral and host proteins, to investigate their contributions to HBV replication across genotypes *in vitro* and *in vivo* and gain new insights into cccDNA transcriptional regulatory mechanisms. This may lead to discovery of novel pan-genotypic strategies for curing HBV infection.

SAT-195

The novel HBx mutation F30V correlates with HCC in vivo, hampers HBV replicative efficiency and enhances anti-apoptotic activity of HBx N-terminus in vitro

Email: rsalpini@yahoo.it

Background and aims: HBV X protein (HBx) is critical for viral gene expression and for the initiation of HBV-induced hepatocarcinogenesis. Here, we investigate HBx genetic-elements correlated with HCC and their impact on i) HBV replicative efficiency, ii) HBx-binding to cccDNA, iii) apoptosis and cell-cycle progression, and iv) HBx structural stability.

Method: This study includes 123 HBV-chronically infected patients: 27 with HCC (77.9% genotype-D; 22.1% genotype-A) and 96 without HCC (75%-D; 25.0%-A). HepG2 cells are transfected by *wild-type* (wt) or mutated linear HBV-genome to assess i) the levels of pre-genomic RNA (pgRNA) and intracellular core-associated HBV-DNA by RT-PCR, ii) HBx-binding onto cccDNA by Chromatine Immune-Precipitations-based quantitative assay, and iii) rate of apoptosis and cell-cycle progression by cytofluorimetry. Scansite and Netphos algorithms are used to predict the probability of phosphorylation of a given residue by Serine (Ser) Kinases.

Results: F30V is the only HBx-mutation correlated with HCC in-vivo (18.5% in HCC vs 1.0% in non-HCC, $p = 0.002$). Result confirmed by multivariable-analysis adjusting for patients' demographics, HBV genotype, serum HBV-DNA and ALT (OR[95%CI]:20.0[2.1-195.0], $p = 0.001$).

In-vitro, F30V determines a 40% and 60% reduction in pgRNA and core-associated HBV-DNA compared to wt ($p < 0.05$), paralleling with a 79% decrease of HBx-binding to cccDNA ($p < 0.01$). F30V also decreased the percentage of apoptotic-cells compared to wt (14.8 ± 6.8% vs 19.1 ± 10.1%, $p < 0.01$) without affecting cell-cycle progression.

By structural analysis, F30V is adjacent to HBx-Ser31, whose phosphorylation by PI3-kinase (PI3K), is known to promote HBV anti-apoptotic activity. Interestingly, F30V increases the probability of Ser31-phosphorylation by PI3K respect to wt (F30V:0.54 vs wt:0.48 and F30V:0.76 vs wt:0.72 according to Scansite and NetPhos, respectively), further supporting its anti-apoptotic activity.

Conclusion: F30V tightly correlates with HBV-induced HCC in-vivo, reduces HBV replicative efficiency by affecting HBx-binding to cccDNA and increases anti-apoptotic HBx activity. This suggests that F30V (although hampering HBV replicative-capacity) may promote hepatocytes survival, thus contributing to mechanisms underlying the initiation of HBV-driven hepatocarcinogenesis. Investigation of viral genetic-markers associated with HCC is crucial to identify patients at higher HCC-risk deserving intensive liver monitoring, and/or early anti-HBV therapy.

SAT-196

The integrated use of highly sensitive HBV markers can predict HBV reactivation in HBsAg-negative/Anti-HBc positive patients from oncohematological setting

Romina Salpini[1], Carlotta Cerva[2], Arianna Battisti[1], Lorenzo Piermatteo[1], Angelica Sacco[1], Vincenzo Malagnino[2], William Arcese[3], Maria Cantonetti[3], Francesca Ceccherini Silberstein[1], Carlo Federico Perno[4], Massimo Andreoni[2], Loredana Sarmati[2], Valentina Svicher[1]. *[1]Tor Vergata University of Rome, Department of Experimental Medicine, Rome, Italy; [2]Tor Vergata University of Rome, Clinical Infectious Disease, Department of System Medicine, Rome, Italy; [3]Tor Vergata University of Rome, Department of Hematology, Stem Cell Transplant Unit, Rome, Italy; [4]University of Milan, Department of Oncology and Haematooncology, Milan, Italy*
Email: rsalpini@yahoo.it

Background and aims: To investigate the role of HBV markers in predicting immunosuppression-driven HBV reactivation (HBV-R) in HBsAg-negative/anti-HBc-positive patients (pts) with hematological malignancies.

Method: HBV-R rate is assessed in 111 HBsAg-negative/antiHBc-positive pts (48 receiving rituximab, 36 HSCT, 27 other chemotherapeutics). All pts received lamivudine prophylaxis (median [IQR] duration:29 [22-41] months) and were prospectively monitored every 3 months during and after prophylaxis completion. The role of HBV markers in predicting HBV-R was evaluated in a subset of 30 pts: 5 developing HBV-R and 25 not developing HBV-R. For these pts, a total of 230 serum samples was tested for high sensitive HBsAg, FujiRebio (HS-HBs; lower limit of quantification [LLOQ]:5mIU/ml, vs 50mIU/ml of routinely used HBsAg assays), anti-HBs and HBV-DNA (LLOQ: 20 IU/ml, Roche). HBV-R is defined as serum HBV-DNA > 20 IU/ml (according to Seto WK, 2016).

Results: At baseline, all pts are HBsAg-negative/antiHBc-positive with undetectable HBV-DNA. Among them, 66.7% is positive to anti-HBs [median (IQR): 151 (45-557)mIU/ml]. HBV-R occurs in 10/111 pts with a 4-year cumulative reactivation rate of 22%. At HBV-R, median (IQR) HBV-DNA is 36 (20-522)IU/ml and ALT is > ULN in 6/10 pts with a median of 88 (60-763)U/L. Among 10 pts with HBV-R, 5 develops HBV-R during and 5 after completing the recommended duration of prophylaxis (median [IQR]months after prophylaxis completion:3[1-16]).

Focusing on the 30 pts, an anti-HBs titer < 100mIU/ml at baseline is the only virological marker correlated with a higher risk to develop HBV-R (HBV-R occurs in 55.6% of pts with anti-HBs < 100mIU/ml and never in pts with anti-HBs > 100mIU/ml, $P = 0.046$). The on-monitoring analysis of virological markers shows that the positivity, even at a single time-point, to HS-HBs (detection failed by the routinely used HBsAg assays) and/or to HBV-DNA (below LLOQ) is another risk factor for HBV-R (3/5 pts with HBV-R vs 0/25 pts without HBV-R are positive to HBV-DNA and/or HS-HBs, $P < 0.001$).

Conclusion: In anti-HBc-positive/HBsAg-negative oncohematological pts, HBV-R frequently occurs after completing the recommended course of anti-HBV prophylaxis suggesting the need to reconsider the duration of prophylaxis in the setting of profound immunosuppression. A close monitoring based on an integrated use of HBV markers (including those with high sensitivity) can help in detecting minimal viral replication predictive of HBV-R, allowing early HBV-R diagnosis.

SAT-197

Quality of life measurement using wrist actigraphy in HCV genotype 1 infected, treatment naïve patients suffering from fatigue and receiving ombitasvir, paritaprevir, and ritonavir tablets and dasabuvir tablets (Viekirax/Exviera; 3D regimen)

Nasser Semmo[1], Beat Müllhaupt[2], Lisa Ruckstuhl[3], Lorenzo Magenta[4], Olivier Clerc[5], Ralph Torgler[3], David Semela[6]. [1]*Hepatology, Department of BioMedical Research, Bern, Switzerland;* [2]*Division of Gastroenterology and Hepatology, Zürich, Switzerland;* [3]*AbbVie AG, Baar, Switzerland;* [4]*Epatocentro Ticino, Lugano, Switzerland;* [5]*Infectious Diseases Department, Neuchatel, Switzerland;* [6]*Division of Gastroenterology, St.Gallen, Switzerland*
Email: nasser.semmo@insel.ch

Background and aims: Physical and mental fatigue is the most common symptom reported by patients with Hepatitis C Virus (HCV), which highly impacts their overall quality of life. This cardinal symptom presents regardless of the stage of liver fibrosis and is difficult to quantify objectively. Similar to other potential reasons for physical fatigue, increasing evidence suggests a direct viral impact on the central nervous system. Data demonstrating a longitudinal change of debilitating physical fatigue and increased daytime physical activity upon treatment (Tx) with 3D regimen are missing to date. The rationale for this observational study is to observe the impact of 3D regimen on physical activity of HCV+ patients suffering from debilitating fatigue by using wrist actigraphy.
Method: HEMATITE is an observational, prospective, open label, single-arm, Swiss multi-centric, real-life study in HCV+ patients (GT1). The study consists of a Tx preparation phase of 4 weeks (wks), a Tx phase with 3D regimen according to routine clinical practice (12 wks) and a post Tx phase (12 wks) to evaluate Tx response. Fatigue was assessed at every visit using the Fatigue Severity Score (FSS) questionnaire, according to routine clinical care. In addition, physical activity data was collected by providing patients with a wrist-worn activity tracker to be worn for 4 wks before Tx (baseline (BL)) and for 4 wks before each visit.
Results: 40/41 patients reached SVR12. The FSS decreased significantly from BL to post Tx visit week 12 (5.92 ± 0.61 vs. 3.34 ± 1.42 (mean±SD); $p < 0.001$). The physical workday daytime activity data could be analyzed from 37 out of 45 (scale down (sd)ITT). Neither the mean activity nor the change of the mean activity between BL and Tx week 12 showed any significance.
Conclusion: As expected > 97% of the patients achieved SVR12 upon 3D regimen therapy. Moreover, the 3D therapy also reduces fatigue in HCV+ patients, as shown by the FSS, suggesting a causative role of HCV in this extrahepatic manifestation. HCV treatment is therefore effective in reducing/eliminating fatigue.

SAT-198

Full-length 5'RACE analysis discriminates all major intracellular and extracellular viral RNAs during the course of infection

Bernd Stadelmayer[1], Diederichs Audrey[2], Neveu Gregory[3], Alam Antoine[3], Fraisse Laurent[3], Carter Kara[3], Testoni Barbara[2], Zoulim Fabien[2,4,5]. [1]*Cancer Research Center of Lyon (CRCL), INSERM U1052, Lyon, France;* [2]*Cancer Research Center of Lyon (CRCL, INSERM U1052, Lyon, France;* [3]*Evotec, Marcy-l'Étoile, France;* [4]*Hospices Civils de Lyon, Lyon, France;* [5]*University of Lyon, Lyon, France*
Email: bernd.stadelmayer@inserm.fr

Background and aims: Covalently closed circular DNA (cccDNA) is the episomal form of the Hepatitis B virus (HBV) genome that stably resides in the nucleus of infected hepatocytes. The amount of cccDNA and its transcriptional activity vary along the natural course of infection and are a main determinant of viral persistence and reactivation. cccDNA is the template for six viral RNAs, i.e. preC- pg-, preS1/2-, S- and HBx-RNA. All viral transcripts share the same 3' end and are all to various degrees subsets of each other. Consequently, transcription of 5' positioned genes obscures the measurement of transcripts starting further downstream, using standard RT and PCR techniques. Especially under infection conditions, it has been difficult to study in depth HBV gene transcription and the differential regulation of each transcript, most importantly that of HBx. Indeed, HBx RNA, whose sequence is common to all viral transcripts, is undetectable by Northern blotting due to sensitivity issues and indistinguishable from the other viral RNAs by qPCR.
Method: We set up an "HBV full-length 5'RACE" technique to specifically measure and characterize the different HBV RNAs. This method takes advantage of anchoring a known sequence at the 5' ends of all HBV transcripts. The different HBV RNAs can then be amplified and resolved by gel electrophoresis according to their molecular weights.
Results: We are able to discriminate all the major HBV RNA species (including HBx RNA) transcribed during the infection cycle in cultured hepatocytes using little starting material. Performing time-course experiments, we confirm HBx to be the first measurable viral RNA after infection of both HepG2-NTCP cells and primary human hepatocytes (PHHs). We find a great diversity in transcription start sites for HBx, giving rise to various HBx transcripts including short HBx transcripts potentially coding for a short version of the X protein. We show that Interferon β treatment leads to the down-regulation of both preC- and pg-RNAs but has no effect on HBx in PHHs. In addition to pg-RNA we find a variety of different HBx transcripts associated with viral particles produced by HepAD38 cells. Finally, apart from pg-RNA and HBx RNA we find at least 2 additional viral RNAs in the plasma of patients.
Conclusion: Our approach should significantly contribute to the understanding of HBV transcription and its regulation during the course of infection and therapy.

SAT-199

Recombinant hepatitis E viruses harbouring tags in the ORF1 protein allow visualisation of the viral replicase

Dagmara Szkolnicka[1], Angela Pollan[1], Noémie Oechslin[1], Jérôme Gouttenoire[1], Darius Moradpour[1]. [1]*Centre Hospitalier Universitaire Vaudois, University of Lausanne, Division of Gastroenterology and Hepatology, Lausanne, Switzerland*
Email: d.szkolnicka@googlEmail.com

Background and aims: Hepatitis E virus (HEV) infection is one of the most common causes of acute hepatitis and jaundice in the world. Our current understanding of the molecular virology and pathogenesis of hepatitis E is incomplete, especially due to the limited availability of functional tools. Here, we developed tagged functional HEV genomes to investigate the open reading frame 1 (ORF1) protein representing the viral replicase.
Method: A selectable subgenomic HEV replicon was subjected to random 15-bp sequence insertion using transposon-based technology, followed by selection in a human hepatoblastoma cell line and characterisation of viable insertion sites. Different tags were cloned into viable insertion sites identified in the ORF1 protein and characterised in the context of full-length viral constructs.
Results: Several functional insertion sites were identified in the ORF1 region, with the highest replication efficacy observed for those mapping to the hypervariable region. HEV genomes harbouring a haemagglutinin (HA) epitope tag or a small luciferase (NanoLuc) at these sites were found to be fully functional and to allow for the production of infectious virus. NanoLuc allowed to quantitatively monitor HEV infection and replication by luciferase assay. HA-tagged constructs allowed to localise the site of HEV RNA replication by the simultaneous detection of ORF1 protein by immunofluorescence and of viral RNA by fluorescence *in situ* hybridisation. Candidate HEV replication complexes were found in the cytoplasm at a site which partially overlaps with ORF2 and ORF3 proteins as well as exosomal markers.
Conclusion: Tagged genomes yield new insights into the HEV life cycle, allowing investigation of the subcellular localisation and

composition of viral replication complexes. These efforts may reveal new angles for therapeutic intervention against hepatitis E.

SAT-200

AMPK activation in response to hepatitis E virus infection inhibited viral infection by attenuating autophagy and promoting innate immunity

Yijin Wang[1], Jingmin Zhao[1]. [1]*Beijing 302 hospital, Beijing, China*
Email: yijinwang927015@163.com

Background and aims: Other than hepatitis B or C virus infection, Hepatitis E virus (HEV) infection is generally asymptomatic or leads to acute and self-limiting hepatitis. However, the mechanism of host-cell defence against HEV is unclear. AMP-activated protein kinase (AMPK) activation is crucial for the regulation of cell homeostasis. We thus investigated the role of AMPK in HEV infection.
Method: Huh-7 and HepG2 cells inoculated with infectious HEV viral particle or transfected with *in vitro* generated HEV genome RNA were used to model HEV infection. Viral replication and genes expression were quantified by quantitative real-time polymerase chain in reaction (qPCR). Activation of AMPK and induction of autophagy were assessed by Western Blotting.
Results: We found HEV infection can trigger AMPK activation by phosphorylation of AMPK at threonine 172 by transfecting HEV viral RNA into host cells or inoculating host cells with infectious HEV viral particle. Meanwhile, HEV also induced autophagy. Inhibition of HEV induced AMPK phosphorylation with specific AMPK inhibitor compound C dose-dependently enhanced HEV replication. Conversely, treatment with pharmacological AMPK activator AICAR strongly inhibited HEV replication. These results suggested that AMPK activation is a potent strategy of host cells for HEV clearance. Interestingly, we found inhibition of AMPK efficiently augmented HEV induced autophagy, evidenced by a marked increase in LC3II/I via decreasing mTOR levels, indicating that AMPK activation upon HEV infection can increase mTOR level to supress HEV induced autophagy. Our previous study showed that rapamycin, an activator of autophagy by inhibiting mTOR, has a potent pro-HEV effect. Together, these results suggested that HEV induced AMPK activation can serve to protect HEV infected cells from autophagy and inhibit HEV infection. We also investigated whether HEV-induced AMPK activation affects innate immunity. Interestingly, interference of AMPK activation significantly supressed the expression of a subset of interferon-stimulated genes (ISGs), which are considered the ultimate antiviral effectors. These results indicated that HEV induced AMPK activation also contributes to stimulation of innate immunity, thereby facilitating cell-defence against HEV.
Conclusion: Here we show that HEV infection can activate AMPK phosphorylation, which attenuates HEV-induced autophagy and increases innate immune signalling. Thus the AMPK activation in response to HEV infection is critical in host cells for rapid viral clearance by coordinating autophagic process and establishing persistent antiviral immunity.

SAT-201

Alternation of lipid metabolism and dysfunction of mitochondria might contribute to HCC development in the absence of overt necroinflammation

Yu-Wei Chiou[2], Chien-Wei Su[3], Jenny Yuh-Jin Liang[2], Jaw-Ching Wu[1]. [1]*Institute of Clinical Medicine, National Yang-Ming University, Taipei City, Taiwan;* [2]*Medical Research Department, Taipei Veterans General Hospital, Taipei City, Taiwan;* [3]*Division of Gastroenterology, Taipei Veterans General Hospital, Taipei City, Taiwan*
Email: jcwu@vghtpe.gov.tw

Background and aims: Chronic hepatitis B virus (HBV) infection is a major cause of hepatocellular carcinoma (HCC). HBV viral load, necroinflammation, cirrhosis, obesity and diabetes are linked to HCC development. However, HCC also develops in patients with normal or minimally elevated ALT levels. The hepatocarcinogenesis mechanisms in these cases remain unclear. To elucidate the molecular mechanisms in these HCC cases, we have developed a panel of HBV transgenic mice with high liver tumor incidences in the absence of overt immune response mimicking human HCC without severe liver necroinflammation.
Methods: HCC and paired liver tissue samples from these mice were analyzed by microarray and metabolomics, and validated by real-time PCR and Western blotting.
Results: Of note, high viral loads were associated with higher tumor incidence (48/158, 30.4%, vs. 2/73, 2.7%, $p < 0.0001$). The effect of integration sites may also play a role in different liver tumor incidences in lineages B00 vs B13 (57.9% vs 14.3%, $p = 0.0151$) and lineage D11, D14 and D23 (16.7%, 41.9% and 13.7%, $p = 0.0026$). Differentially expressed genes analysis of the microarray data based on 7 HCC of HBV transgenic mice vs 5 normal livers of the background lineage C57BL/6 mice revealed that: 1. Lipid catabolism related pathways were down-regulated (TG breakdown: lipg, mgll, $p < 0.0005$; beta-oxidation: acat1, $p < 0.0001$; acaa1a, acaa2, acadsb, acot8, $p < 0005$; Hsd17b4, $p < 0.0001$). 2. Accumulation of lipid was up-regulated (fatty acid synthesis: acly, $p = 0.0058$ and fatty acid uptake: Fabp4, $p = 0.0165$). The epithelial mesenchymal transition (EMT) related genes such as NID1, CD44, Vim, Ahnak, Col1a2, Col3a1, Col5a2, Msn, Serpine1, Sparc, and Timp1 were significantly up-regulated. Gene involved in Warburg effect such as psat1 was up-regulated. Hepatocellular mitochondrial defects were observed in HBV transgenic mice less than 6 months old by ultrastructural analysis of TEM. In non-target metabolomics analysis of liver of HBV transgenic mice vs C57BL/6 mice, the composition of long-chain saturated fatty acids (C14:0, C16:0, C18:0) were elevated and mono- or poly-unsaturated fatty acids (PUFAs) were reduced (C18:1, C18:2, C20:2).
Conclusion: High HBV viral loads, alternation of lipid metabolism and energy production caused by dysfunction of mitochondria might be important for HCC development. These transgenic mice are of value in the study of hepatocarcinogenesis of human HCC in absence of overt necroinflammation and useful platforms in the development of novel therapy.

SAT-202

Endogenous and exogenous IFN responses suppress HDV persistence during proliferation of hepatocytes in vitro

Zhenfeng Zhang[1], Yi Ni[1,2], Stephan Urban[1,2]. [1]*University Hospital Heidelberg, Department of Infectious Diseases, Heidelberg, Germany;* [2]*German Center for Infection Research (DZIF)-Heidelberg Partner Site, Heidelberg, Germany*
Email: stephan.urban@med.uni-heidelberg.de

Background and aims: Hepatitis B virus (HBV) and D virus (HDV) co-infections cause the most severe form of viral hepatitis. Persistence of both viruses makes it challenging to develop curative therapies. Extracellular spreading pathways are important for persistence of both viruses and can be blocked by the entry inhibitor Myrcludex B. However, HDV can also propagate through cell division (Giersch K, *et al.* Gut. 2017). We recently found that HDV replication induces profound IFN response via MDA5 but is insensitive to the response in resting hepatocytes (Zhang Z, *et al.* J Hepatol. 2018). The aim of this study is to evaluate the effect of the IFN response on HDV persistence during hepatocyte proliferation.
Method: To measure cell division mediated HDV amplification, susceptible innate immune competent and immune deficient cell lines were infected with HDV and splitted (1:6) at day 5 post infection and further splitted every 5 days. Different IFNs were applied during cell proliferation. HDV infected cells and viral markers (HDV RNA and antigens) were quantified using immunofluorescence and RT-qPCR.
Results: Over 6 passages following HDV infection, HDV-specific markers were efficiently amplified in HuH7-NTCP cells which are defective to produce IFNs, but profoundly lost in HepaRG-NTCP cells which are innate immune competent. BrdU labeling of newly

synthesized DNA indicated that HDV replication does not impair HepaRG-NTCP cell division. Blocking of the endogenous IFN response by MDA5 depletion and inhibitors targeting the IFN signaling pathway profoundly promoted HDV amplification by cell division, indicating endogenous restriction of HDV amplification by the "self-induced" IFN response. This finding was in line with the significant suppression of HDV persistence by exogenous IFN-α, -β and -λ1 treatment in HuH7-NTCP cells. In addition to the endogenous IFN effect, exogenous IFN further inhibited HDV persistence during HepaRG-NTCP cell division at low infection levels.

Conclusion: Both exogenously and endogenously induced IFN responses restrict HDV persistence during hepatocyte proliferation. This finding helps to understand the clinical observation of the Myr-203 study demonstrating a strong synergism of combining IFN and the entry inhibitor Myrcludex B. The system also provides a cell culture model for the identification of other synergistically acting immune modulators for future clinical combination therapies.

Viral hepatitis A/E: Clinical aspects

Email: behrendt.patrick@mh-hannover.de

Background and aims: Hepatitis E virus (HEV) infection usually causes a self-limiting infection but can lead to chronicity in immunocompromised individuals. The detection and monitoring of infection relies on evaluation of plasma anti-HEV antibodies or plasma and stool HEV RNA. Recently, an HEV antigen (Ag) ELISA has become commercially available which shows high sensitivity in the detection of infection especially in chronically infected individuals. However, its use in monitoring the clinical course of infection has not been investigated so far.

Background and aims: We retrospectively analysed longitudinal urine, stool as well as plasma samples of 8 patients with either acute or chronic HEV infection. We utilized the Wantai HEV antigen ELISA to detect viral proteins. For inhibition of viral antigen detection in urine, the WHO anti-HEV IgG standard was used.

Results: From the eight analysed patients one died due to acute on chronic liver failure and another patient died from acute liver failure. The others resolved the infection either spontaneously or under treatment. In all patients except of one, HEV RNA decreased over time (plasma/stool). In urines, no viral RNA could be detected. Ag levels in plasma and urine remained detectable even after loss of viral RNA. Thereby, we observed high levels of HEV Ag in the urine with delayed reduction over time as compared to HEV Ag in plasma in all tested individuals. For one chronically infected patient who was treated with ribavirin, HEV Ag was detectable in plasma 2 month and in urine 5 month after achieving RNA negativity (Fig. 1). Dilution of HEV Ag positive samples in HEV Ag negative urine and plasma reveals no unspecific modulation of HEV Ag detection. *In vitro*, addition of the WHO anti-HEV IgG standard to HEV Ag positive urine dose-dependently reduces the HEV Ag ELISA values. In line, anti-HEV IgG positive plasma inhibits the detection of HEV Ag in urine.

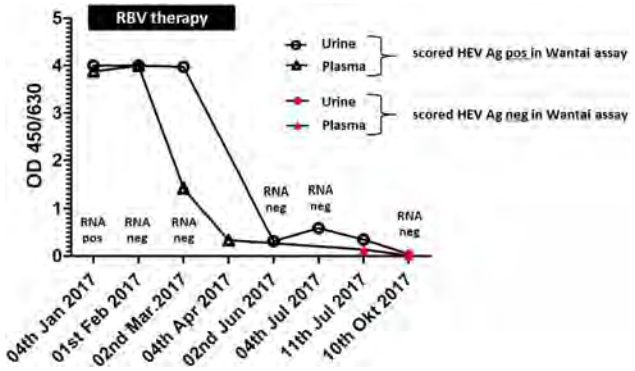

Figure: HEV detection in urine and plasma over time in a chronically infected individual that was treated with ribavirin*
*Off-label use

Conclusion: Collectively, we observed a delayed HEV Ag reduction in plasma and urine of all infected individuals as compared to viral RNA in stool and plasma. Due to the absence of inhibitory anti-HEV IgG antibody, this was more pronounced in urine as compared to plasma in all tested individuals, independent of the clinical course of infection. Evaluation of HEV Ag levels in the urine can be a fast, cheap and easy to perform technique to diagnose as well as monitor HEV infection. The delayed clearance of HEV Ag in urine can be used to determine recent/resolving HEV infections.

Associated risk factors for hepatitis E seroprevalence among liver transplant recipients

Petra Dinjar Kujundžić[1], Oktavija Rode Đaković[2,3], Adriana Vince[2,4], Jelena Prpić[5], Lorena Jemeršić[5,6], Branko Kolarić[7,8], Ana Ostojić[1], Anna Mrzljak[1,4]. *[1]Clinical Hospital Merkur, Zagreb, Croatia; [2]University for Infectious Diseases Dr. Fran Mihaljević, Zagreb, Croatia; [3]University of Zagreb School of Dental Medicine, Zagreb, Croatia; [4]University of Zagreb School of Medicine, Zagreb, Croatia; [5]Croatian Veterinary Institute, Zagreb, Croatia; [6]Veterinary faculty, University of Zagreb, Zagreb, Croatia; [7]Andrija Štampar Teaching Institute of Public Health, Zagreb, Croatia; [8]University of Rijeka Faculty of Medicine, Zagreb, Croatia*

Email: petra.dinjar@gmail.com

Background and aims: Hepatitis E virus (HEV) is an emerging disease in Europe, especially important among solid organ transplant (SOT) recipients who are at greater risk of developing acute and chronic graft hepatitis with progression to cirrhosis. It is proposed that foodborne transmission is the main route of HEV infection in developed countries. However, risk factors for the acquisition of HEV infection among SOT recipients are incompletely understood. This study aimed to determine exposure of HEV infection and associated socio-demographic risk factors.

Background and aims: In this cross-sectional study, 242 Croatian SOT recipients were screened during routine post-transplant out-patient visits. All participants completed a risk factor assessment questionnaire. Blood samples were tested for anti-HEV IgG using an enzyme immune assay (Mikrogen, Germany) and nucleic acid extracts of whole blood were tested by an in-house real-time reverse-transcriptase polymerase chain reaction assay for HEV RNA.

Results: Anti-HEV IgG seroprevalence in Croatian SOT recipients was 24.38%. No SOT patients had HEV viraemia at time of testing. The median time after transplant was 5 years (range 19 years). The majority of the recipients were male (69.0%) and major indication for

SOT was alcoholic liver disease (50.4%). Older age (OR = 1.05; 95%CI = 1.02-1.09), female gender (OR = 2.61; 95%CI = 1.42-4.81), rural area of residence (AOR = 2.17; 95%CI = 1.10-4.27), and specific factors within a household: a farm (AOR = 2.79; 95% CI = 1.31-5.92), a water-well (AOR = 3.09; 95%CI = 1.11-8.57) and a sewage system connected to a septic tank (AOR = 3.38; 95%CI = 1.64-6.95) were detected as potential risk factors, while highest level of education (AOR = 0.05; 95%CI = 0.01-0.43) and a recent travelling experience (AOR = 0.39; 95%CI = 0.17-0.88) as protective factors. Contrary to initial assumptions, production and/or consummation of cured meat and occupational exposure had no statistically significant strength of association with anti-HEV IgG seropositivity.
Conclusion: Prevalence of anti-HEV IgG in SOT recipients in Croatia is 24.38%. Identified socio-demographic factors associated with the seropositivity set up a platform for further research directions to evaluate sources/routes of transmission and clinical impact of HEV infection after SOT.

SAT-206
The impact of hepatitis E virus infection on the Scottish solid organ transplant population

Mhairi Donnelly[1], Sandeep Ramalingam[2], Ingolfur Johannessen[2], Kate Templeton[2], Ines Ushiro-Lumb[3], Leanne Stratton[4], Johnny Cash[4], Kenneth J. Simpson[1]. *[1]Royal Infirmary of Edinburgh, Dept. of Hepatology and Scottish Liver Transplant Unit, Edinburgh, United Kingdom; [2]Royal Infirmary of Edinburgh, Dept. of Virology, Edinburgh, United Kingdom; [3]NHS Blood and Transplant, Microbiology Services, Edinburgh, United Kingdom; [4]Royal Victoria Hospital, Liver Unit, Belfast, United Kingdom*
Email: mhairi.donnelly@nhs.net

Background and aims: Our understanding of HEV infection has evolved with recognition that HEV genotypes 3 and 4 cause autochthonous infection in high-income countries and chronic infection in immunocompromised patients, which may rapidly result in liver cirrhosis. We aimed to assess the impact of HEV infection on the Scottish solid organ transplant (SOT) population.
Background and aims: Patients were identified by the treating physicians and highlighted to the study team; all patients received clinical input from a single hepatologist (KJS). Electronic notes were reviewed and data obtained included patient demographics, type of transplantation, characteristics of HEV infection, treatment and clinical impact of infection.
Results: We identified 27 patients within the Scottish SOT population whose clinical course was affected by HEV infection (renal recipient n = 12, liver recipient n = 9, combined liver/kidney n = 2, simultaneous pancreas/kidney [SPK] n = 2 and live renal donor n = 2). The majority of patients (n = 20) were tested for HEV on the basis of deranged LFTS. The observed consequences of HEV infection are shown below.

Impact/consequence of infection	No. of affected patients	Patient group affected
Iatrogenic infection due to use of grafts from viraemic donors	2	Liver (1), renal (1) recipients
Development of cirrhosis due to chronic infection	2	Renal recipients
Chronic infection requiring treatment	15	Liver, renal, SPK recipients
Infection contributing to need for transplantation	1	Liver cirrhosis
Delay in living organ donation due to donor viraemia	2	Renal living donors (and recipients)

One patient was required to delay IVF treatment due to ribavirin therapy for chronic infection. The patients who developed liver cirrhosis had an episode of decompensation. One of the patients who developed liver cirrhosis died. Two further patients died of unrelated causes. In the patients receiving grafts from viraemic donors, phylogenetic analysis confirmed donor derived transmission via the renal allograft in one patient. In the patient receiving a liver graft from a viraemic donor, the renal recipients from the same donor developed genotype 3c infection with phylogenetic analysis confirming a common source. Both liver and kidney recipients cleared HEV infection without therapeutic intervention.
Fifteen patients required treatment with ribavirin; 3 required treatment with erythropoietin and one patient required admission for blood transfusion.
Conclusion: In Scotland, HEV infection has a wide variety of consequences in the SOT population. Increased awareness of infection and its complications will hopefully lead to increased testing and timely treatment of chronic infection in immunosuppressed populations.

SAT-207
Rabbit HEV in immunosuppressed patients with hepatitis E acquired in Switzerland

Roland Sahli[1], Montserrat Fraga[2], David Semela[3], Darius MORADPOUR[2], Jérôme Gouttenoire[2]. *[1]Institute of Microbiology, Lausanne University Hospital, Lausanne, Switzerland; [2]Service of Gastroenterology and Hepatology, Lausanne University Hospital, Lausanne, Switzerland; [3]Kantonsspital St. Gallen, St. Gallen, Switzerland*
Email: jerome.gouttenoire@chuv.ch

Background and aims: Infection by hepatitis E virus (HEV) genotypes (gt) 3 and 4 has been recognized as a zoonosis in high-income countries. Zoonotic transmission of HEV is believed to result primarily from the consumption of raw pork and game meat. Here, we analyzed HEV sequences in patients who acquired acute or chronic hepatitis E in Switzerland.
Method: HEV genotyping was performed by RT-PCR and Sanger sequencing of plasma samples from 114 patients with PCR-proven acute or chronic hepatitis E likely acquired in Switzerland. Subtype assignment and phylogenetic analyses were performed using the HEVnet genotyping tool (https://www.rivm.nl/en/Topics/H/HEVNet). When indicated, confirmatory RT-PCR amplification of a 289-bp ORF1 region harboring the rabbit-specific 93-nucleotide insertion was performed.
Results: HEV genotyping was successful in 98 of 114 patients, revealing gt 3 in 95 and gt 4 in the remaining three. Sixty-eight of the gt 3 isolates could be assigned to a subtype, including 64 from patients with acute and 4 from patients with chronic infection. Importantly, 76% of these were due to the newly proposed subtype 3 s (Wist V *et al.* Genome Announc 2018). The high frequency of this subtype, identified only in Switzerland so far, indicates that it circulates widely in the country, including in the food chain. Interestingly, three solid organ transplant recipients were found to be infected with rabbit HEV (gt 3ra); two with chronic and one with acute hepatitis E. Phylogenetic analysis revealed that gt 3ra isolates observed in Switzerland cluster with the few isolates previously identified in humans in France (Abravanel F *et al.* Emerg Infect Dis 2017), but also in rabbits from France and Germany. Remarkably, none of the patients with rabbit HEV infection had consumed rabbit meat or been in contact with rabbits, suggesting that this virus has been transmitted through other sources.
Conclusion: Our observations lend support to the recently proposed HEV subtype 3 s circulating and representing the major cause of acute hepatitis E acquired in Switzerland. Rabbit HEV was identified in 2 out of 4 chronically infected individuals while it was identified only in one out of 64 patients with acute hepatitis E of gt 3 which could be subtyped. Although based on a small number of cases, our findings raise interesting questions concerning the source, prevalence, pathogenesis and persistence of the as yet poorly characterized rabbit HEV infection in humans.

SAT-208

Zinc/Ribavirin: A possible treatment option in chronically HEV genotype 3 infected patients without SVR under ribavirin monotherapy

Thomas Horvatits[1], Niels Schübel[2], Nassim Kamar[3], Susanne Polywka[4], Marc Lütgehetmann[4], Karoline Rutter[1], Julian Schulze zur Wiesch[1], Michael P. Manns[5], Ansgar Lohse[1], Anne Marie Roque-Afonso[6], Sven Pischke[1], Patrick Behrendt[5], Vincent Mallet[7]. *[1]University Medical Center Hamburg-Eppendorf, I. Department of Medicine, Hamburg, Germany; [2]Klinikum Osnabrück, Osnabrück, Germany; [3]CHU de Toulouse, Hôpital Rangueil, Service de néphrologie, Dialyse et Transplantation d'Organe, Toulouse, France; [4]University Medical Center Hamburg-Eppendorf, Institute of Medical Microbiology, Virology and Hygiene, Hamburg, Germany; [5]Hannover Medical School, Department of Gastroenterology and Hepatology, Hannover, Germany; [6]Publique Hôpitaux de Paris, Hôpital Paul Brousse, Virology Service, Villejuif, France; [7]Université Paris Descartes, Hôpitaux de Paris, Hepatology service, Paris, France*
Email: t.horvatits@uke.de

Background and aims: Chronic hepatitis E virus (HEV) infection is a cause of cirrhosis and of end-stage liver disease in immunosuppressed patients. About 5% of chronic HEV patients do not respond to ribavirin treatment. Inhibition of HEV RNA-dependent RNA polymerase with zinc salts is reported *in vitro* in HEV1 and HEV3 replicons. Therefore, we aimed to study the anti-HEV efficacy of zinc salts in a cohort of chronic HEV patients who did not respond to ribavirin patients.

Method: We evaluated the antiviral properties of zinc salts on Huh-7.5 cell lines expressing a subgenomic replicon of HEV3 (Kernow) or HEV1 (Sar55). Cell viability was determined with MTT assays. Magnesium served as negative control.

We collected retrospective virological data from 8 chronic HEV patients who did not respond to ribavirin treatment and who had received in 2018 either zinc salt monotherapy (n = 5) or zinc salt and ribavirin combination therapy (n = 3) without modifying immunosuppression. Serum zinc levels were measured in 23 patients with acute (n = 2), chronic (n = 11) and asymptomatic (n = 10) HEV infection. All patients gave informed consent.

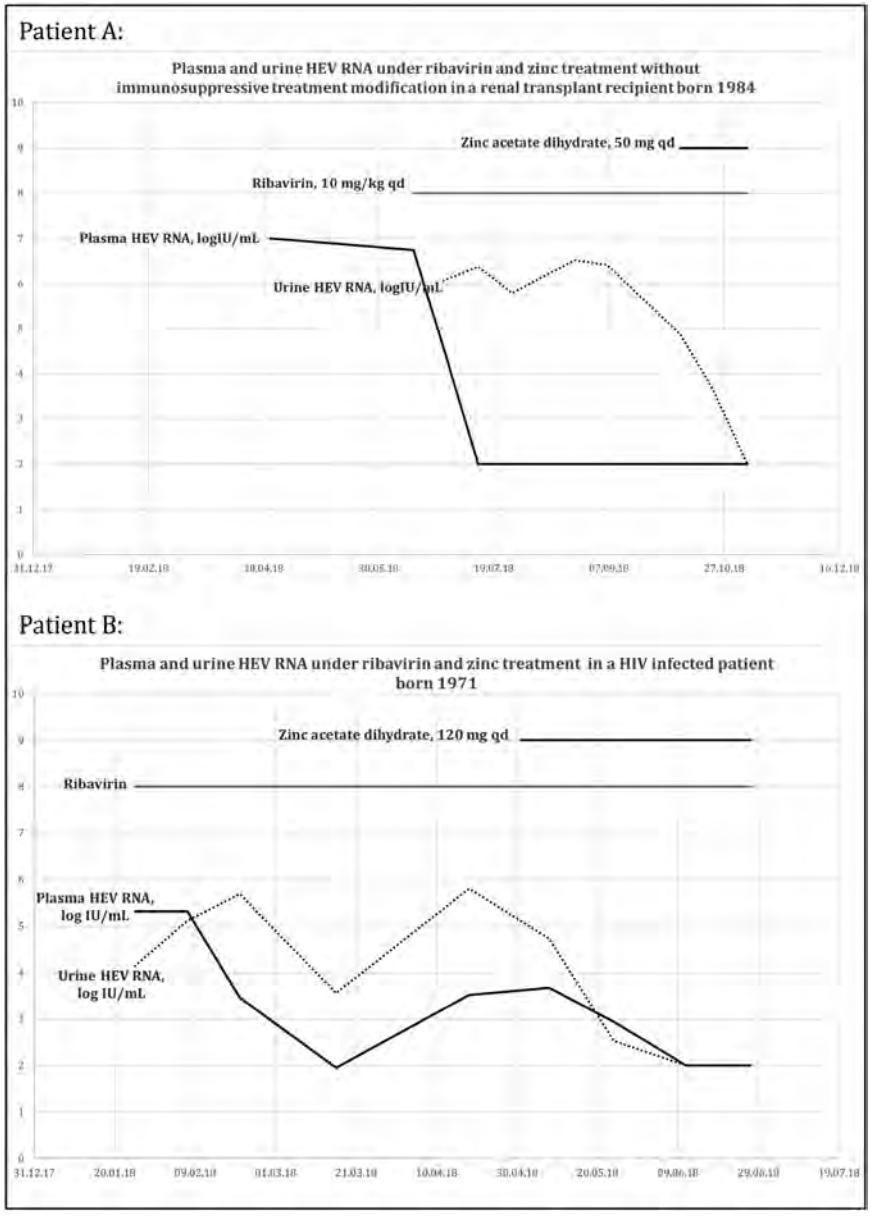

Figure: (abstract: SAT-208): Course viral load in two patients with chronic HEV infection who received zinc/ribavirin treatment

Results: Zinc salts inhibited viral replication *in vitro* with a half maximal inhibitory concentration (IC_{50}) of 130 µM and 115 µM for genotype 3 and 1, respectively. The 50% cytotoxicity concentration (CC_{50}) was 330 µM. Viral clearance was observed in two 2/3 of zinc/ribavirin patients (see figure 1). We did not observe any decrease in viral load among patients who received zinc monotherapy (n = 5). No adverse effect was observed. Serum zinc levels were median 619 mcg/l, 663 mcg/l and 718mcg/l among patients with chronic, acute and asymptomatic HEV infection (chronic vs. asymptomatic: p = 0.049). Serum AST and ALT levels were inversely associated with serum zinc levels (spearman's rho = -0.59; p = 0.006 and –0.42; p = 0.046).
Conclusion: There is a relationship between zinc salt concentration and HEV replication *in vitro and in vivo*.
The potential antiviral effect of zinc/ribavirin treatment should be explored in chronic HEV patients who do not respond to ribavirin treatment. Zinc/ribavirin may be a possible treatment option for patients without SVR under ribavirin monotherapy.

SAT-209
Role of estrogen and its receptors in HEV associated feto-maternal outcomes
Premashis Kar[1], swati singh[1], mradul kumar dagra[1], ashok kumar[2], syed akhtar husain[3]. *[1]Maulana Azad Medical College India, Department of Medicine, New Delhi, India; [2]Maulana Azad Medical College, Department of Obstetrics and Gynaecology, New Delhi, India; [3]Jamia Millia Islamia, Department of Biosciences, New Delhi, India*
Email: premashishkar@gmail.com

Background and aims: Pregnant women infected with HEV develops adverse pregnancy outcomes like, abortions, intrauterine fetal death, still births, neonatal deaths, preterm delivery and maternal mortality. To correlate estrogen and its receptors ESR1α and ESR2β levels with HEV associated feto-maternal outcomes.
Method: A total of 142 pregnant women with HEV infection and 142 pregnant controls were included in study from Department of Obstetrics and Gynaecology and Department of Medicine, Maulana Azad Medical College (MAMC) and associated Lok Nayak Hospital (LNH), New Delhi. Three ml of blood sample was collected in plain for quantification of estrogen, and its receptors ESR1α and ESR2β using commercially available third generation ELISA kits.
Results: The levels of estrogen, ESR1α and ESR2β were considerably higher in HEV infected pregnant women (20.11 ± 18.19 ng/ml, 10.58 ± 3.27 ng/ml, 10.42 ± 4.71 ng/ml, respectively) than pregnant controls (11.74 ± 6.42 ng/ml, 9.11 ± 1.63 ng/ml, 9.01 ± 1.18 ng/ml, respectively) ($p < 0.0001$). It was found that estrogen levels were significantly higher in pregnant women infected with HEV who had preterm delivery, low birth weight babies and Accepted Article This article is protected by copyright. All rights reserved. fetal loss (19.64 ± 17.60 ng/ml, 19.71 ± 17.63 ng/ml, 33.62 ± 23.20 ng/ml, respectively) than who had full term delivery, average birth weight babies and live babies (11.71 ± 8.77 ng/ml, 11.99 ± 9.44 ng/ml, 16.58 ± 14.98 ng/ml, respectively) ($p < 0.05$). A significant negative correlation was observed between baby birth weight and estrogen levels in HEV infected pregnant women.
Conclusion: The high level of estrogen plays an important role in preterm delivery, low birth weight babies and fetal mortality in pregnant women with HEV infection through placental dysfunction. Moreover, estrogen level is a significant predictor for preterm delivery and maternal mortality and ESR2β levels is a significant predictor for maternal mortality in pregnant women infected with HEV.

Circulation of hepatitis a genotypes in Israel 2017-2018: Environmental surveillance supports clinical findings
Yael Gozlan[1], hadar volnowitz[1], Itay Bar-or[2], rivka rich[3], ella mendelson[2,4], Ziv Ben Ari[4,5], Orna Mor[1,4]. *[1]Ministry of Health, Central Virology Laboratory, Reference Laboratory for Viral Hepatitis, Ramat Gan, Israel; [2]Ministry of Health, Central Virology Laboratory, Ramat Gan, Israel; [3]Ministry of Health, Department of Epidemiology, Jerusalem, Israel; [4]Tel Aviv University, Sackler School of Medicine, Ramat Aviv, Israel; [5]Chaim Sheba Medical Center, Ramat Gan, Israel*
Email: orna.mor@sheba.health.gov.il

Background and aims: Hepatitis A virus (HAV) is an important cause of acute viral hepatitis worldwide. In Israel, since the introduction of universal toddler vaccination program in 1999, the number of HAV infections has dramatically decreased. However, outbreaks, in vulnerable populations, identified by serological testing, do occur. The last outbreak of HAV in non-vaccinated MSM, which started in the beginning of 2017, triggered the introduction of a systematic molecular investigation of circulating HAV genotypes in all clinical cases and in environmental samples. This study summarizes the impact of this ongoing surveillance on monitoring such an enteric disease.
Method: Sewage samples collected monthly in 2017 (n = 114) and in 2018 (January-June, n = 56) from 11 main sewage treatment facilities located throughout the country and serum samples (n = 80, 2017; n = 43, 2018) from all HAV IgM positive individuals reported to the ministry of health, during the same study period, were included. Total nucleic acids were extracted with NucliSENS EasyMag (bioMérieu, France). Real-time PCR (RT-PCR) and sequencing of the VP1-2A region was performed according to national protocols. Phylogenetic analysis included comparison to reference HAV strains.
Results: 34% (39/114) and 29% (16/56) of all sewage samples collected in 2017 and 2018, respectively, were HAV positive. While 76% (30/39) and 15% (6/39) of the HAV positive sewage samples in 2017 were HAV-1A and HAV-1B positive, respectively, in 2018 6% (1/16) and 81% (13/16) were HAV-1A and HAV-1B positive, respectively. Similarly, 79% and 19% of the positive clinical cases in 2017 were infected with HAV-1A and HAV-1B while the majority of HAV positive cases in 2018 (88%) were HAV-1B and only 9% were infected with HAV-1A (Figure 1). The location of sewage facilities positive for HAV-1A and 1B highly correlated with patients' residence. Other HAV genotypes (HAV-3a/b) were rare (< 3%); 12% (15/143) of all notified patients were HAV RNA negative and therefore not considered hepatitis A cases.

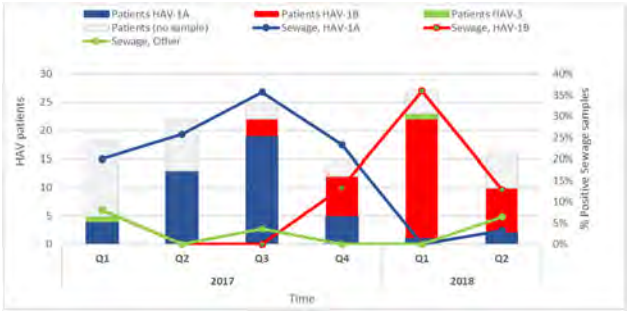

Figure 1: Environmental and clinical HAV surveillance, Israel, January 2017- June 2018

Conclusion: Continuous surveillance of HAV in sewage and confirmation of infection with RNA analysis may assist in correct diagnosis, disease monitoring and identification circulating genotypes in local HAV outbreaks.

SAT-211

HEV infection in Italy: Beyond the hepatic disease

Giovanna Picchi[1], Alessandra Ricciardi[1], Lara Marola[2], Elisabetta Madonna[3], Paola Chionne[3], Umbertina Villano[3], Cinzia Marcantonio[3], Roberto Bruni[3], Michele Equestre[3], Giulio Pisani[3], Nerio Iapadre[1], Maurizio Mariani[1], Antonio Cellini[1], Lucia Orneto[2], Remo Barnabei[2], Simonetta Santini[2], Margherita D'Alessandro[4], Pierluigi Cacciatore[5], Federica Sozio[5], Stefano Necozione[6], Giustino Parruti[5], Maurizio Paoloni[4], Annarita Ciccaglione[3], Alessandro Grimaldi[1]. *[1]Ospedale San Salvatore, Infectious Disease, L'Aquila, Italy; [2]Ospedale San Salvatore, Medical Laboratory, L'Aquila, Italy; [3]National Health Institute, Infectious Diseases, Rome, Italy; [4]Ospedale S. Filippo e Nicola, Infectious Diseases, Avezzano, Italy; [5]Presidio Ospedaliero Pescara, Infectious Diseases, Pescara, Italy; [6]Università L'Aquila, L'Aquila, Italy*
Email: ale.riccia@gmail.com

Background and aims: Hepatitis E virus (HEV) is a RNA virus of Hepeviridae family. In industrialized countries HEV is mainly a zoonosis, spread by pigs, wild boars and deers. In Italy the sero-prevalence reported is 9%, with peak of 49% in the Abruzzo area. Extrahepatic syndromes have been reported.
We describe clinical and virologic features of a population with acute hepatitis in a HEV highly endemic area.
Method: From January 2015 to September 2018, patients admitted to Abruzzo Infectious Disease Departments with elevated liver enzymes and no other acute viral hepatitis were tested for HEV. Acute HEV diagnosis was determined by IgM anti HEV (Wantai®) and HEV-RNA (primers targeting ORF3) presence. Sequencing was carried out by an automated DNA sequencer (Beckman Coulter®). The phylogenetic tree was built using a MEGA 6.06 software. Serologic and virologic analysis were performed at Infectious Diseases Department, National Health Institute, Rome. Anamnestic and clinical data were retrospectively collected.
Results: Out of 97 patients tested, 35 (36%) were diagnosed for acute HEV infection with positive HEV IgM and 32 had detectable HEV-RNA. Genotyping was successful in 24 out of 35 cases and showed all 3 genotype strains (subtypes 3c, 3f, 3e). In the 35 HEV acute cases (85% male, 95% Italian, median age 53 yo), ALT median values were 772 (54-2936) U/L, AST 1282 (95-4312) U/L, Total Bilirubin 5, 08 (0, 44-29.9) mg/dl. HEV-RNA was over 10.000 cp/ml in 44% of patients. Of 32 positive patients in which clinical data were collected, 31% reported onset of gastro-intestinal symptoms, while 40% had extrahepatic symptoms like neurological (arms or legs pain, paresthesia, vertigo, headache), rheumatological (joint pain) or mixed ones, being non-abdominal pain the main clinical feature in 11 patients. Extra-hepatic onset, neurological symptoms, pain and elevated ALT were significantly related to acute HEV infections vs other diagnosis (table 1).

Table 1: Univariate (Chi square test) analysis of clinical variables in HEV-acutely infected population vs other causes of acute hepatitis; other viruses are excluded. OR = Odds ratio; RR = relative risk; CI = confidence interval.

Symptoms	OR/RR	p value	95% CI
Hepatic	0.66	> 0.05	0.25-1.71
Extra-hepatic	16.69	0.0010	1.96-141
Neurologic	14	0.0029	1.62-120.4
Non abdominal pain	1.3043	0.0005	1.0707

Conclusion: In highly endemic area, HEV acute hepatitis represents one third of total acute hepatitis. Extra-hepatic manifestations may be more common than hepatic ones and should raise suspect of HEV aetiology.

SAT-212

Treatment with mTOR inhibitors is an independent risk factor for chronic hepatitis E in transplant patients with increased transaminases levels

Mar Riveiro-Barciela[1,2], Judit Vidal-González[1], Luisa Roade[1], Joan Martínez Camprecios[1], Basilio Rodríguez[3], Manel Perelló[4], Guillem Ortí[5], Virginia Robles[2,6], Cristina Berastegui[7], Jordi Navarro[8], Fernando Martínez-Valle[9], Itxarone Bilbao[2,10], Lluís Castells[1,2], Leonardo Nieto[11], Francisco Rodríguez-Frías[11], Maria Buti[1,2], Rafael Esteban[1,2]. *[1]Liver Unit, Internal Medicine Department, Vall d'Hebron Hospital, Barcelona., Barcelona, Spain; [2]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd)., Barcelona, Spain; [3]Rheumatology Department, Hospital Universitari Vall de Hebrón., Barcelona, Spain; [4]Nephrology Department, Hospital Universitari Vall de Hebrón., Barcelona, Spain; [5]Department of Hematology. Hospital Universitari Vall d'Hebron., Barcelona, Spain; [6]Digestive System Research Unit, University Hospital Vall d'Hebron., Barcelona, Spain; [7]Pneumology Department, Hospital Universitari Vall de Hebrón., Barcelona, Spain; [8]Infectious Diseases Department, Hospital Universitari Vall de Hebrón., Barcelona, Spain; [9]Systemic Autoimmune Diseases Unit, Internal Medicine Department, Hospital Universitario Vall d'Hebron, Barcelona, Spain., Barcelona, Spain; [10]Liver Transplant Unit, Hospital Universitari Vall d'Hebron., Barcelona, Spain; [11]Liver Disease Laboratory-Viral Hepatitis, Vall d'Hebron Institut Recerca-, Hospital Universitari Vall d'Hebron., Barcelona, Spain*
Email: mar.riveiro@gmail.com

Background and aims: Since the description of the first cases of chronic hepatitis E (CHE) in solid-organ recipients in 2008, many cross-sectional studies have analyzed its prevalence in specific groups such as liver or blood marrow transplantation or HIV-infected subjects. However, there is a lack of prospective analysis in more general populations with high risk of CHE. The aim of this study was to analyze the prevalence of CHE and risk associated factors in a cohort of immunocompromised patients with elevated transaminase levels.
Method: Prospective study including immunocompromised patients (solid-organ or bone marrow transplant (BMT), liver cirrhosis, HIV or undergoing immunosuppressant therapy for dermatological, digestive or rheumatic disorders) with elevated ALT levels ≥ 6 months prior to inclusion. Screening of chronic Hepatitis E virus infection was performed by determination of HEV RNA (PCR Light Cycler 480, Roche).
Results: 207 patients were included: 53% male, mean age 55 ± 16, 90% Caucasian. Underlying disease: 32% transplant (35% BMT, 30% liver, 27% kidney, 8% lung), 31% immunosuppressant therapy, 27% liver cirrhosis, 10% HIV. 22% of recruited patients received at least two different immunosuppressant drugs, including 18% with monoclonal antibodies and 32% corticoids. Overall, anti-HCV was detected in 36%, HBsAg in 4% and anti-HEV IgG in 26%. Median ALT levels were 67 IU/ml (IQR 52-101). The only factor associated with higher HEV seroprevalence was age (> 50 years 16% vs 32%, p = 0.013). HEV seroprevalence was similar in those patients undergoing immunosuppression for transplant than dermatological, digestive or rheumatic disorders (21% vs 27%, p = 0.29). Type of immunosuppression, liver cirrhosis, HIV, HBV or HCV infection did not impact on HEV seroprevalence. Overall, 4 (2%) patients presented CHE with persistently positive HEV RNA, all were solid-organ recipients. Prevalence of CHE in transplantation was 6%: 33% for lung, 17% kidney and 0% in liver and BMT. Both calcineurin and mTOR inhibitors were associated with CHE, though the only independent factor associated with CHE was the use of mTOR inhibitors (OR 32, p = 0.003).
Conclusion: Chronic hepatitis E in a cohort of immunocompromised patients with elevated transaminases levels is not infrequent, especially among transplant population undergoing mTOR inhibitors.

SAT-213

Hepatitis E virus prevalence in Flemish blood donors

Ann-Sofie Vercouter[1], Freya Van Houtte[1], Lieven Verhoye[1], Isabel González Fraile[2], Lydia Blanco[2], Veerle Compernolle[1,3], Philip Meuleman[1]. *[1]Ghent University, Department of Diagnostic Sciences, Ghent, Belgium; [2]Centro de Hemoterapia y Hemodonación, Valladolid, Spain; [3]Blood Service of the Belgian Red Cross-Flanders, Ghent, Belgium*
Email: philip.meuleman@ugent.be

Background and aims: Transmission of hepatitis E virus (HEV) through transfusion of blood components has already been reported worldwide. In this study, we assessed the HEV prevalence in Flemish blood donors. Certainly, it is of importance to determine the risk of HEV transmission through blood transfusion, especially for immunosuppressed solid organ transplant patients.

Method: We analysed 38.137 blood donation samples which were collected at the Red Cross Flanders during the period May-June 2015. Previously frozen samples were initially pooled per 6 and screened for the presence of HEV RNA using the cobas® 6800 System (Roche Diagnostics, Pleasanton, CA, USA), which has a limit of detection of 18, 6 IU/ml. In a second phase, RNA reactive pools were deconstructed and analysed individually using the same methodology. Because of volume limitations, individual samples were diluted with an equal volume of PBS. Using a specific ELISA (Wantai, Biological Pharmacy Enterprise, Beijing, China), the presence of HEV IgG was determined in all HEV RNA positive samples, as well as in a selection of 301 randomly chosen samples that scored HEV RNA negative when tested in pool format. HEV-specific IgM (Wantai) was determined in all viraemic samples, as well as in the IgG-positive/RNA-negative samples.

Results: During initial HEV RNA screening, 11 pools reacted positive. After deconstruction, 7 individual blood donations (7/38.137; 0, 02%) were confirmed as HEV RNA positive (range 1, 53 × 102-8, 71 × 103 IU/ml). Serological screening of the RNA positive samples showed that 6 out of these 7 samples were HEV IgM positive, of which 3 donors were also IgG positive. Serological screening was also performed on all samples that constituted the 4 initially HEV RNA reactive pools where RNA positivity was not confirmed on the individual level. This screening showed evidence of IgM and/or IgG seroconversion in 3 out of 4 pools. In the final pool one sample was IgG positive during all analysed time points. These results indicate recent HEV exposure and potentially explains RNA positivity during initial screening. Within 301 randomly selected samples, 27 donations were HEV IgG positive.

Conclusion: Here we show that at least 1:5, 448 of blood donations in Flanders may originate from donors who are actively infected with HEV. Upon transfusion, these donations may pose a major threat towards patients at risk.

SAT-214

Incidence, predictors and prognosis of liver failure in patients with hepatitis E as an acute insult

Yijin Wang[1], Hongyang Liu[1], Qiuwei Pan[2], Jingmin Zhao[1]. *[1]Beijing 302 hospital, Beijing, China; [2]Erasmus medical center, Rotterdam, Netherlands*
Email: jmzhao302@163.com

Background and aims: Genotype (GT) 3 and GT4 hepatitis E virus (HEV) infection has been recently recognized as an important insult of acute or acute-on-chronic liver failure (A (C)LF), but seldom described before. This study aimed to identify the incidence, predictors and short-term outcomes of GT4 HEV related liver failure (HEV-LF).

Method: All the patients with symptoms of suspected acute viral hepatitis were screened for HEV infection in a tertiary hospital in China. Patients with hepatitis E who developed A (C)LF during hospitalization with HEV as an acute insult between November 2011 and September 2017 were recruited as cases. Hepatitis E patients who did not develop liver failure (HEV-non-LF) from January 2015 through September 2017 were enrolled as controls. Patients with liver failure induced by other acute etiologies were also extracted during the same hospitalized period.

Fig. 1

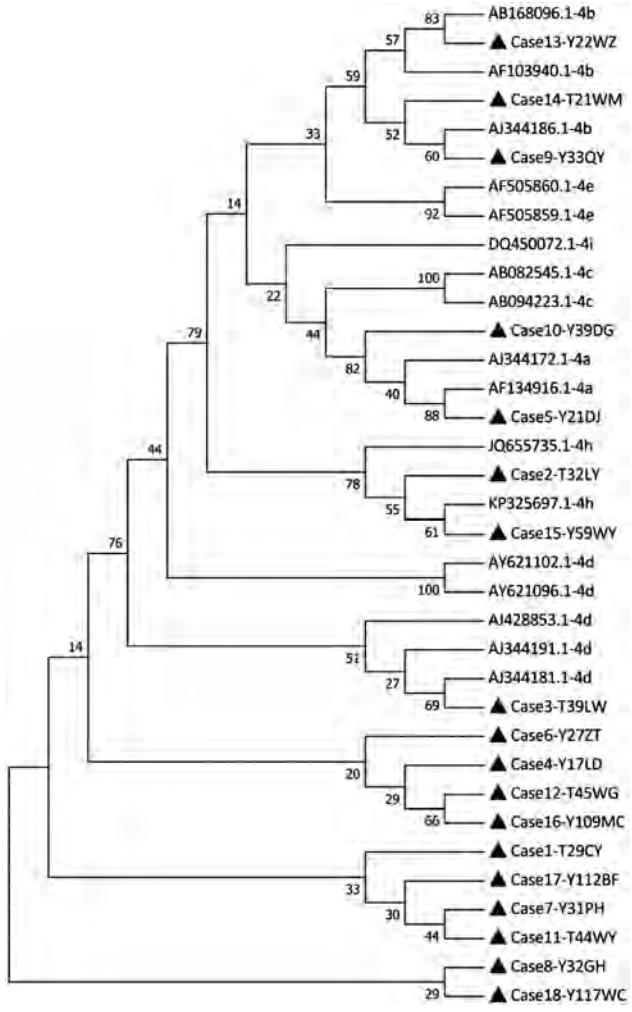

Fig. 2

Results: A total of 737 patients were diagnosed of hepatitis E during the study period, among which 62 (8.41%) developed liver failure with HEV as an acute event. 64.52% HEV-LF patients had chronic liver disease (CLD), significantly higher than HEV-non-LF patients (33.33%). Of note, an overall decline in the number of HEV patients and an increase in the ratio of HEV-LF were observed from year 2012

to 2017 (Fig.1). Sequencing of partial HEV genome has confirmed GT4 HEV strains (Fig. 2). Baseline HEV viral titer is lower in patients who developed A (C)LF than patients who did not ($p = 0.014$), but comparable between HEV-LF patients with favorable and poor outcomes. In the multivariate analysis, electrolyte disturbance (OR 2.4929; $p = 0.029$), ascites (OR 3.9621; $p = 0.003$), spontaneous peritonitis (OR 4.0106; $p = 0.016$), intestines injury (OR 5.2818; $p = 0.049$), lactate dehydrogenase (OR 1.0041; $p = 0.034$), alpha fetoprotein (OR 1.0047; $p = 0.008$) and carbohydrate antigen 125 (OR 1.0047; $p = 0.025$) at inclusion were found to be independent predictors of development of liver failure in short time. Of the 62 HEV-LF patients, 40 (64.52%) became recovered/improved, 20 (32.25%) were failed in response to treatment and 2 (3.23%) died, showing favorable outcomes than A (C)LF induced by other etiologies. Presenting hepatic encephalopathy (OR 6.7218; $p = 0.032$), higher level of glucose (OR 1.9476; $p = 0.005$) and international normalized ratio (OR 8.6245; $p = 0.032$) were independent predictors of poor prognosis of HEV-LF. Cirrhosis is the predominant CLD that associated with development and poor prognosis of A (C)LF in HEV patients compared to alcohol liver disease and chronic hepatitis B.

Conclusion: Patients with GT4 hepatitis E were at high risk to develop liver failure, especially in patients with CLD. Different types of CLDs impacted the incidence and prognosis of HEV-LF distinctively. The identified variables shall help to identify HEV patients with high risk of developing liver failure and the risk population with poor outcomes.

SAT-215

Cryoglobulinemia in asymptomatic, symptomatic acute and chronical HEV infections

Dirk Westhölter[1], Rabea Lübke[1], Susanne Polywka[2], Marc Lütgehetmann[2], Karoline Rutter[1], Peine Sven[3], Julian Schulze zur Wiesch[1], Ansgar Lohse[1], Sven Pischke[1], Thomas Horvatits[1]. [1]*University Medical Center Hamburg-Eppendorf, I. Dep. of Medicine, Hamburg, Germany;* [2]*University Medical Center Hamburg-Eppendorf, Institute of Medical Microbiology, Virology and Hygiene, Hamburg, Germany;* [3]*University Medical Center Hamburg-Eppendorf, Institute of Transfusion Medicine, Hamburg, Germany*
Email: t.horvatits@uke.de

Background and aims: Hepatitis E virus (HEV) infections have been associated with numerous extrahepatic manifestations but a causal relationship still needs to be proven. Especially the assumed association with cryoglobulinemia is still under debate. Therefore, we aimed to test a cohort of blood donors with asymptomatic HEV infection, patients with symptomatic acute hepatitis E and immunosuppressed patients with chronic HEV-infection for cryoglobulinemia.

Method: Between 11/2014 and 10/2018 48 individuals with HEV infection, who presented at our outpatient clinic have been tested for cryoglobulinemia. Patient characteristics (age, ALT levels) have been assessed and patients were stratified according to type of HEV infection. Serum levels of total immunoglobulin G (IgG) available in 42 individuals were analyzed.

Results: Out of 48 individuals 12 (25%) had acute hepatitis E (median AST 825U/l), 13 (27%) had chronic hepatitis E (median AST 195 U/l) and 23 (48%) had asymptomatic HEV infection (median AST 35 U/l). 13 patients were female (27%) and median age was 47 years.

4/48 individuals with HEV infection (8%) tested positive for cryoglobulins in serum. All patients with cryoglobulinemia were male and had no clinical signs of cryoglobulinemia. Cryoglobulinemia occurred more frequently in hepatitis E (chronic: n = 3, acute: n = 1) than in asymptomatic HEV infection (n = 0; p = 0.047). Liver enzymes did not differ between patients with and without cryoglobulinemia (ALT, p = 0.21; bilirubin, p = 0.76). We observed a strong trend towards higher total serum IgG levels in patients with cryoglobulinemia compared to those without (median IgG 15 g/l vs. 10.2 g/l; p = 0.06).

Conclusion: While asymptomatic HEV infection was not associated with cryoglobulinemia, presence of cryoglobulins was observed in patients with acute and chronic hepatitis E. However, whether cryoglobulinemia in patients with acute or chronic hepatitis E has impact on the clinical outcome of the infection needs to be further clarified.

Viral Hepatitis C: Post SVR and long term follow up

SAT-217

Effectiveness and safety of sofosbuvir-based regimens in treatment of chronic HCV patients aged 60 years and older, Egyptian single center experience

Mohamed Said[1], Shereen Abdel Alem[1], Zeinab Abdellatif[1], Hosam Dabes[2], Reem Ahmed[2], Magdi El-Serafy[1]. [1]*Faculty of medicine, Cairo University, Endemic Medicine and Hepatology Department, Cairo, Egypt;* [2]*Medical National Institute, Internal Medicine Department, Damnhour, Beheira, Egypt*
Email: shery_2424@yahoo.com

Background and aims: Since the introduction of direct-acting antivirals (DAAs), the outcomes of hepatitis C (HCV) treatment have shown an improvement in cure rates with minimal side effects. However, data on the virologic response and tolerability of DAAs in elderly patients are still lacking. Aim: to assess the effectiveness and safety profile of different sofosbuvir-based regimens in a large cohort of HCV patients aged 60 years and older in real-life clinical practice.

Method: This was an observational, retrospective single center study enrolled a total of 11290 chronic HCV patients from Damnhour Viral Hepatitis center, who were treated by different sofosbuvir-based regimens. Patients were divided into two groups: patients aged younger than 60 years (n = 9326) and those aged 60 years and older (n = 1964). Baseline demographics, underlying comorbid conditions such as diabetes and hypertension, prior HCV treatment history, HCV treatment regimen, adverse effects, and interruption or discontinuation of therapy were collected. Sustained virological response (SVR) at 12 weeks after the end of treatment and adverse effects were analyzed according to age.

Results: The overall SVR12 was 98.5%. In terms of by age, 98.5%, and 98.4% of the patients aged < 60, and ≥ 60 years achieved SVR12 respectively. At 12-weeks after the end of treatment (SVR12), levels of ALT, AST and Hemoglobin showed a decline among both groups. However, only the percent change for AST and Hemoglobin levels were significantly higher among patients aged 60 years and older (p < 0.05). Albumin, total bilirubin, total leucocytic counts and platelet count, and INR showed an increase among both groups, however none significant difference was observed between both age groups (p > 0.05). All patients were adherent to the prescribed treatment regimen as well as treatment duration and there were no reported interruptions in therapy because of adverse events (AEs). The most frequent reported AEs were headache, fatigue and insomnia among both groups. About 8.1% of patients reported at least one AE during the treatment period, and their incidence was not significantly different between the younger and elderly groups. There was no decompensating event or other serious adverse events reported and there were no deaths during treatment.

Conclusion: In a real-world setting, compared with younger patients, elderly patients had a similar virological response and tolerance to different sofosbuvir-based regimens.

SAT-218

Impact of sofosbuvir-based therapy on renal functions indices in chronic hepatitis c patients who achieved sustained virological response

Rabab Omar[1], Reham Abdelmoniem[1], Mohammed El-Kassas[2], Mohammad El-Sayed[3], Aisha Elsharkawy[1], Zeinab Abdellatif[1], Shereen Abdel Alem[1], Gamal Esmat[1]. *[1]Faculty of medicine, Cairo University, Endemic Medicine and Hepatology Department, cairo, Egypt; [2]Faculty of Medicine, Helwan University, Endemic Medicine department, cairo, Egypt; [3]Faculty of medicine, Cairo University, Endemic Medicine and Hepatology Department, cairo, Egypt*
Email: reham.moniem86@gmail.com

Background and aims: The effect of direct-acting antiviral agents (DAAs) on renal functions in hepatitis C virus (HCV) patients remains controversial. Little data are available on renal toxicity exerted by sofosbuvir (SOF) based therapy in clinical practice. Aim: to evaluate the changes of renal functions indices during and after SOF-based therapy in chronic HCV patients who achieved SVR.
Method: This is a retrospective cohort study of 1004 patients who underwent SOF-based treatment for chronic HCV between 2014 and 2017. Serum creatinine measures before starting DAAs treatment, at end of treatment (EOT) and at12- weeks after EOT (SVR12) were retrieved from patients' database. Estimated glomerular filtration rate (eGFR) was calculated using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula. Patients who didn't achieve SVR, had HIV or HBV co-infections, decompensated cirrhosis, transplant recipients and patients with eGFR less than 30 ml/min/1.73m^2 before antiviral therapy were excluded. Comparison of renal functions indices was performed using the Wilcoxon signed-rank test.
Results: 55.7% of our patients were males, with a median age 53 years, 39.7% had cirrhosis, 45.1% had CKD risk factors including diabetes mellitus (24.7%) and hypertension (20.4%) and 97.4% had a baseline eGFR ≥ 60 ml/min/1.73m^2. Ribavirin was used in 69.6% of patients. median serum creatinine was significantly increased at EOT and SVR12 compared to baseline (0.87 (0.7–1), and 0.83 (0.7-1) vs 0.8 (0.7-0.99) (p = < 0.0001, 0.0002 respectively). median baseline eGFR was 112.1 (90.1-137.6), changing to 108.1 (86.1-134.4) at EOT (p = 0.0003) and 109.7 (87.2-134.3) at SVR12 (p = 0.0002). eGFR was improved in 37.6% of patients, remained unchanged in 15%, and worsened in 47.4% at EOT compared to baseline. No significant changes were found between eGFR measures in patients who received sofosbuvir-based therapy without ribavirin at different time points, while for patients who received sofosbuvir-based therapy with ribavirin, median baseline eGFR was 111.9 (89.8-139.1), changing to 106.4 (84.04-130.7) at EOT (p < 0.0001) and 109.8 (87.3-134.4) at SVR12 (p = 0.0001) (figure1).

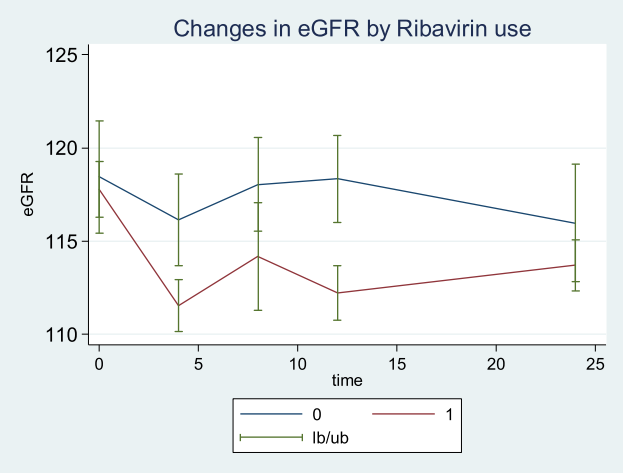

Figure 1: changes in eGFR in chronic HCV patients receiving SOF-based therapy with ribavirin vs without ribavirin.

Conclusion: SOF-based therapy is associated with decreased eGFR among HCV patients who received ribavirin. Renal function should be monitored during and after SOF-based therapy which includes ribavirin.

SAT-219

Effect of treatment of hepatitis C by directly acting antivirals on chronic hepatitis C and B co-infected patients

Afify Ahmed[1], Neveen Elantouny[1], Amal Zidan[2], Ayman Sadek[1], Mohamed Elrasad[3]. *[1]Zagazig University, Internal Medicine, Zagazig, Egypt; [2]Zagazig University, Clinical Pathology, Zagazig, Egypt; [3]Dnchal Hepatology Teaching Hospital, Internal Medicine, Damanhour, Egypt*
Email: amedms@gmail.com

Background and aims: Hepatitis C virus (HCV) and hepatitis B virus (HBV) co-infection has a well-known impact on the disease severity and prognosis. The treatment options should be chosen wisely. However, the information concerning many aspects of dual infection, especially reactivation issue during or after completion of directly acting antivirals (DAAs), remains largely incomplete and heterogeneous. We aimed to investigate the risk of HBV reactivation during HCV treatment by DAAs in co-infected patients.
Method: We conducted a prospective cross-sectional cohort study in Al-Mahalla Hepatology Teaching Hospital, Gharbia, Egypt from the period between August 2016 and April 2018. Out of 3689 HCV patients screened for HBV, twenty patients showed co-infection in the age group of 18-70 years old after exclusion of HIV, autoimmune, haematological, and neoplastic disorders. We followed-up the patients for 24 weeks.
Results: Four patients had a negative HBsAg before DAAs treatment, one of them had detectable HBV viral load (occult HBV), with all of the 20 patients had a positive anti-HBc. Eight patients (40%) showed reactivation during DAAs treatment (figure 1). Five males and three females. Three patients with SOF/DAC/RBV regimen, two patients with SOF/DAC regimen, and three patients with SOF/SIM regimen.

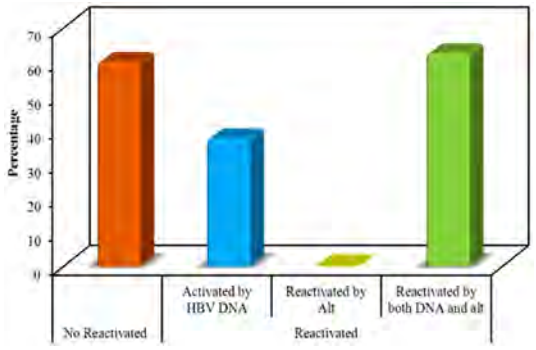

Figure: Distribution of the studied cases according to Reactivation (n = 20)

Conclusion: HBV reactivation during DAA therapy occurred with a respectful number. HBV screening is recommended both before, and during DAAs therapy regardless of the HBV status and the class of DAAs used.

SAT-220

Higher frequency of occult HCV infection in HIV/HCV coinfected patients with advanced liver disease: Post DAAs treatment observation

Sabrina Bagaglio[1], Emanuela Messina[1], Riccardo Vercesi[1], Giulia Morsica[1], Stefania Salpietro[1], Alba Bigoloni[1], Liviana Della Torre[1], Vinci Concetta[1], Adriano Lazzarin[1], Caterina Uberti-Foppa[2], Hamid Hasson[1]. *[1]San Raffaele Hospital, Milan, Italy; [2]University Vita-Salute San Raffaele, Milan, Italy*
Email: bagaglio.sabrina@hsr.it

Background and aims: Occult hepatitis C virus (HCV) infection (OCI) is defined as the presence of the HCV genome in either hepatocytes or

peripheral blood mononuclear cells (PBMCs) without detection of HCV RNA in serum. One study, analyzing the frequency of OCI both in naïve and DAAs treated patients showed a prevalence of 23% in HCV monoinfected patients. In this study, frequency of OCI resulted significantly higher in cirrhotic patients (73%) than in non-cirrhotic ones (24%, p = 0.0008).We aimed to evaluate the frequency of OCI in HIV/HCV co-infected patients with SVR12 after DAAs treatment and to explore clinical and virological characteristics associated with the presence of OCI.

Method: Fifty-three HIV/HCV co-infected patients with SVR12 after DAAs treatment, attending at Infectious Diseases Division of San Raffaele Hospital, Milan from 2015-2018 with available PBMCs sample at end of treatment and/or at week12 post treatment, were included in the study. In our analysis, OCI was defined as the presence of the HCV genome in PBMCs, determined by qualitative detection of 5' non coding region in this compartment, despite HCV RNA < 12 IU/ml measured in plasma. HCV-RNA negative patients in PBMCs were classified as no-OCI. Clinical and virological data were collected at baseline and provided as median and quartiles. Advanced liver disease (ALD) was defined as liver stiffness, measured by using transient elastography (TE), > 10 kpascal, and by a FIB-4 > 3.25 value. Mann-Whitney non parametric test or Fisher exact test were used to compare clinical and virological variables, as appropriate.

Results: OCI was detected in 43/53 (81%) patients: 30/31 (97%) patients with ALD and 13/22 (59%) patients without ALD (p = 0.0008). Comparison of clinical and virological variables between OCI and no-OCI showed that: liver stiffness [12.3 (6.8-20.6) vs 6.6 (6.2-7.0) kpascal, p = 0.002] and FIB-4 score [2.01 (1.4-4.2) vs 1.49 (0.8-2) (p = 0.009)] were significantly higher in OCI than in no-OCI. Additionally, CD4+ cells count [709 (445-926) vs 816 (743-1023) cells/mmc, p = 0.048] and CD8+ cells count [793 (569-1038) vs 1110 (833-1509) cells/mmc, p = 0.033], were higher in no-OCI patients. ALD resulted associated with a higher risk of OCI both considering liver stiffness (OD 0.048, p = 0.0008) or FIB-4 value (OD 0.15, p = 0.0756).

Conclusion: In our study population of HIV/HCV co-infected patients with SVR12 after DAAs treatment, a high frequency of OCI detected at end of treatment and/or at week12 post treatment, was observed. A less preserved HIV related immunological status and ALD were related with a major probability to maintain HCV infection in PBMCs.

SAT-221

Autoantibodies to apolipoprotein A1 (apoA-1): A new prognostic biomarker in HCV infection

Margaret Bassendine[1], Sabrina Pagano[2], Simon Bridge[3], David Sheridan[4], Isaac Shawa[4], Matthew Cramp[4], Simon Taylor-Robinson[5], Dermot Neely[6], Nicolas Vuilleumier[2].
[1]Newcastle University, Institute of Cellular Medicine, Newcastle upon Tyne, United Kingdom; [2]Geneva University Hospitals, Geneva, Switzerland; [3]Northumbria University, Newcastle upon Tyne, United Kingdom; [4]Plymouth University, Plymouth, United Kingdom; [5]Imperial College, London, United Kingdom; [6]Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, United Kingdom
Email: mbassendine@doctors.org.uk

Background and aims: Chronic HCV infection is associated with an increased risk of atherosclerosis and cardiovascular mortality, despite an ostensibly favourable lipid profile Autoantibodies directed against apoA-1 (AAA-1) are a new biomarker of cardiovascular disease (CVD). High density lipoprotein (HDL) inhibits HCV-neutralizing antibodies by stimulating cell entry via activation of the scavenger receptor BI, an entry factor for HCV and a HDL receptor. ApoA-I is the principal component of HDL and amphipathic helices of apoA-I are critical for its binding to SR-B1. The AAA-1 response is biased towards the C-terminal alpha-helix of the protein.

We reported the presence of AAA-1 in 14/27 patients with advanced HCV and now extend this to 244 individuals: 29 with spontaneous resolution of HCV (SR), HCV RNA negative individuals after sustained virological response (SVR, n = 88) and patients with chronic HCV (CHCV, n = 127).

Method: Serum samples were obtained from HCV Research UK and Hepatology Research Group, Plymouth, UK and assayed for AAA-1 IgG by ELISA and lipids as previously described.

Results: CHCV patients had a high incidence of AAA-1 [59/127 (46.4%), 28/61 (46%) GT1 and 31/66 (47%) GT3]. This was significantly higher (p = 0.004) than HCV SR-5/29 (17%) were positive for AAA-1, similar to the rate in the general population (19.9%). 33/88 (37.5%) SVR sera were AAA-1 positive [n.s compared to CHCV group (p = 0.209)].

CHCV patients had dyslipidaemia with significantly lower total cholesterol, non-HDL-C, triglyceride and apolipoprotein B (p < 0.001) compared to patients with SVR and HCV SR [table]. This impacts on conventional cardiovascular risk factors which lose predictive power in chronic HCV infection.

Biochemical characteristic (median)	Spontaneous resolvers (n=29)	Chronic HCV (n=126)	SVR to antiviral therapy (n= 89)	P value
Total cholesterol (C) (mmol/L)	4.40	3.90	4.40	<0.001
Non-HDL-C (mmol/L	3.35	2.75	3.30	<0.001
Triglyceride (mmol/L)	1.75	1.00	1.50	<0.001
HDL-C (mmol/L)	1.00	1.10	1.00	0.032
Apolipoprotein A1 (g/L)	1.32	1.47	1.37	0.148
Apolipoprotein B (g/L)	0.81	0.76	0.89	<0.001
Triglyceride/HDL-C ratio	1.62	0.91	1.32	<0.001
Cholesterol/HDL-C ratio	4.78	3.46	4.27	<0.001
ApoB/ApoA1 ratio	0.60	0.51	0.66	<0.001

Conclusion: In contrast to spontaneous resolution after HCV infection, there is a high incidence of AAA-1 autoantibodies in CHCV which often persist after SVR. We hypothesise that these autoantibodies facilitate HCV persistence in predisposed individuals. Their role in modulating HCV entry and in CVD in CHCV warrants further study. This novel biomarker may be an independent predictor of CVD in HCV infection after SVR.

Email: maiabutsashvili@gmail.com

Background and aims: Georgia, a country with a large burden of hepatitis C, launched an ambitious hepatitis C elimination program in 2015. The aim of this study was to assess the long-term outcomes among patients with advanced liver fibrosis treated with direct acting antivirals (DAAs) who achieved sustained viral response (SVR).

Method: Four clinics providing hepatitis C diagnostic and treatment services in Georgia as part of national elimination program participated in the study. Patients treated with DAAs as part of the hepatitis C elimination program with advanced liver fibrosis defined

as fibrosis score ≥ F3 by elastography or FIB4 score ≥ 3.25, were treated during May to December 2015, completed a full course of the DAA treatment, and achieved SVR at week 12-24 post treatment were eligible for the study. Follow-up occurred between November 2017 and June 2018. Baseline and post treatment values (at least two years following completion of treatment) for liver fibrosis level (by elastography or FIB4 score), alanine aminotransferase (ALT), aspartate aminotransferase (AST), platelet count (PLT), spleen size and existence of ascites were evaluated among the study participants.
Results: A total of 600 patients were recruited and met the eligibility criteria. Mean age of participants was 52.2 years (range 27-85) and the majority 515/600 (85.8%) were male. Liver stiffness, defined as kpa, decreased a mean of 8.6 kpa (from 23.89 to 15.26) from baseline to follow-up (p <.0001). Among those whose fibrosis was measured by FIB4, the mean decrease was 1.41, from 3.52 to 2.11, (p <.0001). Mean ALT and AST levels decreased from 111.5 to 30.8 (p <.0001) and 89.7 to 30.3 (p < 0.05), respectively. The mean PLT count increased from 159 000 to 182 300 per microliter (p < 0.0001). Mean spleen sizes decreased significantly from 136X56 mm to 132X53 mm (p <.001). Among those with ascites at baseline (n = 17), 10 (58.8%) experienced resolution, while among the 583 patients without ascites at baseline, 9 (1.5%) were noted to have ascites during the follow-up examination.
Conclusion: Significant improvement of liver fibrosis level and clinical and laboratory parameters were observed two years after achieving SVR among patients with advanced liver fibrosis treated with DAAs.

SAT-223

AA genotype of the deSNP rs6726639 of gene MERTK (MER Tyrosine Kinase) is associated with development of hepatocellular carcinoma after hepatitis C virus clearance

Vincenza Calvaruso[1], Stefania Grimaudo[1], Salvatore Petta[1], Rosaria Maria Pipitone[1], Giuseppe Cabibbo[1], Elisabetta Conte[1], Bianca Magro[1], Francesca Rini[1], Ciro Celsa[1], Lorenza Di Marco[1], Calogero Camma[1], Antonio Craxi[1], Vito Di Marco[1]. *[1]University of Palermo, Gastroenterology and Hepatology Unit, Di.Bi.M.I.S., Palermo, Italy*
Email: vincenza.calvaruso@unipa.it

Background and aims: In patients with cirrhosis, the risk for hepatocellular carcinoma (HCC) development after hepatitis C virus (HCV) clearance is not canceled altogether. MERTK (MER Tyrosine Kinase) gene, located in chromosome 2, is a regulator of tumor-associated macrophages (TMA) involved in the modulation of inflammatory responses and angiogenesis. We evaluated the role of the Single Nucleotide Polymorphism (deSNP) rs6726639 of MERTK gene in the development of HCC in patients with a sustained virologic response (SVR) after treatment with Direct Antiviral Agents (DAAs).
Method: All consecutive patients with HCV cirrhosis (90% Child-Pugh class A and 10% Child-Pugh class B) treated with DAAs between March 2015 and December 2016 who obtained a SVR were evaluated for HCC occurrence by Kaplan-Meier curves and variables associated with HCC development were analyzed by Cox regression analysis. Genotyping for rs6726639 deSNP was carried out using the TaqMan SNP genotyping allelic discrimination method (Applied Biosystems, Foster City, CA, USA) on blood samples stored before treatment.
Results: Among 516 patients (mean age 66.9 ± 10.4 years, 57.9% men, 71.5% with esophageal varices) included in this analysis, 93 (18.0%) carried out the AA genotype, 215 (41.6) the AC genotype and 208 (40.4%) the CC genotype of rs6726639 deSNP.
During follow-up (median 25 ± 7 months) 28 patients (5.4%) developed HCC. By multivariate Cox regression analysis, platelet count < 120x 10^9/L (HR 5.72; 95%CI: 1.97-16.63; p = 0.001), Child-Pugh class B (HR: 3.09; 95%CI:1.31-6.89; p = 0.009) and the AA genotype of rs6726639 deSNP (HR 3.04; 95%CI: 1.40-6.62; p = 0.005) were independently associated to HCC occurrence.
Combining the rs6726639 deSNP genotype with clinical factors, we developed a risk profiling model with HCC rates ranging from 0.5% (best risk profile) toward 33% (worst risk profile).
Conclusion: The AA allele of rs6726639 deSNP of MERTK gene is associated with a higher risk of developing HCC in patients with cirrhosis after HCV eradication by DAAs. The identification of risk profiles is an important step forward in establishing prediction models for HCC development.

SAT-224

Design and validation of a risk prediction model for hepatocellular carcinoma development after sustained virological response in chronic hepatitis C patients

Ho Soo Chun[1], Beom Kyung Kim[1,2,3], Seung Up Kim[1,2,3], Jun Yong Park[1,2,3], Do Young Kim[1,2,3], Sang Hoon Ahn[1,2,3], Kwang-Hyub Han[1,2,3], Cheol-Hyung Lee[4], Yun Bin Lee[4], Eun Ju Cho[4], Su Jong Yu[4], Yoon Jun Kim[4], Jung-Hwan Yoon[4], Jeonghoon Lee[4]. *[1]Department of Internal Medicine, Yonsei University College of Medicine, Seoul, Korea, Rep. of South; [2]Institute of Gastroenterology, Yonsei University College of Medicine, Seoul, Korea, Rep. of South; [3]Yonsei Liver Center, Severance Hospital, Seoul, Korea, Rep. of South; [4]Department of Internal Medicine and Liver Research Institute, Seoul National University College of Medicine, Seoul, Korea, Rep. of South*
Email: ksukorea@yuhs.ac

Background and aims: Hepatocellular carcinoma (HCC) can develop after eradication of the hepatitis C virus. We designed and validated a HCC development risk score (HCC-SVR score) based on independent predictors for chronic hepatitis C (CHC) patients after sustained virological response (SVR).
Method: Between 2003 and 2016, 669 CHC patients achieved SVR through antiviral therapy. A new HCC-SVR score was developed based on the multivariate Cox proportional hazards regression model.
Results: After SVR achievement, HCC developed in 19 (2.8%) patients. HCC occurred more frequently in older, male patients and was associated with liver cirrhosis, hypertension, diabetes, lower platelet count, higher alpha-fetoprotein, higher aspartate and alanine aminotransferase, lower total cholesterol, and higher FIB-4 level (all p < 0.05). A multivariate analysis revealed that FIB-4 independently predicted HCC development (hazard ratio [HR] = 1.080), together with male gender (HR = 8.189) and alpha-fetoprotein level (HR = 1.060) (all p < 0.05). The HCC-SVR score based on independent predictors successfully predicted the risk of HCC development (area under receiver operating characteristic curve [AUC] = 0.771 at 2 years, 0.991 at 6 years, and 0.739 at 10 years). When the study population was stratified into three groups according to HCC-SVR risk score (0-2 points as low-risk, 3-7 points as intermediate-risk, and 8-9 points as high-risk), the cumulative incidence rate of HCC was significantly different between the groups (all p < 0.05 by log-rank tests). The accuracy of HCC-SVR score was maintained in a validation cohort (n = 524) (AUC = 0.728 at 2 years, 0.809 at 6 years, and 0.970 at 8 years).
Conclusion: This HCC-SVR score enables the ability to conduct risk stratification for HCC development in CHC patients at the time of SVR.

SAT-225

The risk of hepatic decompensation is reduced, but not abolished after direct-acting antivirals: The role of portal hypertension

Elton Dajti[1], Federico Ravaioli[1], Antonio Colecchia[1,2], Giovanni Marasco[1], Maria Letizia Bacchi Reggiani[1], Luigina Vanessa Alemanni[1], Mariarosa Tamé[1], Stefano Brillanti[1,3], Francesco Azzaroli[1], Giuseppe Mazzella[1], Davide Festi[1]. *[1]University of Bologna, Bologna, Italy; [2]Borgo Trento, University Hospital, Verona, Italy; [3]University of Siena, Research center for the study of hepatitis, Siena, Italy*
Email: antonio.colecchia@aovr.veneto.it

Background and aims: Little evidence is available on the risk of portal hypertension (PH)-related complications, such as hepatic decompensation (HD), after direct-acting antivirals (DAAs) in

	Number at risk

Figure: (abstract: SAT-224)

patients with HCV-related advanced chronic liver disease (ACLD). Our aims were: a) to evaluate the incidence of HD after DAAs and confront it to a historical cohort of untreated patients; b) to estimate the effect of DAA treatments on HD.

Method: We performed in our tertiary centre a cohort study in 146 ACLD patients treated with DAAs and with available liver (LSM) and spleen (SSM) stiffness measurement both before and 6 months after end-of treatment; the patients were subsequently prospectively follow-up. A historical cohort of 92 consecutively enrolled untreated cirrhotic patients with active HCV-infection was used as a control group. A propensity score stabilized inverse probability weighting approach was used to account for differences between groups. A weighted Cox regression analysis was used to evaluate the predictors of the main outcome.

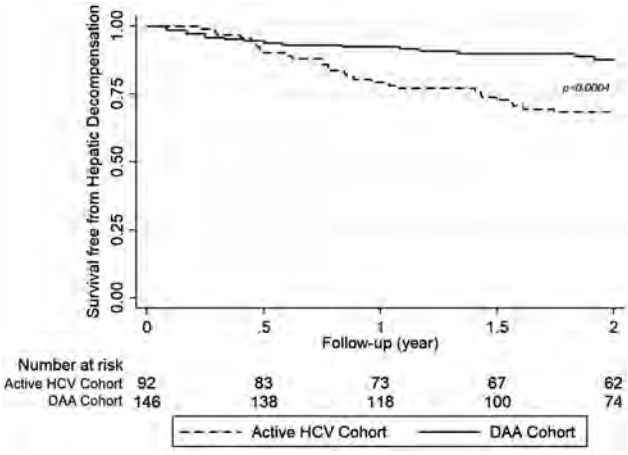

Figure: Kaplan-Meier curves of two-year HD-free survival in the active HCV and the DAA cohort.

Results: Median follow-up in the DAA cohort was 33.5 (22-38) months. The HD incidence in this cohort was 7.07 (4.56-10.96) per 100-person-years (PYs), significantly higher than in the active HCV cohort, 19.75 (13.81-28.25) per 100 PYs. **Figure 1** shows that the 2-year event-free survival was significantly higher in the DAA cohort. (0.004). DAA therapy was an independent protective factor for HD development (hazard ratio [HR], 0.177; 95%Interval-of-confidence [IC], 0.081-0.390), whereas previous HD (HR, 5.982; 95%CI, 2.434-14.702) and higher SSM values (HR, 1.025; 95%CI 1.006-1.045) were associated with a higher risk of the event. HD-free survival statistically differed

Conclusion: The risk of HD is markedly reduced after DAA therapy, but it is not abolished. Patients with severe PH, whether identified by clinical parameters, such as previous HD, or non-invasive approach (SSM), will continue to decompensate independently from etiological treatment, and therefore should be closely monitored.

SAT-226

beneficial effects of DAAs on right cardiac function in hcv patients with low-mild liver fibrosis

Email: andrea.dalbeni@aovr.veneto.it

Background and aims: Hepatitis C virus (HCV)-related chronic infection has been associated with a higher incidence of cardiovascular (CV) diseases. Systemic chronic inflammation, specific viral cytotoxicity on either the endothelium or the myocardium or an unexpectedly high prevalence of CV risk factors in HCV patients, may represent etiological factors. In a few studies, a reduced right and left ventricular function and morphology were found in patients affected by HCV hepatitis but the causality of the association is still debated.

Method: Eighty-six non-obese and non-diabetic HCV-patients (59.5 ± 12.0y; males 52%) with fibroscan-documented low-mild liver fibrosis, eligible for virus eradication with DAAs (Direct-Acting Antivirals), were included. Fifty-six of them were compared with 52 control subjects matched for age, sex and CV risk factors at baseline. A transthoracic echocardiography was performed at baseline (T0) in all participants and repeated in all HCV patients after successful eradication (6 months later, T1).

Results: At baseline, no differences in ejection fraction, MAPSE, E/A ratio and indexed Left Ventricular Mass (LVMi) were detected whereas Relative-wall Thickness (RWT) was higher in HCV patients as compared to matched controls. Right indexed atrial volume, basal ventricular diameter and pulmonary pressure were higher in HCV participants. After virus eradication, left atrial volume, tele-diastolic diameter and LVMi were lower as compared to baseline. Indexed right atrial volume, basal ventricular diameter, TAPSE, pulmonary arterial pressure and vena cava diameter decreased significantly.
Conclusion: The study shows a concentric remodelling of left ventricle and structural modifications in the right sections along with a higher pulmonary pressure in HCV subjects. Treatments with DAAs is associated with regression of most cardiac alteration indicating a direct involvement of the HCV virus in cardiac alterations, reversible after etiological treatment.

SAT-227

Clinical but not genetic variables predict the development of hepatocellular carcinoma in hepatitis C cirrhotic patients treated with direct-acting antivirals: A 3-year study in 509 patients

Elisabetta Degasperi[1], Enrico Galmozzi[1], Floriana Facchetti[1], Roberta D'ambrosio[1], Roberta Soffredini[1], Marta Borghi[1], Riccardo Perbellini[1], Massimo Iavarone[1], Angelo Sangiovanni[1], Pietro Lampertico[1]. [1]*CRC "A. M. e A. Migliavacca" Center for Liver Diseases, Division of Gastroenterology and Hepatology, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, University of Milan, Milano, Italy*
Email: elisabetta.degasperi@unimi.it

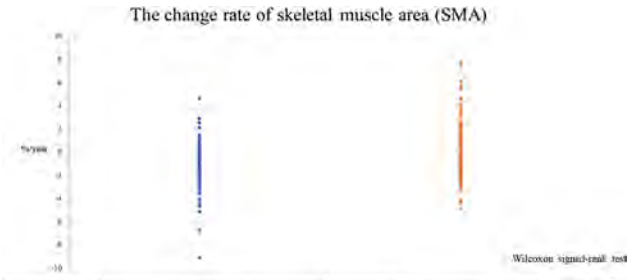
Background and aims: Several single nucleotide polymorphisms (SNPs) have been associated with increased hepatocellular carcinoma (HCC) risk in viremic and Interferon-cured hepatitis C virus (HCV) cirrhotics, but the role of these genetic predictors in patients treated with direct-acting antivirals (DAA) is still undefined. The study aimed to assess the association between nine SNPs and HCC in a large cohort of DAA-treated patients.
Method: Consecutive HCV cirrhotics receiving DAA between December 2014-2016 in a single Center were enrolled. Cirrhosis was defined clinically, histologically or non-invasively (LSM ≥ 12 kPa). HCC was diagnosed and staged according to international recommendations. Patients were genotyped for 9 genes: TLL1 rs17047200, PNPLA3 rs738409, MBOAT7 rs641738, TM6SF2 rs5842926, IL28B rs12979860, MERTK rs4374383, MERTK rs6726639, EGF rs4444903 and GCKR rs1260326.
Results: 509 patients were analyzed: median age 64 (28-87) years, 58% males, 50% HCV-1b, median LSM 19.4 (12.0-75.0) kPa, 87% CPT-A, 11% with previous HCC. Overall, genotypes distribution was as follows: TLL1 AA (72%), AT (26%), TT (2%); PNPLA3 CC (46%), CG (41%) GG (13%); MBOAT7 CC (29%), CT (49%), TT (22%); TM6SF2 CC (91%), CT (8%), TT (1%); IL28B CC (22%), CT (54%), TT (24%); MERTK rs4374383 GG (37%), GA (48%), AA (15%); MERTK rs6726639 CC (37%), CA (49%), AA (14%); EGF AA (31%), AG (47%), GG (22%); GCKR CC (26%), CT (48%), TT (26%). Demography and clinical features of the patients were similar across SNPs genotypes. After 33 (3-47) months from DAA start, 56 patients developed HCC (3-year estimated cumulative probability of 14%). Male sex (HR 3.78, p = 0.008), diabetes (HR 3.5, p = 0.001) and LSM (HR 1.09, p = 0.001) were baseline independent predictors of HCC. Cumulative rates of HCC were independent of SNPs genotypes (TLL1 p = 0.92, PNPLA3 p = 0.25, MBOAT7 p = 0.69, IL28B p = 0.37, MERTK rs4374383 p = 0.07, EGF p = 0.8, TM6SF2 p = 0.6, MERTK rs6726639 p = 0.09, GCKR p = 0.91). Main HCC features did not differ across SNPs genotypes, such as nodules number (single: TLL1 p = 0.16, PNPLA3 p = 0.47, MBOAT7 p = 0.57, TM6SF2 p = 0.64, IL28B p = 0.68, MERTK rs4374383 p = 0.64, MERTK rs6726639 p = 0.59, EGF p = 0.79, GCKR p = 0.19), and time to HCC onset (TLL1 p = 0.46, PNPLA3 p = 0.14, MBOAT7 p = 0.17, TM6SF2 p = 0.49, IL28B p = 0.87, MERTK rs4374383 p = 0.96, MERTK rs6726639 p = 0.65, EGF p = 0.77, GCKR p = 0.27).
Conclusion: In a large cohort of DAA-treated HCV cirrhotics, clinical but not genetic features predict HCC risk.

SAT-228

Sustained virologic response induced by direct-acting antivirals suppresses skeletal muscle loss in patients with type C liver disease

Kei Endo[1], Takuro Sato[1], takuya okamoto[1], Yasuhiro Takikawa[1]. [1]*Iwate Medical University School of Medicine, Division of Hepatology, Department of Internal Medicine, Morioka, Japan*
Email: keiendo@iwate-med.ac.jp

Background and aims: Chronic liver disease is a typical disorder of secondary sarcopenia that adversely affects the quality of life and clinical outcomes of patients. The effect of treatment of the primary disease (hepatitis C virus [HCV] elimination) on skeletal muscle mass has not been clarified. This study aimed to determine whether patients with HCV who achieved sustained virologic response (SVR) by direct-acting antivirals (DAAs) therapy improved skeletal muscle mass.
Method: We selected patients with HCV treated with DAAs therapy between 2014 and 2017. The inclusion criteria for the present study were as follows: (1) achieved SVR 24 by DAAs; (2) observation period evaluable by CT more than 1 year before and after DAAs. The exclusion criteria were as follows: (1) hospitalized for more than 1 month during an observation period; (2) Child-Pugh class B or C. We evaluated the cross-sectional area of the skeletal muscles (cm^2) at the third lumbar vertebra (L3) by abdominal CT. We used an image analysis software (SliceOmatic 5; Tomovision, Canada). The L3 skeletal muscle area was measured thrice: at the initial, start of DAAs, and final during the follow-up period. The Δ skeletal muscle area (SMA)/year (%/y) before the DAAs period was calculated as (SMA at the start of DAAs CT scan – SMA at the initial CT scan/SMA at the initial CT × 100/interval between CT scans (y)). The ΔSMA/y (%/y) after the DAAs period was calculated as (SMA at the final CT scan – SMA at the start of DAAs CT scan/SMA at start of DAAs CT × 100/interval between CT scans (y)). We compared ΔSMA/y (%/y) before and after the DAAs period.
Results: Eighty-six patients were enrolled in this retrospective study. The median age of the patients was 72 years, and 49 (57%) patients were men. In addition, 49 (57%) and 38 (43%) patients were diagnosed with chronic hepatitis (CH) and liver cirrhosis (LC), respectively. HCV genotype and DAA drugs were as follows: 1a:1b:2a:2b = 2:71:9:4, daclatasvir + asunaprevir/ledipasvir + sofosbuvir/sofosbuvir + ribavirin/elbasvir + grazoprevir:34/27/13/12. The median observational periods (CT interval) before and after DAAs were 3.27 and 2.37 years, respectively. SMA measured at the start DAA (second) CT indicated a significant decrease compared with the initial CT values (116.1 cm^2 vs 112.5 cm^2, p < 0.01). In contrast, no significant change was found between start DAAs (second) and final CT values (112.5 cm^2 vs 113.4 cm^2, p = 0.84). The change rate of SMA measured after DAA periods indicated a significant increase compared with that before the DAA periods {–0.03% (– 4.83%-7.66%) vs – 0.89% (– 9.10%-4.67%), p < 0.01}.
Conclusion: Viral eradication by DAAs (SVR) improved liver function, as well as suppressed the decrease in skeletal muscle area in patients with type C liver disease.



n=87	before DAA periods	After DAA periods	P
ΔSMA (%/year)	-0.89 (-9.10 – 4.67)	-0.03 (-4.83 – 7.66)	<0.01

SAT-229

Risk of hepatocellular carcinoma in patients with chronic hepatitis C and stage-3 liver fibrosis after sustained virological response with direct acting antivirals

Maria Sanchez-Azofra[1], Inmaculada Fernández Vázquez[2], Maria Luisa Garcia[3], Lourdes Dominguez[4], Conrado Fernández-Rodríguez[5], Lucia Bonet[6], Marisa Montes[7], Pablo Ryan[8], Francisco Gea[9], Antonio Diaz Sanchez[10], Marian Garcia-Mayor[11], María Luisa Manzano[2], Leticia Gonzalez Moreno[3], Otilia Bisbal[4], Luz Martín Carbonero[7], Maria Luisa Gutierrez[5], Antonio Guerrero García[9], Miguel Rivero[10], Maria Elena Portales[11], Antonio Olveira Martin[1], Pilar Castillo[1].

Email: maryazofra@gmail.com

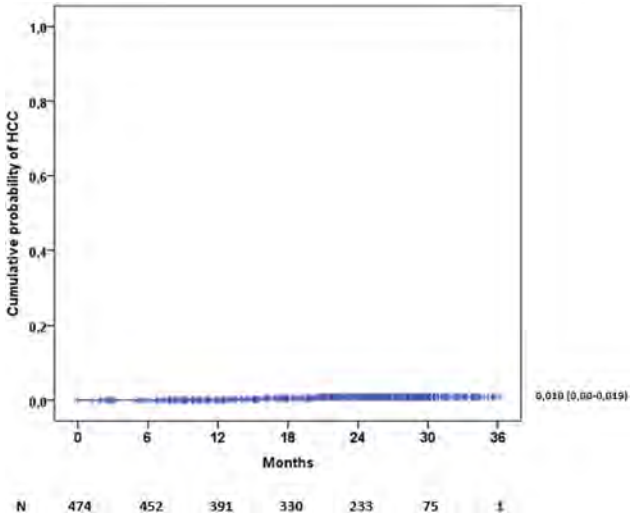
Background and aims: Current guidelines recommend life-long hepatocelullar carcinoma (HCC) surveillance in patients with stage 3 liver fibrosis (F3) after sustained virological response (SVR). However, the real incidence of HCC in this population is not well established and is based on retrospective studies from the Interferon-based treatment era. It also implies a substancial burden for both patients and the Health Systems. We aim to determine the HCC incidence in F3 patients after SVR with direct-acting antivirals (DAA).

Method: multicenter, ambispective, observational study. Inclusion criteria: Chronic hepatitis C; baseline F3 (transient elastography [TE] 9.5-14.5 kPa); SVR after DAA-based treatment from January to December 2015. Exclusion criteria: HCC diagnosed before SVR12; concomitant liver disease, cirrhosis or portal hypertension criteria. Abdominal ultrasounds were performed and HCC diagnosed according to EASL and AASLD guidelines.

Results: 474 patients were eligible for analysis. Median age 56.8 years (P25 51.8; P75 65.9), 60.34% males, 8.72% HCV-genotype 3, 41.41% met criteria of metabolic syndrome (MetS). 35.02% smokers, 13.59% significant alcohol consumption, 19.41% HIV co-infection, 14.95% post-SVR altered liver test. Baseline TE median values were 11.2 kPa (P25 10.2; P75 12.6). Median follow-up was 23.6 months (P75 16; P75 28.4).

Three hepatic tumors were diagnosed: two HCC and one cholangiocarcinoma. None with metabolic syndrome or HIV co-infection. One patient with HCC had genotype 3 and the patient with cholangiocarcinoma consumed alcohol. Baseline TE values of these patients were 11.8, 12 and 10Kpa.

Cumulative HCC incidence was 1% (IC 95% 0-1.9) at 36 months (Figure 1) and the HCC incidence rate 0.35 per 100 patients-year (IC 95% 0.07-1.02).



Conclusion: Patients with chronic hepatitis C and baseline F3 have a very low risk of developing HCC after SVR with DAA, below the threshold considered cost-effective for HCC screening (1, 5/100/year).

SAT-230

HCV re-infection among HIV-infected MSM in New York City

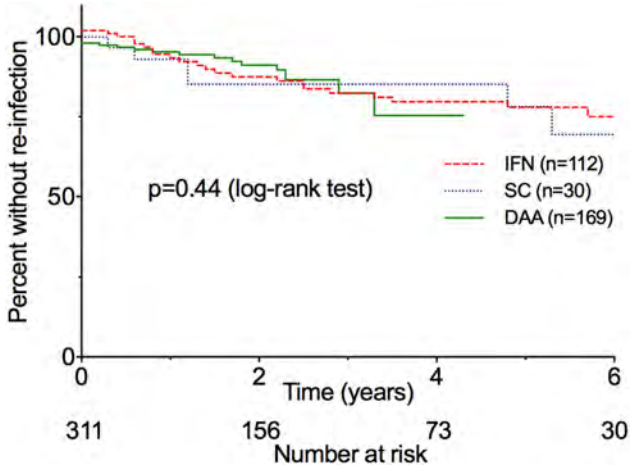
Jesse Carollo[1], Stephanie Factor[1], Gabriela Rodriguez-Caprio[1], Asa Radix[2], Stephen Dillon[3], Rona Vail[2], Krisczar Bungay[3], Robert Chavez[4], José Lares-Guia[5], Daniel Fierer[1]. *[1]Icahn School of Medicine at Mount Sinai, Infectious Diseases, New York, United States; [2]Callen-Lorde Community Health Center, New York, United States; [3]Gotham Medical Group, New York, United States; [4]AIDS Healthcare Foundation, New York, United States; [5]Office of José Lares-Guia, New York, United States*
Email: daniel.fierer@mssm.edu

Background and aims: HCV re-infection rates after IFN treatment in HIV-infected MSM in Europe are much higher than primary infection rates, ranging from 3-15%. The primary HCV infection rate in New York City (NYC) was reported by the NYC Department of Health as 0.6/100 person-years (PY), but there are no data on re-infection rates in the United States or NYC, including among those cured with all-oral direct-acting antiviral (DAA) therapy.

Method: We assessed all HIV-infected MSM from our NYC cohort for clearance of HCV. Clearance was defined as SVR 12 if by treatment, or undetectable HCV VL for ≥ 12 weeks if by spontaneous clearance (SC). Re-infection was defined as new HCV viremia after clearance. Clinical onset of re-infection was defined as the date of the 1st-noted ALT elevation or HCV viremia. Observation time was defined as the period between 12 weeks after completion of therapy or SC, and either the clinical onset of HCV re-infection or the last undetectable HCV VL in those not re-infected.

Results: We identified 278 HIV-infected MSM with documented clearance of primary HCV infection and ≥ 4 weeks follow-up. Median age was 45 years; 173 (62%) were white, 44 (16%) black, 59 (21%) Hispanic. Genotypes of the primary HCV infections (n = 267) were 1a in 212 (79%), 1b in 25 (9%), 2b in 19 (7%), 3a in 4 (2%), and 4d in 7 (3%). Median CD4 count was 579 cells/uL; median HIV VL was < 50 copies/ml. We found 46 re-infections among 39 (14%) men between 2006 and 2018, a median of 1.7 (IQR 0.8, 3.3; range 0.2-11.8) years after clearance. Genotypes of the HCV re-infections (n = 41) were 1a in 32 (78%), 1b in 2 (5%), 2a in 5 (12%), 3a in 1 (2%), and 4d in 1 (2%). Including the re-infections, follow-up was available for 311 episodes of HCV clearance among the 113 (36%), 168 (54%), and 30 (10%)

infections cleared with IFN, DAA, and SC, respectively. Median follow-up time was 1.9 (IQR 0.8, 3.5; range 0.1-11.8) years, for a total of 808 PY. The overall HCV re-infection rate was 5.7/100PY (95% CI 4.2, 7.3). Time to HCV re-infection did not differ among the groups (p = 0.44, log-rank test) (Figure).



Conclusion: The HCV re-infection rate in our large cohort of HIV-infected MSM in NYC was almost 10-fold higher than the primary infection rate in NYC, was comparable to Europe rates, and was independent of whether clearance was by IFN or DAA treatments, or by SC. Most HCV re-infections occurred in the first 2 years after clearance, but infections continued for more than 11 years. These data suggest that long-term surveillance is warranted for all HIV-infected MSM after clearance of HCV. Further, strategies to reduce HCV infections and re-infections are needed to meet the goal of eliminating HCV in these men who are at high risk for HCV infection and re-infection.

SAT-231

Impact of the HCV cure with DAAs in the use of concomitant medication and the serum lipid profile: Follow-up data one year after the SVR12

Elena González-Colominas[1], Marc Batlle[2], Inés Monge-Escartín[1], Xavier Duran[3], Ana Viu[2], Marta de Antonio[1], Santiago Grau[1], Xavier Bessa[2], Jose A. Carrión[2]. *[1]Hospital del Mar, Pharmacy Department, Barcelona, Spain; [2]Hospital del Mar. IMIM. UAB, Liver section, Gastronterology Department, Barcelona, Spain; [3]IMIM., Methodology and Statistical Support Unit., Barcelona, Spain*
Email: 95565@parcdesalutmar.cat

Background and aims: Patients with chronic hepatitis C (CHC) have several associated comorbidities and concomitant medication (CM). Treatment with direct-acting antivirals (DAA) achieve a sustained virological response (SVR12) in 95% of patients. Recently, it has been reported an increase of cholesterol serum levels (Hernandez-Conde et al., JVH2018) and systemic vascular resistance (Lens et al., Gastroenterology2017) after SVR12. The aim was to evaluate the impact of SVR12 with DAAs in the concomitant medication and the serum lipid profile.
Method: Prospective study of patients with CHC treated with DAAs (January 2015-September 2016) with SVR12. Demographic characteristics, clinical variables, and concomitant medication (CM) were analyzed at baseline and one year after SVR12. The CM was classified according to its anatomical therapeutic chemical classification system (ATC). The differences of the CM between baseline and follow-up were analyzed using the Stuart-Maxwell test and the serum lipid profile with ANOVA test. Patients were categorized according to the increase/decrease in the number of drugs of each ATC and the differences were analyzed by Chi-square test.
Results: We included 226 patients with SVR12 and median age of 59 (25-86): males (55.8%), Charlson index ≥ 4 (54.4%), cirrhosis (48.7%) and HOMA ≥ 3 (45, 7%). A 73.5% of the patients received CM (31% renin-angiotensin system agents, 30.5% antacids, 27.4% diuretics, 19.9% beta-blockers, 16.4% anti-diabetic drugs, 11.5% calcium-channel blockers and 7.1% lipid-lowering agents). A 49.6% were taking at least one drug with antihypertensive effect. During follow-up, total cholesterol serum levels increased from 161 to 179 mg/dL (p < 0.001). A significant increase in the use of lipid-lowering drugs was registered in the global cohort (p = 0, 009) and in patients < 65 (p = 0, 005). A significant trend to the increase of antihypertensive drugs was observed in patients ≥ 65 (p = 0, 06). Patients with an increase in the use of lipid-lowering drugs (n = 12) had a BMI ≥ 30 in a higher proportion (50% vs. 23.8%, p = 0.042). Patients with increased use of antihypertensive drugs (n = 27) presented a greater proportion of age ≥ 65 years (70.4% vs. 37.9%, p = 0.001), Charlson index ≥ 4 (92.6% vs. 49.2%, p < 0.001) and cirrhosis (81.5% vs. 44.2%, p < 0.001). Patients with increased use of antihypertensive drugs presented independently higher Charlson Index (≥ 4) (OR = 6.01, 95% CI: 1.1-32.6, p < 0, 001).
Conclusion: The cure of chronic hepatitis C is associated with a significant increase in cholesterol serum levels and in the use of lipid-lowering drugs, even in young patients, as well as an increase in the use of antihypertensive drugs in patients with comorbidities. However, it would be advisable to evaluate this effect in more extensive cohorts and for a longer period after SVR12 before making a solid recommendation.

SAT-232

Reinfection following successful HCV DAA therapy among people with recent injecting drug use

Jason Grebely[1], Evan B Cunningham[1], Olav Dalgard[2], Behzad Hajarizadeh[1], Brian Conway[3], Jeff Powis[4], Julie Bruneau[5], Jordan Feld[6], Phillip Read[7], Curtis Cooper[8], Janaki Amin[9], Philip Bruggmann[10], Karine Lacombe[11], Catherine Stedman[12], Margaret Hellard[13], Pip Marks[1], Adrian Dunlop[14], Alberto Moriggia[15], Tanya Applegate[1], Alain Litwin[16], Gail Matthews[1], Gregory Dore[1]. *[1]UNSW Sydney, The Kirby Institute, Sydney, Australia; [2]Akershus University Hospital, Oslo, Norway; [3]Vancouver Infectious Diseases Center, Vancouver, Canada; [4]South Riverdale Community Health Centre, Toronto, Canada; [5]Centre Hospitalier de l'Université de Montréal, Montréal, Canada; [6]Toronto General Hospital, Toronto, Canada; [7]Kirketon Road Centre, Sydney, Australia; [8]Ottawa Hospital Research Institute, Ottawa, Canada; [9]Macquarie University, Faculty of Medicine and Health Sciences, Sydney, Australia; [10]Arud Centres for Addiction Medicine, Zurich, Switzerland; [11]Hôpital Saint-Antoine, Paris, France; [12]Christchurch Hospital and University of Otago, Christchurch, New Zealand; [13]The Burnet Institute, Melbourne, Australia; [14]Newcastle Pharmacotherapy Service, Newcastle, Australia; [15]Fondazione Epatocentro Ticino, Lugano, Switzerland; [16]University of South Carolina School of Medicine, Greenville, United States*
Email: jgrebely@kirby.unsw.edu.au

Background and aims: HCV direct acting antiviral (DAA) therapy is effective in people who inject drugs however, little is known about HCV reinfection following DAA therapy among people who have recently injected drugs and/or people receiving opioid substitution therapy (OST). The aim of this study was to evaluate HCV reinfection following successful DAA therapy among people with recent injecting drug use.
Method: SIMPLIFY and D3FEAT are phase IV clinical trials of DAA therapy among people with recent injecting drug use (IDU; last six months) or those receiving OST, through a network of 25 international sites (SIMPLIFY: sofosbuvir/velpatasvir for 12 weeks in people with recent injecting; D3FEAT: paritaprevir/ritonavir/dasabuvir/ombitasvir±ribavirin for 12 weeks in people with recent injecting or receiving OST). This analysis assessed HCV recurrence from end of treatment response (ETR) through 24 weeks post-ETR (SVR24).

Results: Overall, 179 participants (72% male, median age 48 years) had an ETR and at least one subsequent follow-up visit in SIMPLIFY (n = 97) and D3FEAT (n = 82). At treatment initiation, 80% (n = 144) reported IDU in the past 6 months, 54% (n = 97) reported IDU in the past month, and 60% (n = 108) were receiving OST. IDU between ETR and follow-up was reported in 70% (n = 125). HCV recurrence was observed in nine participants including three cases of HCV relapse and six cases of reinfection. Over 168 person-years (py) of follow-up, the incidence of reinfection was 3.6/100 py (95% CI 1.6-7.9). There were no cases of reinfection among those who did not report ongoing injecting drug use after ETR. The incidence of reinfection in those with ongoing injecting after ETR (124 py of follow-up) was 4.8/100 py (95% CI 2.2-10.7/100 py).
Conclusion: HCV reinfection can occur following HCV DAA therapy among people with ongoing injecting drug use following DAA therapy, with higher rates of HCV reinfection observed among people with ongoing injecting drug use following therapy.

SAT-233

Hepatitis C virus reinfection following antiviral treatment among people who inject drugs: A systematic review, meta-analysis, and meta-regression

Behzad Hajarizadeh[1], Evan B Cunningham[1], Heather Valerio[1], Marianne Martinello[1], Hannah Reid[1], Matthew Law[1], Naveed Janjua[2,3], Håvard Midgard[4], Olav Dalgard[5], John Dillon[6], Matthew Hickman[7], Julie Bruneau[8], Gregory Dore[1], Jason Grebely[1]. *[1]UNSW Sydney (University of New South Wales), The Kirby Institute, Sydney, Australia; [2]British Columbia Centre for Disease Control, Vancouver, Canada; [3]University of British Columbia, School of Population and Public Health, Vancouver, Canada; [4]Oslo University Hospital, Department of Gastroenterology, Oslo, Norway; [5]Akershus University Hospital, Oslo, Norway; [6]University of Dundee, Ninewells Hospital and Medical School, Dundee, United Kingdom; [7]University of Bristol, Population Health Sciences, Bristol, United Kingdom; [8]Centre Hospitalier de l'Université de Montréal, Montréal, Canada*
Email: bhajarizadeh@kirby.unsw.edu.au

Background and aims: Among individuals with ongoing injecting drug use (IDU), HCV reinfection following successful therapy can compromise treatment outcome. This systematic review assessed HCV reinfection rate after treatment among people with recent IDU and those receiving opioid substitution therapy (OST).
Method: Bibliographic databases and conference abstracts were searched for studies assessing HCV reinfection rate after treatment among people with recent IDU or those receiving OST. Meta-analysis was used to cumulate reinfection rates and meta-regression to explore factors associated with heterogeneity across studies.
Results: Twenty-two eligible studies were included [total person-years follow-up (PYFU) = 5112], including sub-population data of people with recent IDU (19 studies, PYFU = 4116) and people receiving OST (11 studies, PYFU = 1905). Recent IDU definition varied across studies (IDU during HCV treatment or post-treatment follow-up most commonly used). HCV reinfection rate was 5.4 per 100 PYFU (95%CI: 3.2, 8.9) among people with recent IDU, and 2.7 per 100 PYFU (95%CI: 1.4, 5.4) among those receiving OST. Reinfection rate was comparable between post-interferon-containing therapy (4.6 per 100 PYFU; 95%CI: 2.4, 8.8), and post-DAA therapy (3.4 per 100 PYFU; 95%CI: 2.3, 5.1). In stratified analysis, reinfection rate was 1.3 per 100 PYFU (95%CI: 0.5, 3.2) among people receiving OST with no recent IDU, 3.6 per 100 PYFU (95%CI: 1.5, 9.1) among those with recent IDU who also received OST, and 4.6 per 100 PYFU (95%CI: 2.1, 10.3) among those with recent IDU, not receiving OST. In adjusted meta-regression analysis, longer follow-up was significantly associated with lower reinfection rate [adjusted Rate Ratio (aRR) for each year increase in mean/median follow-up: 0.79 (95%CI: 0.67, 0.92; P = 0.005), while using end of treatment as the start point of time-at-risk of reinfection, compared to 12 weeks post-treatment (SVR12) or later, was significantly associated with higher reinfection rate (aRR: 2.54 (1.28, 5.04; P = 0.011). Diagnosis of reinfection following end of treatment was based on virus sequencing data, or genotype-switch.
Conclusion: Post-treatment HCV reinfection rate was the highest among people with recent IDU, not receiving OST. Higher rate in studies assessing reinfection from the end of treatment and lower rate in studies with longer follow-up suggested higher risk of reinfection early post-treatment. Harm reduction services are required to reduce the reinfection risk while regular post-treatment HCV assessment is required to detect and treat reinfection early.

SAT-234

Risk of hepatocellular carcinoma and efficacy of direct-acting antivirals in patients with concurrent hepatitis C virus

Elizabeth Harrod[1,2,3], Ritu Agarwal[1], Parissa Tabrizian[1], Madhavi Rayapudi[1], Aftab Ala[2,3], Isabel Fiel[1], Myron Schwartz[1], Douglas Dieterich[1], Scott Friedman[1], Behnam Saberi[1]. *[1]Icahn School of Medicine at Mount Sinai, New York, United States; [2]Royal Surrey County Hospital, Guildford, United Kingdom; [3]University Of Surrey, Guildford, United Kingdom*
Email: elizabeth.harrod@gmail.com

Background and aims: Direct-Acting Antivirals (DAAs) have enabled us to cure more than 90% of patients with hepatitis C virus (HCV), though recent data suggests that HCV patients are less likely to achieve sustained virological response (SVR) in the presence of hepatocellular carcinoma (HCC). Although it is known that cirrhotic patients with HCV are at risk for HCC development, even in the DAA era, our understanding of HCC risk in non-cirrhotic DAA-cured patients is limited due to the novelty of these agents. We aimed to investigate the histological characteristics and evaluate SVR in patients who developed HCC in the context of DAA-treated HCV.
Method: We retrospectively evaluated 62 patients who underwent liver resection at Mount Sinai Hospital New York for HCV-related HCC, between November 2013 and June 2018 inclusive. The study was approved by the institutional review board. Demographic, clinical and pathological data were collected from our surgical specialty database and medical records where available. Data analysis was performed with Fisher's analysis using GraphPad.
Results: The mean age of our cohort was 65 years (range 49-78 years) and 75.8% [47/62] of these were male. The majority of patients had genotype 1 infection (67.7% [42/62]) and the most common HCV treatment amongst the 55 patients receiving DAA therapy was Ledipasvir/Sofosbuvir (53% [33/52]). The average MELD, platelet count, INR and AFP were 7, 197x10^9/L, 1 and 451 ng/dL respectively. The overall proportion of patients with stage 1, 2, 3, and 4 fibrosis by resection histology were 4%, 21%, 25% and 50% respectively (Fig 1A). The proportion of patients with grade 1 inflammation was significantly higher in patients with undetectable HCV at the time of resection compared to active HCV cases (53.9% [14/26] vs 13.9% [5/36], p = 0.0017) (Fig 1B). The overall SVR rate in DAA-treated patients was 85.5% [47/55]. Patients undergoing DAA treatment post-resection were significantly more likely to achieve SVR compared to those treated prior to resection (72.4% [21/29] vs 100.0% [26/26], p = 0.0048).
Conclusion: HCC continues to be a major complication in patients with HCV in the DAA era. In this study, we demonstrate that a subgroup of DAA-treated patients with minimal liver inflammation and/or liver fibrosis continue to be at risk for HCC. The mechanism behind this, although interesting, is unclear and deserves further investigation. We also show that patients treated with DAAs after HCC resection were more likely to achieve SVR than those treated prior to resection. Although more data is needed regarding the timing of HCC treatment, this supports recent data demonstrating that patients with active HCC are less likely to achieve SVR compared to patients with cured HCC.

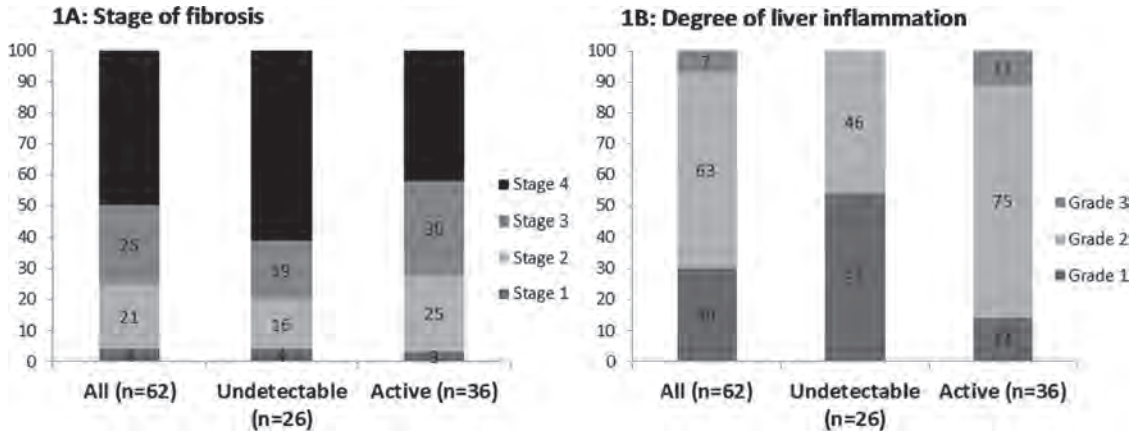


Figure 1: Stage of fibrosis & liver inflammation (Batts-Ludwig score) in cured HCV cases compared with active HCV cases at the time of liver resection.

Figure: (abstract: SAT-234)

SAT-235

Low HCV reinfection incidence following DAA treatment scale-up in people living with HIV in Australia

Samira Hosseini Hooshyar [1], Marianne Martinello[1,2,3], Jasmine Yee[1], Sofia Bartlett[1], Phillip Read[4], David Baker[5], Jeffrey Post[6], Robert Finlayson[7], Mark Bloch[8], Joseph Doyle[9], David Shaw[10], Margaret Hellard[9,11], Kathy Petoumenos[1], Pip Marks[1], Tanya Applegate[1], Gregory Dore[1,2], Gail Matthews[1,2]. *[1]The Kirby Institute, University of New South Wales (UNSW), Sydney, Australia; [2]St Vincent's Hospital, Sydney, Australia; [3]Blacktown Mt Druitt Hospital, Blacktown, Australia; [4]Kirketon Road Clinic, Sydney, Australia; [5]East Sydney Doctors, Sydney, Australia; [6]The Albion Centre, Sydney, Australia; [7]Taylor Square Private Clinic, Sydney, Australia; [8]Holdsworth House Medical Practice, Sydney, Australia; [9]Burnet Institute, Melbourne, Australia; [10]Royal Adelaide Hospital, Adelaide, Australia; [11]Alfred Hospital, Melbourne, Australia*
Email: shosseini@kirby.unsw.edu.au

Background and aims: Rapid uptake of direct-acting antiviral (DAA) therapy from 2016 in Australia, particularly among people living with HIV (PLWH), provides the opportunity to achieve HCV elimination. HCV reinfection could compromise HCV elimination efforts, especially if risk behavior increases.
Method: The Control and Elimination of HCV from HIV-infected individuals within Australia (CEASE-D) is an ongoing observational cohort study. HIV/HCV (antibody positive) co-infected individuals (≥ 18 years) were enrolled from 14 primary and tertiary clinics in Australia. Participants completed a questionnaire at enrolment (July 2014-March 2017) and first follow-up visit (June 2017-May 2018). We evaluated HCV reinfection incidence, and longitudinal injecting and sexual risk behaviour.
Results: Of 402 HIV/HCV antibody-positive participants (mean age 49 years, gay and bisexual male (GBM) 80%, cirrhosis 13%), 290 (72%) had detectable HCV RNA at enrolment. HCV treatment uptake among those with detectable HCV RNA was 7% in 2014, 10% in 2015, 80% in 2016, and 35% in 2017, and the proportion with detectable HCV RNA declined from 82% in 2014 to 8% in 2018. Reinfection was reported in five participants through follow-up (incidence 0.81 per 100 person years, 95% CI 0.34-1.94), all of whom identified as GBM. At baseline, injecting drug use (IDU) ever was reported by 79%, and current IDU (within six months) by 36%. Amphetamines (30%) were the most common drug injected. During follow-up there was no change in injecting risk, with 35% reporting current IDU (p = 0.715), and injecting frequency and sharing rates also stable. Among GBM, 53% reported condom-less anal intercourse (CLAI) with one or more casual male partners (CMP) and 34% reported group sex at enrolment, compared to 40% CLAI with CMP and 25% group sex at follow-up (p = 0.002 and p = 0.020 respectively). The proportion with detectable HCV RNA declined in all risk sub-populations, including those reporting current IDU (2014: 87%, 2018: 10%) and high risk sexual behavior (2014: 83%, 2018: 10%).
Conclusion: HCV reinfection following DAA therapy was very low, despite ongoing risk behaviour. The probable explanation is rapid and large HCV RNA decline, comparable DAA therapy uptake among high- and low-risk sub-populations, and no increase in injecting or sexual risk behaviour. HCV elimination should be achievable among PLWH in the near future.

SAT-236

Post-treatment fibrotic modifications overwhelm pretreatment liver fibrosis in predicting HCC in CHC patients with curative antivirals

Ming-Lung Yu[1], Chung-Feng Huang[1]. *[1]Kaohsiung Medical University Hospital, Kaohsiung Medical University, Hepatobiliary Division, Department of Internal Medicine, Kaohsiung City, Taiwan*
Email: fish6069@gmail.com

Background and aims: Liver fibrosis determined hepatocellular carcinoma (HCC) occurrence in chronic hepatitis C (CHC) patients with sustained virological response (SVR). We aimed to determine whether post-treatment fibrotic modification overwhelmed pre-treatment fibrotic status in terms of long-term HCC prediction.
Method: 265 SVR patients with paired biopsies before and after antiviral therapy were enrolled for analysis of the association of fibrotic changes with HCC.
Results: Eighteen of the 265 (6.8%) patients developed HCC over 1931 person-years. Cox regression analysis without post-treatment fibrosis as a covariant revealed that factors predicted HCC included age (hazard ratio [HR]/confidence intervals [CI]: 1.07/1.01-1.13, P = 0.01), male gender (HR/CI: 4.57/1.45-14.36, P = 0.009), diabetes (HR/CI: 3.60/1.32-9.85, P = 0.01) and pretreatment advanced fibrosis (HR/CI: 2.73/1.05-7.07, P = 0.039). Advanced fibrosis in post-treatment status replaced pretreatment fibrosis as the most critical determinant of HCC when it was included for analysis (HR/CI: 3.53/1.34-9.30, P = 0.01). The incidences of HCC among patients with fibrotic modification from F0-2 to F0-2, F34 to F0-2, F0-2 to F34 and F34 to F34 were 0.41%, 0.84%, 1.68% and 3.05%, respectively (p = 0.004). Compared to patients whose fibrotic stage remained at F0-2 before and after treatment, the HCC risk decreased and did not differ among those whose fibrotic stage improved from F34 to F0-2. However, HCC risk increased significantly and gradually in patients whose fibrotic stages changed from F0-2 to F34 (HR/CI: 4.13/1.11-15.36, P = 0.035) and

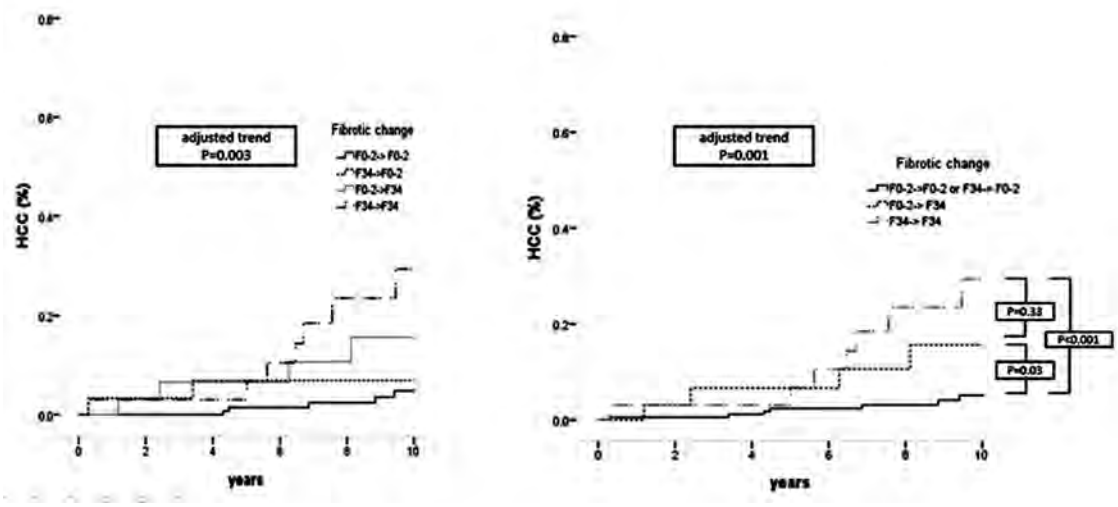

Figure: (abstract: SAT-236)

whose fibrotic stages remained at F34 before and after treatment (HR/CI: 7.47/2.37-23.55, P = 0.001) (trend P = 0.003).
Conclusion: Post-treatment fibrotic modifications overwhelmed pretreatment fibrotic statuses in predicting HCC.

SAT-237

Histological improvement of hepatitis C virus patients after achieving sustained virological response with direct-acting antivirals

Rui Huang[1], Huiying Rao[2], Lai Wei[2]. [1]*Peking University People's Hospital, Peking University Hepatology Institute, Peking University Health Science Center, Beijing, China;* [2]*Peking University People's Hospital, Peking University Hepatology Institute, Peking University Health Science Center, Beijing, China*
Email: weilai@pkuph.edu.cn

Background and aims: Liver biopsy findings after successful chronic hepatitis C virus (HCV) eradication with direct-acting antivirals (DAAs) has not been well stated. To this end, we collected liver biopsy samples of patients with chronic HCV infection who accepted successful antiviral therapy with DAAs.
Method: Patients with chronic HCV infection with sustained virological response (SVR) after treatment of DAAs were invited. Patients who had both pretreatment and follow-up liver biopsies were evaluated for histological changes. Biopsy slides were assessed by Ishak system. Histological improvement was defined as a

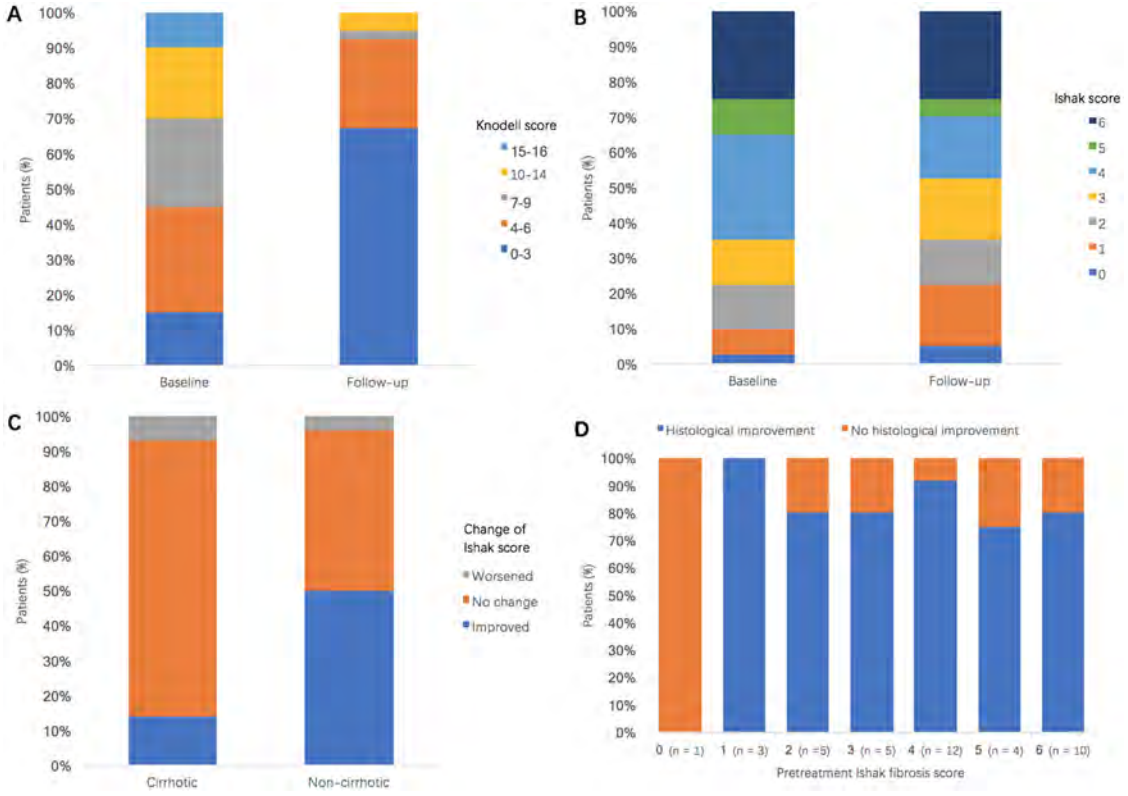

Figure: (abstract: SAT-237)

reduction in Knodell necroinflammation score of ≥ 2 points with no worsening of Knodell fibrosis after end of treatment (EOT). Regression of liver fibrosis was defined as a ≥ 1-point decrease in Ishak score.

Results: 40 patients with available paired liver samples were included into the analysis. Follow-up biopsies were obtained after an average of 6 months from EOT (range: 6-7 months). The mean age was 41.6 ± 14.6 years with 50% (20/40) males. 58% (23/40) patients were genotype 1 and 35% (14/40) patients were diagnosed as cirrhosis. Knodell score were judged as 10-14 and 15-16 in 20% (8/40) and 10% (4/40) patients, respectively. 83% (33/40) patients achieved improvement of HAI ≥ 2 (figure 1A. Distribution of Knodell necroinflammatory scores in 40 patients with results available at each time point, p = 0.000). Periportal interface hepatitis, confluent necrosis, focal lytic necrosis and focal inflammation and portal inflammation were evaluated in the modified HAI grading system. In 40% (16/40) patients the decrease in periportal hepatitis scores was two points or greater. The proportion with no confluent necrosis increased from 70% (28/40) at baseline to 95% (38/40) after EOT (p = 0.000). Respectively, 70% (28/40) and 25% (10/40) patients had a decrease or no change in focal lytic necrosis and focal inflammation score between baseline and follow-up biopsy (p = 0.000). 80% (32/40) patients had decreased portal inflammation scores between pretreatment and follow-up biopsy; 48% (19/40) patients had a decrease of two points or greater. 95% (38/40) patients' fibrosis staging improved or didn't worsen (figure 1B. Distribution of Ishak fibrosis scores in 40 patients with baseline and follow-up liver biopsies, p = 0.547). Overall, regression of liver fibrosis was documented in 38% (15/40) of patients. Change of Ishak scores according to cirrhotic status was shown in figure 1C (Change of Ishak score according to cirrhosis, p = 0.000). 85% (33/39) patients reached the criterion of histological improvement (figure 1D. Histological improvement according to pretreatment Ishak fibrosis score, p = 0.0000).

Conclusion: Significant histological improvement was seen in patients with chronic HCV infection after SVR with DAAs in this paired liver biopies analysis.

SAT-238

The impact of SVR from direct acting antiviral and interferon-based treatments for HCV on hepatocellular carcinoma risk in a large population based cohort

Naveed Janjua[1,2], Stanley Wong[1], Carmine Rossi[1,2], Maryam Darvishian[1,2], Amanda Yu[1], Zahid A Butt[1,2], Eric Yoshida[2], Alnoor Ramji[2], Jordan Feld[3], Mawuena Binka[1,2], Sofia Bartlett[1,2], Dr. Margo Pearce[1,2], Maria Alvarez[1], Hasina Samji[1], Mark Tyndall[1,2], Mel Krajden[1,2]. *[1]BC Centre for Disease Control, Vancouver, Canada; [2]The University of British Columbia, Vancouver, Canada; [3]Toronto General Hospital, University Health Network, Toronto Centre for Liver Disease, Toronto, Canada*
Email: naveed.janjua@bccdc.ca

Background and aims: We evaluated the effect of sustained virologic response (SVR) from direct acting antiviral (DAA) and interferon-based treatments on hepatocellular carcinoma (HCC) risk among those with and without cirrhosis in a large population based cohort in Canada.

Method: We used data from the BC Hepatitis Testers Cohort, which includes ~1.3 million individuals tested for HCV since 1990, linked with data on medical visits, hospitalizations, cancers prescription drugs and mortality. Patients who received DAAs or interferon treatments were followed from the end of treatment to HCC, death or December 31, 2016. We assessed HCC risk among those who did and did not achieve SVR by treatment type using multivariable competing risk proportional hazard models.

Results: Of 12, 776 eligible individuals, 3, 905 received DAAs while 8, 871 received interferon-based treatments and were followed for a median of 1.0[range:0.6-2.7] and 7.9[range:4.4-17.1] years, respectively. 3613 and 6575 achieved SVR with DAAs and interferon based treatments, respectively. Among DAAs treated patients 36 HCC cases were identified, 26 in SVR group. The HCC incidence rate was 6.9 (95%CI: 4.7-10.1)/1000 person-yr (PY) in the SVR and 38.2 (95% CI:20.6-71.0) in the no-SVR group (p < 0.001), with higher rates among those with cirrhosis (SVR: 20.7, no-SVR: 133.5). Among those treated with interferon-based treatments, 340 cases of HCC were identified, 99 in SVR group. HCC incidence rate was 1.8 (95%CI: 1.5-2.2) in the SVR and 13.9 (95%CI: 12.3-15.8) in the no-SVR group (p < 0.001). There was steepest increase in cumulative incidence in those with cirrhosis/no-SVR followed by those with SVR/cirrhosis and no-SVR/no-cirrhosis while increase in incidence among SVR/no-cirrhosis group was a slower and lower (**Figure**). In multivariable model, compared to no-SVR from interferon, SVR from DAA and interferon based treatments resulted in significant reduction in HCC risk (adjusted subdistribution hazard ratio (asHR) DAA = 0.30, 95% CI:0.19-0.48 and asHR interferon = 0.2, 95%CI:0.16-0.26). In model by cirrhosis status, higher reduction in HCC risk was observed among those without cirrhosis (DAA-asHR = 0.28, 95%CI:0.16-0.50/ Interferon-asHR = 0.17, 95%CI:0.13-0.22) compared to those with cirrhosis (DAA-asHR = 0.40, 95%CI: 0.19-0.87/interferon-asHR = 0.56, 95%CI:0.34-0.91).

Conclusion: DAA-related SVR is associated with in 70% reduction in HCC risk. Reduction was lower in those with cirrhosis and among those treated with DAA, related with poor comorbidity profile at treatment. These findings indicate early treatment could further reduce HCC risk.

SAT-239

Real life data on elbasvir/grazoprevir efficacy, safety and drug-drug interaction profile in patients with chronic hepatitis C viral infection: A prospective analysis in the PITER cohort

Maria Giovanna Quaranta[1], Stefano Rosato[1], Luigina Ferrigno[1], Daniela Caterina Amoruso[2], Monica Monti[3], Paola Di Stefano[4], Roberto Filomia[5], Fiammetta Tamburini[6], Guglielmo Migliorino[7], Alberto Zanetto[8], Elisabetta Degasperi[9], Luisa Cavalletto[10], Giuseppina Brancaccio[11], Pierluigi Blanc[12], Marco Cannizzaro[13], Castelli Eleonora[10], Giulia Morsica[14], Anna Licata[15], Loreta Kondili[1]. *[1]Istituto Superiore di Sanità, Rome, Italy; [2]Gragnano Hospital, Gragnano (Napoli), Italy; [3]Interdepartmental Centre MASVE, University of Florence, Florence, Italy; [4]Spirito Santo General Hospital, Pescara, Pescara, Italy; [5]University Hospital of Messina, Messina, Italy; [6]Umberto I Hospital-"Sapienza" University, Rome, Italy; [7]San Gerardo Hospital, Monza, Italy; [8]University of Padua, Padua, Italy; [9]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Università degli Studi di Milano, Milan, Italy; [10]University Hospital of Padua, Padua, Italy; [11]Second University of Naples, Naples, Italy; [12]S.M. Annunziata Hospital, Florence, Italy; [13]Villa Sofia-Cervello Hospital, Palermo, Italy; [14]San Raffaele Hospital, Milan, Italy; [15]University Hospital P. Giaccone, Palermo, Italy*
Email: loreta.kondili@iss.it

Background and aims: In a previous real life study, based on data retrieved by the PITER cohort, it was reported that of HCV chronic infected patients, undergoing direct acting antiviral (DAA) therapy (sofosbuvir-based or paritaprevir/ritonavir, ombitasvir and dasabuvir) and taking comedications, 30% (with mild liver disease stage) and 44% (with moderate to severe liver disease stage), are at risk of potential drug-drug interactions (DDI).

Following the recent introduction of elbasvir/grazoprevir (EBR/GZR) we aimed to evaluate the prospective profile of efficacy and safety combined with real life comedication profile used at the beginning, during and at the end of the DAA therapy in each of treated patient.

Method: Data from patients, who were consecutively enrolled in PITER by 15 clinical centers and were treated with EBR/GZR, with at least three months of follow-up after the end-of-treatment, were evaluated. Comedications profile in terms of no changes, drugs interrupted, or modified as posology, or those added were evaluated and their potential DDI were assigned according to HepC Drug

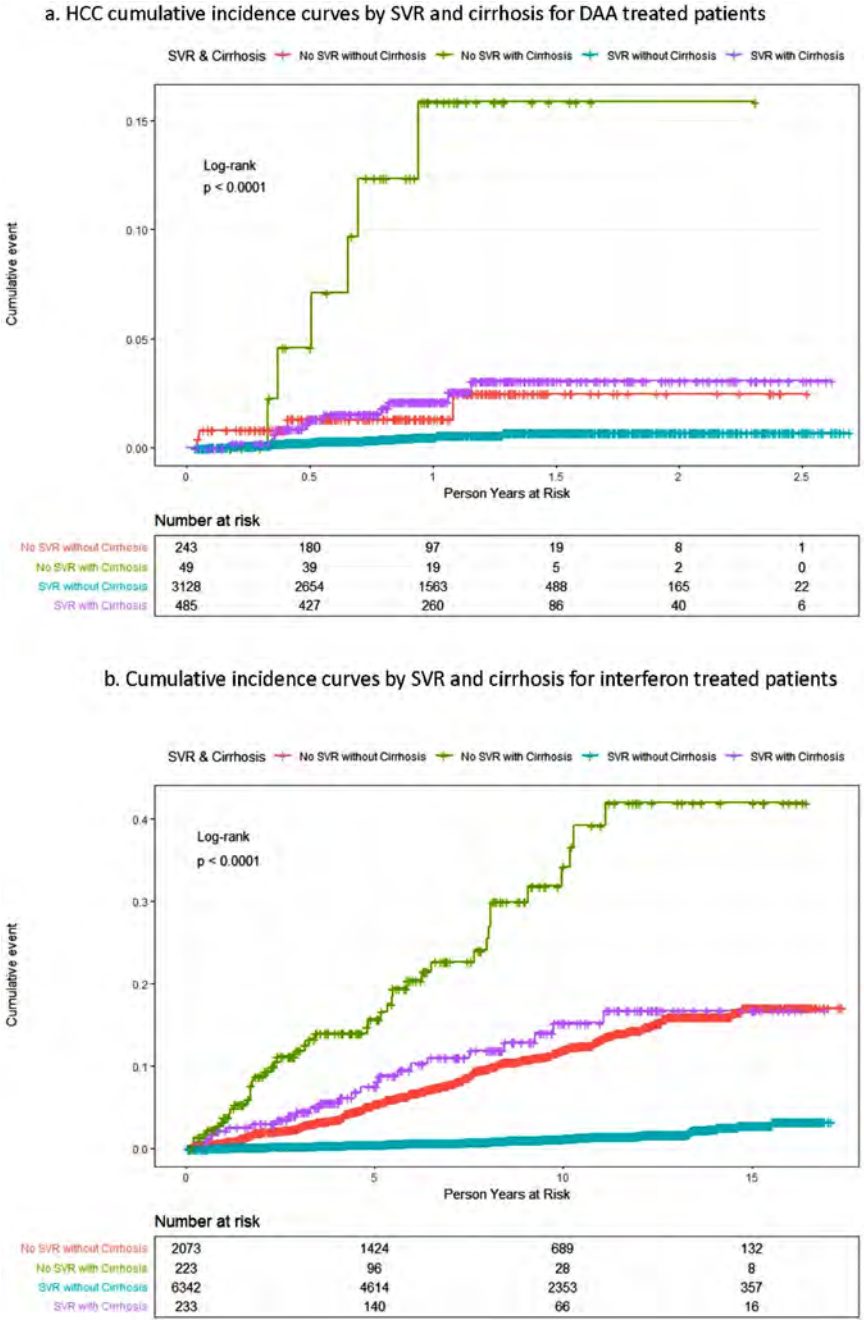

Figure: (abstract: SAT-238) HCC cumulative incidence curves by SVR and cirrhosis status

Interactions (www.hep-druginteractions.org). Overall, 312 patients with at least 12 weeks response following the end of treatment (mean age 63 ± 10 years; 44% male, 90% of genotype 1 of whom 81% HCV GT1b, 85% with Fibrosis stage ≤ F3 and 15% with child A liver cirrhosis) were evaluated.

Results: The 12 weeks Sustained Virological Response (SVR12) was reached in 299 (96%), 13 (4%) of patients failed to reach the SVR12. Gender, age, fibrosis stage, previous interferon therapy, presence of diabetes and fatty liver were not related to failure by logistic regression analysis. Of 312 treated patients, 187 (60%) had at least one comobidity (median: 2 range: 1-6 comorbidities). Follow-up data on comedications used pre, during and at the end of EBR/GZR treatment were available in 182 patients. Of these patients, 21% have taken 1 drug, 24% two drugs, 17% three drugs and the remaining 38% from 5 to 10 drugs. Of 328 comedications used during the DAA therapy, 3% were modified in posology, 2% were interrupted and 3% were new drugs added. None of changes was due to potential DDI. None but statins (in 2% of patients) were reported to require monitoring by HepC Drug Interactions. However, no changes were recorded for the statins, which were used at the lowest dosage recommended during the DAA therapy. Regarding the safety profile, EBR/GZR was well tolerated. An increase in ALT levels were observed in 12 (4%) of treated patients during therapy (with values lower than 2 times of normal levels in 6 patients and lower than 3 times of normal in the remaining 6), all in patients with fibrosis stage lower than F3.

Conclusion: EBR/GZR demonstrated high cure rates and a very good safety profile. No drug-drug interactions were recorded in this real

life cohort of treated patients with different comorbidities and comedications used.

SAT-240

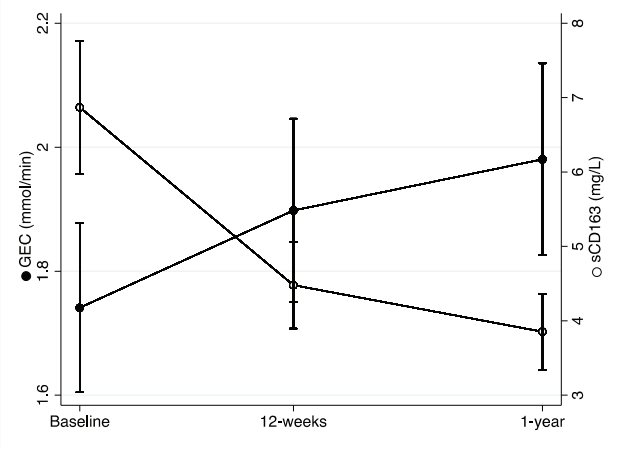
Metabolic liver function improves 12 weeks after successful sofosbuvir-based direct-acting antiviral therapy in patients with chronic hepatitis C and advanced liver disease

Tea Lund Laursen[1], Cecilie Brøckner Siggard[1], Konstantin Kazankov[1], Thomas Damgaard Sandahl[1], Holger Jon Møller[2], Lena Hagelskjær Kristensen[3], Britta Tarp[4], Alex Laursen[5], Henning Grønbæk[1]. *[1]Aarhus University Hospital, Hepatology and Gastroenterology, Aarhus N, Denmark; [2]Aarhus University Hospital, Clinical Biochemistry, Aarhus N, Denmark; [3]Viborg Regional Hospital, Department of Medicine, Viborg, Denmark; [4]Silkeborg Regional Hospital, Diagnostic Centre, Silkeborg, Denmark; [5]Aarhus University Hospital, Infectious Diseases, Aarhus N, Denmark*
Email: tealaurs@rm.dk

Background and aims: Sofosbuvir-based direct-acting antiviral (DAA)-therapy is very efficient in clearing chronic hepatitis C (CHC) infections, however, the effects on metabolic liver function and the potential rate of recovery are unknown. We aimed to investigate the effects of DAAs on metabolic liver function, macrophage activation, liver stiffness, and continuous reaction time (CRT) in CHC patients with advanced liver disease.

Method: We investigated 71 Danish CHC patients with advanced liver disease (TE > 10kPa) before, during, and after 12-24 weeks of sofosbuvir-based DAA-therapy. Metabolic liver function was estimated by galactose elimination capacity (GEC), macrophage activation by plasma sCD163 and sMR levels (ELISA), liver stiffness by FibroScan or acoustic radiation force impulse (ARFI)-scans, and reaction time as CRT.

Results: All patients achieved sustained virologic response, except one patient with reinfection. Metabolic liver function improved at follow-up (all: 1.74 vs. 1.98 mmol/min) both in patients with cirrhosis ($n = 56$) and those with advanced liver disease ($n = 15$) ($p < 0.0005$). The majority of this effect occurred within 12 weeks post-treatment. The sCD163 and sMR levels decreased rapidly during the study period (sCD163: 6.9 vs. 3.9; sMR: 0.37 vs. 0.30 mg/L) as did liver stiffness (17.8 vs. 12.1 kPa) ($p < 0.0001$, all). The CRT improved at one-year follow-up (1.86 vs. 2.09, $p = 0.05$). sCD163 levels correlated with GEC and liver stiffness at baseline; however, there were no associations between changes in sCD163 or sMR and changes in GEC or liver stiffness during follow-up.



Conclusion: Successful DAA-therapy of CHC proves beneficial in advanced liver disease as metabolic liver function rapidly improves in combination with reduced macrophage activation and liver stiffness.

SAT-241

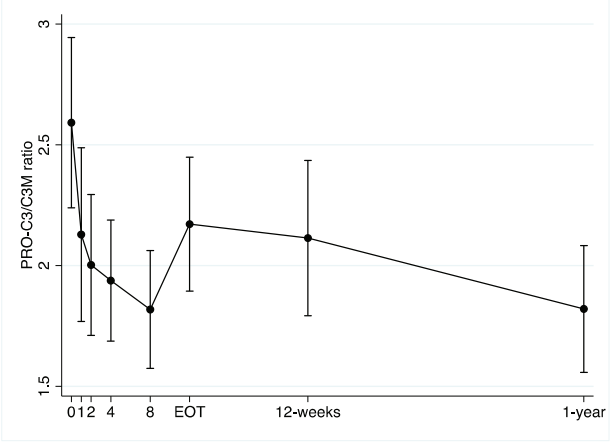
The dynamics of two plasma markers of type III collagen formation and degradation in the course of chronic hepatitis C viral clearance with direct-acting antiviral therapy

Tea Lund Laursen[1], Ida Villesen[2], Diana Leeming[2], Morten Karsdal[2], Natasja Gudmann[2], Henning Grønbæk[1]. *[1]Aarhus University Hospital, Hepatology and Gastroenterology, Aarhus N, Denmark; [2]Nordic Bioscience, Herlev, Denmark*
Email: tealaurs@rm.dk

Background and aims: In chronic hepatitis C (CHC) fibrosis and cirrhosis, imbalanced extracellular matrix (ECM) turnover is prominent. ECM turnover generates protein fragments, which reflect liver fibrosis. PRO-C3 is a neo-epitope reflecting type III collagen formation, whereas C3M is a marker of matrix metalloproteinase-9 mediated degradation of type III collagen. It is unknown how ECM turnover is affected after viral clearance with direct-acting antiviral (DAA) therapy. We aimed to assess the dynamics of PRO-C3 and C3M with DAA-therapy in CHC patients with advanced liver disease.

Method: PRO-C3 and C3M were assessed in plasma by competitive ELISAs before, during, and after 12-24 weeks of DAA-therapy in 77 Danish CHC patients; 14 with advanced liver disease (F3) and 63 with cirrhosis. Liver stiffness was evaluated at baseline, end of treatment (EOT), and 12-weeks and one-year post-treatment using FibroScan or acoustic radiation force impulse scans.

Results: At baseline, the level of PRO-C3 was 24.0 ng/ml (95% CI: 21.2-26.8) and it decreased with 22% ((11-32), $p < 0.0001$) during treatment. There was an additional decrease of 16% ((4-27), $p = 0.01$) at follow-up with the PRO-C3 level ending up at 15.6 (13.6-17.5) one-year post-treatment. The PRO-C3 level was not significantly increased in the patients with cirrhosis compared with the patients with advanced liver disease ($p = 0.15$), however PRO-C3 correlated with liver stiffness at baseline, and 12-weeks and one-year post-treatment ($r > 0.39$, $p < 0.02$). The C3M level was 9.3 ng/ml (8.6-10.0) at baseline and the decrease over time was more discrete. The level decreased with 6% ((2-10), $p = 0.001$) from baseline to end of treatment ending at 8.5 (7.8-9.2) at one-year follow-up. The decrease over time was similar for cirrhosis patients and patients with advanced liver disease and the cirrhosis patients had 20% ((1-46), $p = 0.04$) higher C3M levels at all time points. Additionally, C3M correlated with liver stiffness at baseline, at the end of treatment and one-year post-treatment ($r > 0.33$, $p < 0.006$).



Conclusion: PRO-C3 and C3M, two markers of type III collagen formation and degradation, decrease during and after DAA-therapy in CHC patients with advanced liver disease and are associated with liver stiffness at baseline and during follow-up. These results indicate an altered balance between collagen formation and degradation after viral clearance suggesting a potential favourable effect on liver fibrosis.

SAT-242

Liver stiffness measurement is not a predictive factor of HCC in HCV patients with severe fibrosis who achieved SVR by DAA

Aline Le Cleach[1], Violaine Ozenne[2], Marie Lequoy[2], nicolas Carbonell[2], Tony Andreani[2], Sara Lemoinne[2], Armelle Poujol-Robert[2], Christophe Corpechot[2], Olivier Chazouillères[2]. [1]*Saint Antoine Hospital, Hepatology, Paris, France;* [2]*Saint Antoine Hospital, Paris, France*
Email: aline.lecleach@aphp.fr

Background and aims: Hepatitis C virus (HCV) infection is a leading cause of cirrhosis and hepatocellular carcinoma (HCC) worldwide. New direct acting antivirals (DAA) have strongly modified the natural course of HCV. Yet, risk of HCC remains even after sustained virologic response (SVR), specially among patients with pretreatment severe fibrosis. As transient elastography (TE) is one of the leading non-invasive tool to assess liver fibrosis, our aim was to determine whether changes in liver stiffness measurement (LSM) of patients achieving SVR with DAA can help to identify patients at high-risk of HCC.
Method: We reviewed all patients treated for an HCV infection in Saint-Antoine Hospital, Paris, France between November 2013 and January 2018. Inclusion criteria were 1) no prior history of HCC, 2) pretreatment severe fibrosis or cirrhosis, as defined based on liver biopsy, reliable results of LSM (F3 ≥ 9 kPa, F4 ≥ 12 kPa) or on clinical, biochemical and radiologic features of cirrhosis, 3) SVR achievement as defined by undetectable HCV RNA 3 months after the end of treatment (EOT) with DAA only, 4) at least one ultrasound imaging after EOT. Exclusion criteria were HIV infection or any other hepatic comorbidities excepted for excessive alcohol intake and metabolic syndrome. The factors associated with HCC risk were studied using a logistic regression analysis.
Results: A total of 177 patients with severe fibrosis were included (61% male, median age 60 yrs, cirrhosis 65%, median follow-up 2.5 yrs). Pre-treatment, post-treatment, and pre- and post-treatment values of LSM were available in 159, 129 and 111 patients, respectively. There was a significant decrease in LSM with a median of 14.1 kPa in pre-treatment and 10 kPa in post treatment ($p < 0.001$). Seven HCC (4%) occurred in a median time of 2.45 years (range, 1 yr-3, 3 yrs) from EOT. These patients (median age 57 yrs, 100% male) had a median pretreatment value of LSM of 24.8 kPa (range, 12.9 kPa-30.4 kPa). In logistic regression analysis, neither pre- or post-treatment values of LSM, nor its absolute or relative changes after treatment were associated with HCC risk.
Conclusion: In this single center, retrospective study including HCV patients with severe fibrosis who achieved SVR after DAA treatment, pre- and post-treatment values, as well as individual changes of LSM were not predictive of HCC occurrence, suggesting that selection of patients for HCC surveillance program in this specific population should not be based on LSM.

SAT-243

Ledipasvir/sofosbuvir is highly effective and safe in patients with chronic hepatitis B virus and hepatitis C virus coinfection: Final study results

Email: vithika.suri@gilead.com

Background and aims: Patients coinfected with hepatitis C virus (HCV) and hepatitis B virus (HBV) have more rapid liver disease progression and worse outcomes than patients monoinfected with either HBV or HCV. Cases of HBV reactivation during HCV treatment have been reported in the IFN era and with direct acting antivirals (DAAs). This study evaluated the safety and efficacy of an all-oral treatment with ledipasvir (LDV)/sofosbuvir (SOF) for 12 weeks in patients with chronic HCV and HBV coinfection. Here we present the final study results through follow-up week 108.
Method: 111 patients chronically infected with HCV genotype (GT) 1 or GT2 and HBV (positive for serum HBsAg) were enrolled into this open-label study to receive LDV 90 mg/SOF 400 mg (once daily) for 12 weeks. Following treatment, patients were monitored for safety (HBV DNA reactivation) and efficacy for a total of 108 weeks. HBV DNA reactivation is defined as a post-baseline increase from baseline to ≥ LLOQ or > 1 log10 IU/ml in patients that were < LLOQ or ≥ LLOQ at baseline, respectively.
Results: Baseline characteristics included: mean age 55 years, 62% female, 67% treatment naive, 84% without cirrhosis, 61% GT1, and HBeAg negative (99%) with a mean baseline HBV DNA of 2.1 log10 IU/ml. SVR12 was 100% and through week 96 of post treatment follow-up; there were no viral relapses. HBV DNA reactivation occurred in 73% of patients; 12% of whom also had a corresponding ALT increase > 2x ULN. To date, 8 patients have started HBV therapy per Taiwanese treatment guidelines. The majority (86%) of HBV reactivations occurred by post treatment week 12, followed by an additional 11% by the end of Year 1 and 3% by the end of Year 2. 90% of HBV reactivations were asymptomatic with no patient developing clinical symptoms. Through 96 weeks of follow-up, 19 patients had serious adverse events (AEs), 1 patient withdrew consent, and 2 patients died; none were considered drug related. The most common AEs reported (≥ 5% of patients) were headache, fatigue, upper respiratory infection, dizziness, malaise, nephrolithiasis, myalgia and HBV reactivation. Full data through follow-up week108 for all patients will be provided.
Conclusion: In patients with chronic HCV/HBV infection, LDV/SOF for 12 weeks resulted in an SVR12 rate of 100%. Although most patients had an increase in HBV DNA, only 8 patients started HBV therapy. LDV/SOF treatment remains a highly effective, safe and tolerable regimen in patients with HCV/HBV coinfection.

SAT-244

Mixed cryoglobulinemia patients with persisting symptoms after SVR are characterized by B-cell clonality markers

Serena Lorini[1], Laura Gragnani[1], Veronica Santarlasci[1], Monica Monti[1], Umberto Basile[2], Luisa Petraccia[1], Francesco Madia[1], Silvia Marri[1], Lorenzo Martini[1], Eleonora Carradori[1], Adela Xheka[1], Patrizio Caini[1], Adriano Pellicelli[3], Lorenzo Cosmi[1], Francesco Annunziato[1], Anna Linda Zignego[1]. [1]*University of Florence, Department of Clinical and Experimental Medicine, Florence, Italy;* [2]*Catholic University of the Sacred Heart, Rome, Italy;* [3]*Azienda Ospedaliera San Camillo Forlanini, Rome, Italy*
Email: a.zignego@dmi.unifi.it

Background and aims: MC is a HCV-related lymphoproliferative disorder. HCV eradication using IFN-free DAA therapy can improve or heal MC. However, persistence or relapse of the syndrome may be observed in SVR patients. This may be due to the overcoming of point of no-return in the lymphomagenesis cascade with persisting B-cell

clonal expansion or to different, non evolving conditions (e.g. the occurrence of irreversible organ/tissue damage). Consequently, it is conceivable that the evaluation of B-cell clonal expansion may greatly help with a correct clinical, prognostic and therapeutic approach.
Method: We prospectively evaluated consecutive HCV patients treated with DAAs and the following features: Group A: SVR MC patients with complete clinical response; Group B: SVR MC patients maintaining symptoms. B-cell clonal expansion was evaluated by: flow cytometry, Free Light Chains ratio (κ/λ) and t (14;18).
Results: We evaluated 98 patients: 56 group A and 42 group B (mean FU 17 months, range: 3-36). At least one clonality marker was detected in 30/42 (71%) patients with persisting symptoms, including five patients with lymphoma in hematological remission after DAAs. Three patients had systemic symptoms (e.g. itchiness, nocturnal sweating) suggestive of the LPD evolution. Patients negative for B-cell clonality, were generally characterized by persisting arthralgia, sicca syndrome, and neuropathy. κ/λ ratio was altered in 48% of cases, flow cytometry in 16% and t (14;18) in 39%. In 24% of cases more than one marker was detected.
Conclusion: Previous studies showed the association between MC and B-cell clonal expansion. In this study, the detection of B-cell clonality markers was associated with persisting symptoms of MC and with more severe pre-therapy disease, including patients with lymphoma in remission. This suggests the hypothesis of having gone beyond the LPD point of no-return and the rationale for specific treatment (e.g. rituximab). Furthermore, this study strongly suggests that the κ/λ ratio may be a very useful and easy clonality marker in MC patients with persisting symptoms.

SAT-245

Prospective evaluation of the impact of hepatitis C cure on sexual dysfunction

Zoe Mariño[1], Sergio Rodriguez-Tajes[1], Sabela Lens[1], Concepció Bartres[1], Loreto Nacar[2], Anna Pla[1], Anna Miralpeix[1], Mónica Gonzalez[3], Joaquim Sarquella[3], Lydia Sastre[1], Ricard Navinés[2], Rocío Martin-Santos[2], Xavier Forns[1]. *[1]Liver Unit, Hospital Clínic Barcelona, Universitat de Barcelona, IDIBAPS, CIBEREHD, Barcelona, Spain; [2]Psychiatry and Psycology Department, Hospital Clinic Barcelona, UB, IDIBAPS, Centro de Investigación Biomédica en Red de salud mental (CIBERSAM), Barcelona, Spain; [3]Andrology Department, Fundació Puigvert, Barcelona, Spain*
Email: xforns@clinic.cat

Background and aims: Hepatitis C virus (HCV) infected patients have a high rate of sexual dysfuntion (SD). Current antiviral therapies with direct acting antivirals (DAA) improve quality of life in cured patients, but there are very few data analyizing changes in sexuality after cure.
Method: Prospective inclusion of patients receiving DAA (April-Dec 2017) recording clinical and demographic variables. Self-reported sexuality was obtained at baseline (BL) pre-DAA and 48 weeks after DAA (FU48) by means of: 1)Changes in Sexual Functioning Questionnaire (CSFQ-14) for assessing SD (< 47 males; < 41 women), comprising dimensions of excitation/orgasme and desire; 2)CSFQ-VAS (analogical scale ranging 0-100 in sexuality); 3)PHQ9 test (assessing major depression[MD] if PHQ9 ≥ 10). Patients were also asked about the fear to transmit HCV to their partner/s and HCV-related limitations in their sexual lifes. Results were expressed in median/IQR (25-75) and n (%), as appropriate. Paired samples were analyzed by means of McNemar and T-tests.
Results: 83% of patients starting DAA in the study period accepted to participate (n = 186); preliminary data of 90 patients cured with DAA and available BL-FU48 data are reported. Median age was 55 (49-61) years; 59% men; 83.1% F0-2. Up to 64.7% of cases presented SD: 58% men and 74% women. Median BL CSFQ-VAS was 50 (20-67.5). 27% of patients reported fear for HCV sexual transmission and 21.1% of cases were limited in their sexual behaviours. At follow-up [43 (37-50) weeks], a significant improvement was observed in the self reported evaluation of sexuality [FU48 CSFQ-VAS 60 (40-80), p < 0.01], together with a significant improvement in CSFQ-14 score (p = 0.03). The latter was explained by improvements in sexual excitation (p = 0.018) and orgasm (p = 0.04).Nevertheless, the overall SD prevalence was not significantly reduced (64.7% vs 53.8%, p = 0.11). SD persistence in FU48 was independently associated with age (OR 1.13 [1.05-1.2], p = 0.001), and major depression coexistance (OR 0.15 [0.04-0.59], p = 0.007)
Conclusion: Sexual dysfuncion is highly prevalent among patients infected with HCV. HCV elimination after treatment was associated with a significant improvement in specific sexual domains (excitation and orgasm). Nevertheless, the prevalence of sexual dysfunction remained high and was independently associated with age and major depression.

SAT-246

Overall survival and incidence of liver-related events in a cohort of cirrhotic patients treated with direct antiviral agents: Results from a multicenter study

Chiara Masetti[1], Massimo Marignani[2], Raffaella Lionetti[3], Umberto Vespasiani Gentilucci[4], Francesco Santopaolo[1], Martina Milana[1], Paola Begini[2], Chiara Taibi[3], Ubaldo Visco Comandini[3], Giovanni Galati[4], Giampiero D'offizi[3], Angelico Mario[1]. *[1]Tor Vergata University Hospital, Liver and Transplant Unit, Rome, Italy; [2]Sant'Andrea University Hospital, Digestive and Liver Disease Unit, Rome, Italy; [3]Lazzaro Spallanzani Hospital, Infectious Disease and Hepatology Unit, Rome, Italy; [4]University Campus Biomedico, Internal Medicine and Hepatology Unit, Rome, Italy*
Email: chiara.masetti12@gmail.com

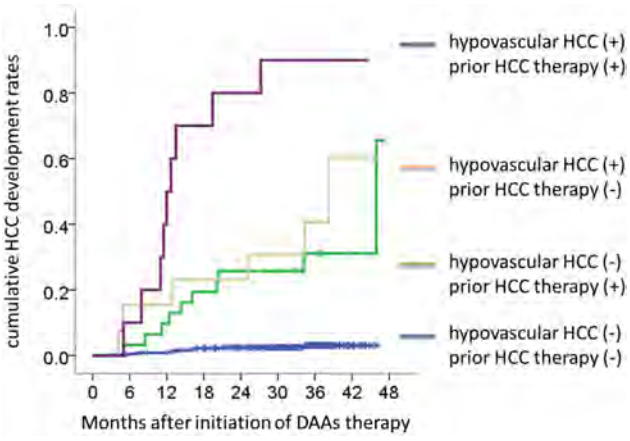
Background and aims: Introduction of direct-acting antiviral agents represented a revolution in HCV management, allowing treatment also in patients with advanced liver disease. Little is known about the long-term effects of antiviral therapy on disease progression, liver-related complications and survival. Aim of our study was to investigate the onset of clinical events and the long-term effects of treatment on surrogate markers of fibrosis and portal hypertension in a large cohort of cirrhotic patients treated at four third-level hospitals in Rome.
Method: The cohort included 352 patients treated with DAA with a median follow-up of 28.5 months from the end-of-treatment. Most patients were males (217/352, 61.6%), with compensated cirrhosis (CPT A 85.4%, MELD score 9.1 ± 3.0) and without clinically significant portal hypertension (61.9%); median age was 63.6 years and genotype 1b was the most frequent (41.5%); 57.5% of patients were naive to previous antiviral treatments. APRI and FIB-4 scores were calculated and paired Student T-test was used to compare markers of advanced disease at baseline and after treatment.
Results: Overall SVR12 was 94.3%, being significantly higher in patients with compensated than decompensated cirrhosis (97.6% vs 76%, p 0.000001). Both APRI and FIB-4 scores significantly decreased after treatment (p = 0.0002 and 0.0003, respectively). During follow-up 42 patients (11.9%) died, 16 underwent liver transplant (4.5%). Cause of death was liver-related in 25 patients (59.5%) and due to extrahepatic diseases in 17 (40.5%), resulting in a liver-related mortality rate of 3%/yr (0.9% for HCC). In the surviving 310 patients, 62 liver-related events were recorded (20%), the most frequent being *de-novo*/recurrent HCC (35, 56.4%), followed by ascites (9, 14.5%), and variceal bleeding (10, 16.1%). The annual incidence were 3.2% and 1.6% for *de-novo* and recurrent HCC respectively, and 3.7% for other liver-related events. At logistic regression analysis, platelet count, clinically significant portal hypertension and a previous history of HCC were independent predictors of liver-related events development.
Conclusion: Despite the high SVR rates and the related improvement of surrogate markers of fibrosis observed after DAA treatment, patients with cirrhosis remain at risk of developing major liver-related complications, thus requiring strict surveillance during the follow-up. HCC still represents the most frequent liver-related event.

SAT-247

The evaluation of the inhibitory effect of oral anti-hepatitis C virus agents on carcinogenesis

Seiichi Mawatari[1], Akihiro Moriuchi[1], Shuzo Tashima[1], Ai Kasai[1], Sho Ijuin[1], Kazuaki Tabu[1], Kohei Oda[1], Akio Ido[1]. [1]*Kagoshima University Graduate School of Medical and Dental Sciences, Digestive and Lifestyle Diseases, Kagoshima, Japan*
Email: mawatari@m2.kufm.kagoshima-u.ac.jp

Background and aims: Hepatocellular carcinoma (HCC) occurs as a result of hepatic inflammation and/or changes in the tumor microenvironment. Direct-acting antivirals (DAAs) against hepatitis C virus (HCV) exert high anti-HCV activity and are expected to show anti-inflammatory effects associated with HCV elimination. Furthermore, HCC is known to dedifferentiate from hypovascular tumors, such as dysplastic nodules or well-differentiated HCC, to hypervascular tumors. However, whether or not DAAs prevent carcinogenesis is unclear. We therefore examined whether or not DAAs can suppress the growth and hypervascularization of hypovascular tumors.
Method: Patients with HCV genotype 1 infection were treated with Daclatasvir and Asunaprevir therapy. Hypovascular tumors were diagnosed by contrast-enhanced magnetic resonance imaging or computed tomography before therapy. We analyzed the cumulative incidence of HCC, i.e. the growth or hypervascularization of hypovascular tumors, and compared the findings by the presence of hypovascular tumors.
Results: We enrolled 478 patients, 25 of whom had hypovascular tumors. Forty-eight patients had a history of HCC therapy, and 10 of them (20.8%) had hypovascular tumors. The mean size of hypovascular tumors was 11 mm. The sustained virologic response (SVR) rate was 87.7%. Forty-one patients (8.6%) developed HCC, including 16 of the 25 with hypovascular tumors (64.0%). Among the patients who achieved SVR without prior HCC therapy, the respective cumulative HCC development rates of patients with and without hypovascular tumors were 15.4% and 1.1% per year, 23.1% and 2.5% per 2 years, and 40.7% and 3.1% per 3 years. In contrast, among patients with a history of curative HCC therapy, the respective cumulative HCC development rates in those with and without hypovascular tumors were 40.0% and 9.7% per year, 80.0% and 25.8% per 2 years, and 90.0% and 31.1% per 3 years. A Cox proportional-hazards analysis showed that the history of HCC therapy (hazard ratio: 9.629, 95% confidence interval: 4.334-21.392), presence of hypovascular tumor (7.343, 3.311-16.287), alpha-fetoprotein level at SVR judgment (1.015, 1.009-1.022), and baseline albumin level (0.324, 0.126-0.834) were independent risk factors for developing HCC.



Conclusion: Hypovascular tumors developed into HCC at a high rate despite the elimination of HCV by DAAs. We should confirm the presence of hypovascular tumor before starting DAA treatment.

SAT-248

Patients treated for HCV and listed for LT in a French multicenter study: What happens at 3 years?

Email: lucymeunier66@gmail.com

Background and aims: Combinations of DAA have shown excellent results to treat HCV-infection in cirrhotic patient but some issues remain unresolved regarding efficacy in patients awaiting liver transplantation (LT) and impact on access to LT. Our aim is to study the impact of HCV treatment on hepatic function, delisting and outcomes of patients listed for HCC or decompensated cirrhosis.
Method: This is an observational, multicenter, and retrospective analysis from 18 LT centers in France, of patients treated for HCV and listed for LT. Complete clinical and biological response (CBR) to HCV treatment was defined by bilirubinemia < 35 μmol/l, Tp > 50% and absence of ascites or hepatic encephalopathy, partial response by change of Child score class and no response by stability or aggravation.
Results: 183 HCV-positive patients who received antiviral therapy with an IFN-free regimen while awaiting LT between November 2013 and June 2015 were enrolled in this study. The mean follow-up since the end of treatment was 39.6 months (± 1.5). The LT indication was HCC in 106 (58%) patients and decompensated cirrhosis in 77 (42%) patients. Most of the patients were male (145, (79%)) with a median age of 59 years-old (± 2.2). Comorbidities were also collected: diabetes (49, (27%)), alcohol consumption (39, 21%), arterial hypertension (45, (25%)) and dyslipidemia (8, (4%)). Majority of patients were genotype 1 (104, (57%)) treated with DAA plus ribavirin for 99 patients. SVR rate was 83%. At baseline, mean MELD was 12 (6-32) and mean Child B9 for patients listed for decompensated cirrhosis. Among these patients, 10 (16%), 22 (35%) and 31 (49%) had respectively a CBR complete, partial and no response. 40 patients (52%) with decompensated cirrhosis were transplanted, 36 are alive. 37 patients (48%) were not transplanted: 6 are inactive and 26 were delisted (21 for improvement) and 4 developed HCC during the follow-up. Among patients listed for HCC, 80 (75%) were transplanted, 73 are alive. Only 8 patients (7.5%) have been delisted for HCC progression. No case of HCC recurrence has been reported. Predictive factors of delisting will be presented at the meeting.
Conclusion: HCV-treatment in patients awaiting LT allows delisting for improvement in 27% (21/77) of cases. After treatment only 7.5% (8/106) of HCC-patients were delisted for drop out. We did not collect any HCC recurrence post-LT.

SAT-249

Increased cardiovascular risk associated with chronic hepatitis C infection still remains at SVR24

Ann Monaghan[1], Megan Kennedy[1], Philip O'gorman[1], Hynes Barbara[2], Clodagh Quinn[2], Sara Naimimohasses[2], Susan Mckiernan[2], Suzanne Norris[2], John Gormley[1]. *[1]Trinity College Dublin, Discipline of Physiotherapy, Dublin 2, Ireland; [2]St James's Hospital, Hepatology Department, Dublin 8, Ireland*
Email: anmonagh@tcd.ie

Background and aims: Chronic hepatitis C infection (HCV) is associated with fatty liver, impaired glucose metabolism and dyslipidemia. When combined with pre-existing obesity due to improper diet, physical inactivity and reduced cardiorespiratory fitness, cardiovascular (CV) risk is a potentially significant cofactor for morbidity post DAA treatment outcomes. This study examined CV risk in patients who had achieving SVR

Method: HCVRNA positive mono-infected patients commencing DAA therapy were recruited from a Hepatology clinic in Dublin, Ireland. Maximal aerobic capacity (VO2max) was used as an indicator of cardiorespiratory fitness and was assessed via a submaximal exercise test using breath by breath gas analysis (Cosmed K4b2). Liver stiffness and liver fat were examined by transient elastography. Blood samples were analysed for levels of fasting plasma glucose, fasting insulin and lipids. Anthropometric measures including blood pressure, height, weight, BMI, body fat %, and waist circumference were also measured. All measures were taken at baseline prior to commencing DAA therapy and were repeated at SVR24. Paired T test were used to assess changes from baseline in normally distributed variables. For non-normally distributed variables, Wilcoxin-signed rank tests were used.

Results: 32 participants (15 female, 17 male, mean age 45 ± 14) were recruited for this study. While reductions in steatosis measures ($p < 0.05$) were observed, mean CAP scores 6-months post SVR remained elevated above 220 $dB.m^{-1}$. Furthermore, mean total cholesterol, HDL, LDL increased from baseline. A significant increase in triglycerides was observed ($p < 0.00$). Maximal aerobic fitness and measures of anthropometry remained similar to baseline, with the exception of waist circumference which was significantly increased at SVR24 ($p < 0.01$). No significant change was noted in cardiorespiratory fitness, and remained below average age and gender norms for the majority of participants at SVR24.

Table 1

	Mean(SD) pre-treatment	Mean(SD) 6 months post SVR	P value
Liver Stiffness (kPa)	5.3 (5.1)	5.6 (4.1)	P < 0.09*
Steatosis (CAP)	254.43 (63.12)	231.16 (48.37)	P < 0.05*
VO2max (ml/min/kg)	31.62 (10.62)	32.38 (10.03)	P = 0.451*
% of n with below average fitness	90	74	
Fasting glucose (mmol/L)	4.90(0.80)	5.00 (0.50)	P = 0.807*
Fasting Insulin (mmol/L)	11.00 (7.90)	9.60 (9.20)	P = 0.522*
Total Cholesterol (mmol/L)	4.42 (1.19)	4.78 (1.10)	P = 0.073*
HDL (mmol/L)	1.46 (0.49)	1.49 (0.50)	P = 0.611*
LDL (mmol/L)	2.61 (0.80)	2.73 (0.93)	P = 0.268*
Triglycerides (mmol/L)	0.87 (0.56)	1.10 (0.68)	P < 0.00**
Systolic Blood Pressure	127 (15)	127 (15)	P = 0.604*
Weight (kg)	78.20 (13.48)	78.28 (14.06)	P = 0.910*
BMI (kg/m2)	27.33 (4.30)	27.38 (4.43)	P = 0.888*
% Body Fat	33.00 (9.91)	33.22 (10.42)	P = 0.659*
Waist Circumference	91.39 (11.75)	93.2 (12.10)	P = 0.011*
Waist-Hip ratio	0.88 (0.08)	0.89 (0.09)	P = 0.310*

*Significant change from baseline

*Paired T test

**Wilcoxon Signed rank test*

Conclusion: This study demonstrates that HCV-associated CV risk persists following SVR, due to elevated cholesterol levels and sustained fatty liver evident at SVR24. Clinical implications include the need for extended monitoring of lipids, anthropometry and steatosis post treatment. Moreover, patients with pre-existing fatty liver may benefit from lifestyle modification programmes targeted at weight loss and increasing physical activity post SVR to mitigate this increased CV risk.

Email: mromerogomez@us.es

Background and aims: HCV has the ability to cause both metabolic impairments and extrahepatic manifestations, mainly cardiovascular disease. Endothelial (EMPs) and platelets (PMPs) microparticles are novel biological markers of endothelium injury and atherosclerosis. The aim of this study was to analyze the endothelial dysfunction by measuring soluble markers, such as cell free DNA (cfDNA) and the dynamics of apoptotic microparticles, before and after DAAs therapy and their subsequent impact on cardiovascular risk.

Method: Prospective and multi-center study that included 114 patients with hepatitis C treated with DAAs therapy. Baseline, week 12 and one year follow-up after therapy following determinations were performed: (i) Whole lipid profile (ii) adhesion soluble markers and oxidative stress markers in plasma (iii) cellular injury markers including circulating cfDNA and microparticles (MPs), endothelial MPs (EMPs), platelet-derived MPs (PMPs) and total MPs (AV+) by flowcytometry.

Results: Mean age was 53 ± 10 years, 69% (79/114) male, 75% (85/114) genotype 1 and 39% (45/114) cirrhotics. Further, 32% (37/114) suffered from arterial hypertension and 21% (24/114) were diabetics. 60% (68/114) of patients received sofosbuvir-based therapy, ribavirin was added in 37% (42/114) of patients. In patients who reached SVR, total cholesterol (165.9 ± 37.6 mg/dl *vs.* 185 ± 40.6 *vs.* 182.3 ± 36.4 mg/dl; p < 0, 001), LDL (96.6 ± 34.7 mg/dl *vs.* 117.8 ± 38.3 mg/dl *vs.* 110.9 ± 33.1 mg/dl; p < 0.001) and ApoB (89.9 ± 27.5 *vs.* 99.8 ± 31.3 *vs.* 101.7 ± 29.5; p < 0, 001) levels were found to be significantly increased after 12 weeks of treatment and one year compared to baseline. On the other hand, HDL and ApoA levels remained stable after therapy (p = 0.492; p = 0.591). VCAM and e-selectin levels significantly decreased from week 12 after treatment, but oxLDL and oxLDL antibodies were not modified with respect to baseline (p = 0.105; p = 0.589), a trend was seen in VEGF levels (227.8 ± 93 *vs.* 222.9 ± 95.5 *vs.211*±106.9, p = 0.079)). Regarding to cell injury markers, cfDNA did not decrease (p = 0.589), total MPs (AV+), EMPs and PMPs levels were found to be statistically lower one year after treatment than at baseline. Finally, this decrease of total MPs was more evident in non-hypertensive patients (n = 63) (MPs: 19661 ± 136.9 *vs.* 11597 ± 3640 *vs.* 9847 ± 520.1; p = 0.04;EMPs: 478 ± 68 *vs.* 269 ± 39.6 *vs.* 352 ± 78; p = 0.001).

Conclusion: Eradication of hepatitis C virus produces a decrease in VCAM, e-selectin, total MPs, PMPs and EMPs, suggesting an improvement of endothelial function when reaching SVR. These effects are more evident in patients with no or early cardiovascular risk.

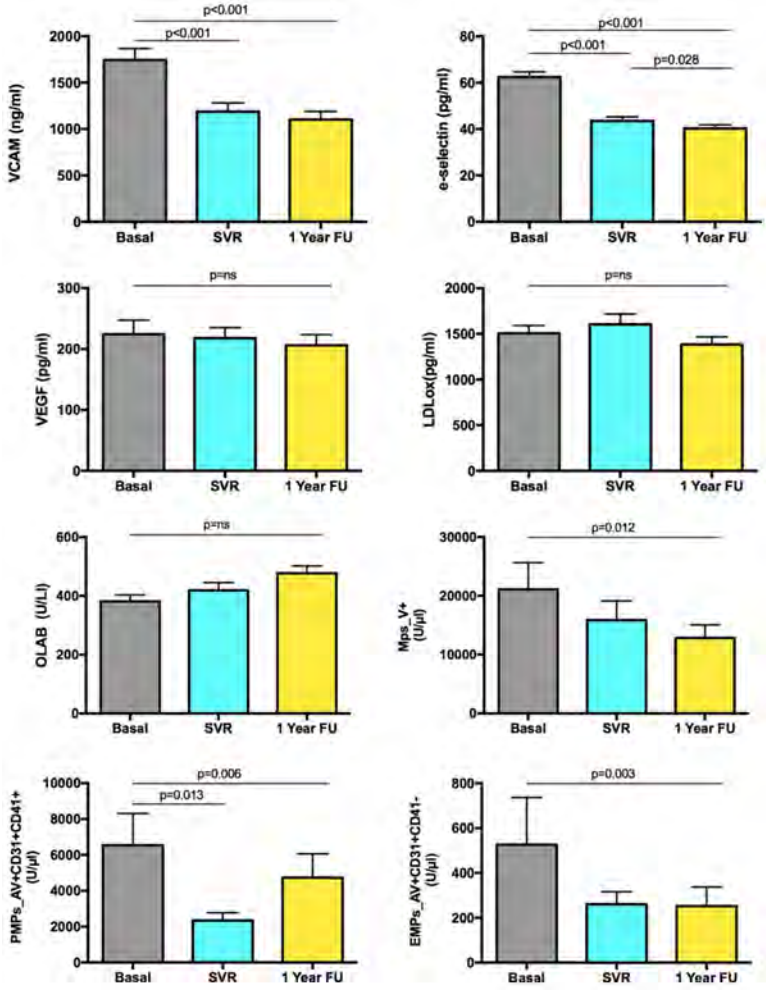

Figure: (abstract: SAT-250)

SAT-251

The association of serum IFN-λ3 levels with liver fibrosis and hepatocarcinogenesis in chronic hepatitis C patients treated with direct-acting antiviral agents

Miyako Murakawa[1,2], Yasuhiro Asahina[1,3], Emi Inoue[1], Mina Nakagawa[1], Jun Tsuchiya[1], Ayako Sato[1], Masato Miyoshi[1], Tomoyuki Tsunoda[1], Fukiko Kawai-Kitahata[1], Sayuri Nitta[1], Yasuhiro Itsui[1], Seishin Azuma[1], Sei Kakinuma[1,3], Mamoru Watanabe[3]. *[1]Tokyo Medical and Dental University, Gastoenterology and Hepatology, Tokyo, Japan; [2]Tokyo Medical and Dental University, Clinical Laboratory, Tokyo, Japan; [3]Tokyo Medical and Dental University, Liver Disease Control, Tokyo, Japan*
Email: asahina.gast@tmd.ac.jp

Background and aims: Although the efficacy of hepatitis C virus (HCV) treatment is improved dramatically by direct-acting antiviral agents (DAAs), the assessment of hepatocellular carcinoma (HCC) remains important even after HCV eradication. IFNL3 polymorphisms are associated with liver fibrosis and inflammation in chronic hepatitis C (CHC) patients, but its impact on carcinogenesis remains controversial and little is known about its effects after viral clearance. To determine the contribution of IFN-λ3 to hepatocarcinogenesis after HCV clearance, we analyzed IFNL3 genotypes and serial serum IFN-λ3 levels in CHC patients who achieved sustained virological responses (SVR).
Method: A total of 201 CHC patients who achieved SVR were enrolled (Peg-IFN/RBV+TVR 13, Peg-IFN/RBV+SMV 21, DCV/ASV 15, LDV/SOF 116, SOF/RBV 36). Serum samples were collected sequentially and IFN-λ3 levels were quantified by chemiluminescence enzyme immunoassay. The IFNL3 polymorphism (rs8099917) was genotyped in 195 patients.
Results: 125 patients were rs8099917 T/T and 70 patients were non-T/T. Serum IFN-λ3 levels did not differ significantly with IFNL3 genotype. Serum IFN-λ3 levels dropped markedly by 1 week and remained at low levels up to 24 weeks after the end of treatment. Pre-treatment IFN-λ3 levels were higher in patients with higher ALT ($p < 0.001$), FIB-4 index ($p < 0.001$) and WFA+M2BP levels (< 0.001), but not related to the histological fibrosis stage ($p = 0.15$). Moreover, Pre-treatment IFN-λ3 levels did not differ regardless of HCC development ($p = 0.932$), either. On the other hand, after HCV eradication, serum IFN-λ3 levels were significantly higher in patients who developed HCC ($p = 0.016$) and were associated with a higher potential for hepatocarcinogenesis, such as a higher frequency of non-hypervascular hypointensive nodules ($p = 0.046$), higher stages of liver fibrosis ($p < 0.001$), and higher post-treatment levels of ALT ($p < 0.001$), FIB-4 index ($p = 0.001$) and WFA+M2BP ($p < 0.001$).
Conclusion: Serum IFN-λ3 levels after HCV clearance are associated with the potential for HCC development. IFN-λ3 may be a helpful clue for elucidating the relationships among immunologic status, liver fibrosis, liver inflammation, and hepatocarcinogenesis, after achieving SVR.

SAT-252

Long-term effect of direct-acting antivirals therapy in patients with hepatitis C-related decompensated cirrhosis: Russian single academic center experience

Ekaterina Nabatchikova[1], Dzhamal Abdurakhmanov[1], Teona Rozina[1,2], Elena Nikulkina[1], Elena Tanashchuk[1], Sergey Moiseev[1,2]. *[1]Sechenov First Moscow State Medical University, Moscow, Russian Federation; [2]Lomonosov Moscow State University, Moscow, Russian Federation*
Email: e.nabat4ikova@gmail.com

Background and aims: Successful direct-acting antivirals (DAAs) therapy have shown early improvement of liver function in patients with decompensated cirrhosis. However, little is known about the long-term benefits of HCV-eradication in these patients. The aim of our study was to assess the follow-up effect of sustained virological response (SVR) on liver function and portal hypertension in decompensated cirrhotic patients.
Method: We conduct a single-center prospective study among 48 patients with HCV-related decompensated cirrhosis successfully treated by DAAs between March 2015 and April 2018. The clinical, laboratory, imaging data were evaluated before treatment (BT), at the time of SVR and last follow-up observation (FU).
Results: The mean patients age was 53.5 ± 10.6 years, 58%-males, 77%-treatment-naïve, 67% had a HCV genotype 1, 81%-Child-Pugh (CP) class B, 85% received sofosbuvir-based therapy, 54%-with ribavirin, for 12 or 24 weeks. The median FU time was 18 (6-36) months. A significant improvement was found in most liver function parameters, among clinical markers of portal hypertension only the presence of ascites showed a significant difference (Table). At last observation 54% of patients switched to a CP class A, 6 (67%) out of 9 patients with CP class C switched to class B, 3 (7.7%) worsened to CP class C. Baseline higher bilirubin (≥ 50 Umol/l, HR 2.82; $p = 0.034$) and lower albumin (< 28 g/l, HR 2.59; $p = 0.026$) and male gender (HR 3.37; $p = 0.03$) were significantly and independently associated with absence of re-compensation at last observation.

Table:

Parameter	BT	SVR	FU	p value
Albumin, g/l, mean ± SD	31.0 ± 3.9	33.6 ± 4.5	35.8 ± 5.6	< 0.001
< 28 g/l, n (%)	11 (23)	5 (10.4)	4 (8.3)	0.002
Bilirubin, Umol/l, mean ± SD	32.9 ± 14.8	30.4 ± 14.6	29.4 ± 14.5	0.098
≥ 50 Umol/l, n (%)	6 (12.5)	5 (10.4)	6 (12.5)	0.779
Prothrombin time, %, mean ± SD	61.6 ± 14.7	62.9 ± 10.1	67.4 ± 11.6	0.002
≤ 60%, n (%)	28 (58.3)	21 (43.7)	13 (27.1)	< 0.001
Platelets count, 10^9/l, mean ± SD	82.5 ± 54.5	84.7 ± 51.3	85.7 ± 52.4	0.802
Ascites, n (%)	33 (68.7)	20 (41.7)	19 (39.6)	< 0.001
Varices F2/F3, n (%)	31 (64.6)	31 (64.6)	31 (64.6)	0.973
Encephalopathy, n (%)	18 (37.5)	15 (31.2)	15 (31.2)	0.307

Conclusion: SVR is associated with improvement of liver function, however, has no significant effect on severity of portal hypertension. Patients with more severe baseline liver decompensation, probably, still remain the candidates of liver transplantation despite HCV-eradication.

SAT-253

Impact of HCV clearance on HCC development and patient survival: Propensity score-matched analysis of an ongoing database of 2173 CHC patients

Mina Nakagawa[1], Yasuhiro Asahina[1], Jun Tsuchiya[1], Ayako Sato[1], Tomoyuki Tsunoda[1], Masato Miyoshi[1], Emi Inoue[1], Fukiko Kawai-Kitahata[1], Miyako Murakawa[1], Sayuri Nitta[1], Yasuhiro Itsui[1], Seishin Azuma[1], Sei Kakinuma[1], Makoto Tomita[2], Mamoru Watanabe[1]. *[1]Tokyo medical and dental university, Department of Gastroenterology and Hepatology, Tokyo, Japan; [2]Tokyo medical and dental university, Clinical Research Center, Tokyo, Japan*
Email: asahina.gast@tmd.ac.jp

Background and aims: With the development of potent direct-acting antiviral agent (DAA) combinations, an almost 100% sustained virological response (SVR) was achieved, even in patients with high risk of developing hepatocellular carcinoma (HCC), but the question of whether the suppressive effect of viral eradication by IFN-free regimens on hepatocarcinogenesis and survival will be equivalent to that obtained by IFN-based regimens has remained to be solved especially for HCC recurrence. The aims of this study were to evaluate the HCC development and patient survival in CHC patients treated with DAAs after antiviral treatment.

Method: This registry study is an ongoing, non-interventional, study, and consists of multicenter observational cohorts of 2173 CHC patients who were treated with IFN-based (n = 1148) or IFN-free (n = 1025) patients that prospectively follows from December 2004 to November 2018. Cumulative de novo HCC and recurrence rates were compared using propensity score-matched analysis by EZR on R commander (Ver. 1.24). Independent factors associated with de novo or recurrence rates of HCC were analyzed using Cox proportional regression analysis using an SPSS software package (version 24).
Results: As for IFN-free therapies, the 3-year incidence of de novo HCC was 3%, and of recurrence was 49.2%. Propensity score-matched analysis showed no significant difference in de novo HCC (p = 0.137) and recurrence (p = 0.150) rates among groups treated with IFN-based or IFN-free therapies. In univariate and multivariate analysis, post-treatment $WFA^{+}M2BP$ level was independently associated with de novo HCC (p = 0.032, HR (95%CI) = 3.367 (0.098-0.902)), and post-treatment AFP level with recurrence after SVR (p = 0.038, HR (95%CI) = 2.907 (0.125-0.943)). Although significant difference was not found so far (p = 0.143), among patients with previous history of HCC, the 3-year survival rate was 92.6% for IFN-based, and 82.4% for IFN-free treatment respectively.
Conclusion: Propensity score-matched analysis showed no significant difference in de novo HCC and recurrence rates among groups treated with IFN-based or IFN-free therapies. Although significant difference was not found so far, among patients with previous history of HCC, the 3-year survival rate was lower in patients treated with IFN-free therapy, so longer-term longitudinal studies about cumulative incidences of survival in larger cohorts are required to reveal the prognostic improvement for CHC patients.

SAT-254

Incidence of hepatocellular carcinoma and mortality after HCV elimination by all-oral DAA therapy: Results from a large-scale, multicenter cohort study

Email: eogawa@gim.med.kyushu-u.ac.jp

Background and aims: HCV treatment has become much easier than ever because of short-term, well-tolerated regimens with all-oral DAAs. However, as much data as possible on the de novo and recurrent hepatocellular carcinoma (HCC) are urgently needed to better manage HCC surveillance after HCV elimination. The aim of this study was to evaluate HCC development and mortality among Japanese patients with chronic HCV infection following the achievement of sustained viral response (SVR) by all-oral DAAs.
Method: This large-scale, multicenter cohort study included 2, 847 consecutive patients from 2014 who achieved SVR by all-oral DAAs, divided into groups with (n = 321) or without previous HCC (n = 2, 526). We excluded patients aged < 20 years, decompensated cirrhosis, co-infection with HBV/HIV, or a history of organ transplantation. The Kaplan-Meier method and Cox proportional hazard analysis were used to calculate the cumulative HCC incidence, related factors of HCC, and mortality.
Results: During the observational period (median: 2.6 years), 195 (7.2%) patients developed HCC. The one- and three-year cumulative rates of de novo HCC were 0.5% and 2.1% for the non-cirrhosis patients, respectively. In contrast, the rates for the cirrhosis group were 4.5% and 10.5%, respectively (log-rank test: p < 0.001). In multivariable Cox analysis, age (OR 1.03, P = 0.033), cirrhosis (OR 2.22, P = 0.045), serum albumin at the end of treatment (EOT) (OR 0.39, P = 0.008), and EOT-alpha-fetoprotein (AFP) level (OR 1.01, P < 0.001) were extracted as predictors of de novo HCC. The one- and three-year cumulative rates of HCC recurrence were 19.7% and 42.4%, respectively. A non-curative procedure with transarterial chemoembolization shortly after HCC treatment (< one year) had a strong impact on the rate of HCC recurrence (two-year cumulative HCC recurrence rate: > 60%). The three-year cumulative mortality rates for non-HCC and previous HCC patients were 0.6% and 10.7%, respectively (log-rank test: p < 0.001). The liver-related complications, mainly HCC, were responsible for approximately three-quarters of all deaths for those with previous HCC.
Conclusion: After HCV elimination, older age, cirrhosis, and a high level of EOT-AFP were strongly associated with the development of de novo HCC. Especially for HCC patients treated with non-curative procedures, HCC recurrence will commonly occur, irrespective of SVR.

SAT-255

Long-term safety and efficacy results in hepatitis C virus genotype 1-infected patients receiving ombitasvir/paritaprevir/ritonavir + dasabuvir ± ribavirin in the TOPAZ-I and TOPAZ-II trials

Fred Poordad[1], Rui Sarmento E. Castro [2], Armen Asatryan[3], Humberto Aguilar[4], Patrice Cacoub[5], Douglas Dieterich[6], Rui Marinho[7], Armando Carvalho[8], Asma Siddique[9], Yiran Hu[3], Mariem Charafeddine[3], Mark Bondin[3], Nader Khan[3], Daniel Cohen[3], Franco Felizarta[10]. *[1]The Texas Liver Institute, San Antonio, United States; [2]Hospital de Santo António, Porto, Portugal; [3]AbbVie, Inc, North Chicago, United States; [4]Louisiana Research Center, Shreveport, United States; [5]Hôpital La Pitié-Salpêtrière, Paris, France; [6]Mount Sinai School of Medicine, New York, United States; [7]Centro Hospitalar de Universitário Lisboa Norte and Medical School of Lisbon, Lisbon, Portugal; [8]Hospitais da Universidade de Coimbra, Coimbra, Portugal; [9]Virginia Mason Hospital and Seattle Medical Center, Seattle, United States; [10]Private Practice, Bakersfield, United States*
Email: poordad@txliver.com

Background and aims: In phase 3 clinical trials, the triple direct-acting antiviral (3-DAA) regimen consisting of ombitasvir/paritaprevir/ritonavir plus dasabuvir (OBV/PTV/r + DSV)±ribavirin (RBV) (paritaprevir identified by AbbVie and Enanta) had shown high rates of sustained virologic response (SVR) at post-treatment week (PTW) 12 (SVR12) in HCV genotype (GT) 1-infected patients. Here, we report the long-term efficacy, and clinical outcomes in patients receiving 3-DAA ± RBV in TOPAZ-I and TOPAZ-II (TOPAZ) studies.
Method: TOPAZ studies are ongoing, phase 3b, open-label trials. Enrolled patients were HCV GT-1-infected treatment-naïve or interferon-experienced ± cirrhosis and are being evaluated for the long-term suppression and impact of SVR on liver disease progression through 5-years post-treatment. Treatment consisted of OBV/PTV/r +

DSV ± RBV for 12 or 24 weeks, based on HCV GT 1a/b subtype and cirrhosis status as per label. Roche CTM test was used to detect HCV RNA levels. SVR, and liver-related clinical outcomes at PTWs104 and 156 are reported.

Results: 2211 patients were enrolled in the TOPAZ studies. Majority of patients were male (52.8%), white (93.4%), < 65 years of age (88.4%) with 51.7% GT1a and 48% GT1b infection. 55.1% patients were treatment-naïve; 70.6% had high baseline HCV RNA levels (≥ 800, 000 IU/ML); and 16% had compensated cirrhosis (F4). To date, > 99% patients have maintained SVR since PTW12 at both PTWs104 (1904/1909) and 156 (660/662). Clinical outcomes related to progression of liver disease are shown in **Table 1**. Cirrhotic (C) patients showed higher mean reduction in baseline FIB-4 score than non-cirrhotic (NC) patients {PTW104: −0.3 (NC), −2 (C); PTW156: −0.4 (NC), −2 (C)}. Out of 251 patients with F4 at baseline, 164 and 67 improved to ≤ F3 at PTWs104 and 156, respectively (33 and 172 patients had missing METAVIR score at PTWs104 and 156). Mean increase from baseline in platelet count and albumin was 15.4 × 10^9/l and 3.1 g/l, respectively, at PTW104; and 21.8 10^9/l and 2.5 g/l, respectively, at PTW156. Child-Pugh (CP) score decreased from ≥ 6 at baseline to < 6 in 34 patients at PTW104, and in all 5 patients at PTW156.

Table 1: Clinical outcomes

	TOPAZ-I and II (N = 2211) n (%)
All cause death	26 (1.2)
Liver related death	1 (< 0.1)
Hepatic decompensation	
Cirrhotic patients	8 (0.4)
Liver transplantation	
Cirrhotic patients	2 (< 0.1)
Hepatocellular Carcinoma (HCC)	12 (0.5)
Fibrosis stage (F0-F1), n	3
F3	4
F4	5
Composite of any clinical outcomes	42 (1.9)

Conclusion: A high proportion of patients who achieved SVR with 3-DAA ± RBV in the TOPAZ studies showed long-term sustainability of SVR, with improvements in liver disease markers including FIB-4, METAVIR, CP scores, and platelet counts, and a low frequency of clinical outcomes related to long-term progression of liver disease. No new safety signals were detected.

SAT-256

Influence of metabolic syndrome on fibrosis regression regulated by LOXL-2 after SVR

Angela Puente[1,2], Miguel Posadas[3], Jose Ignacio Fortea[1,2], Agustin Garcia[1,2], María Teresa Arias Loste[1,2], Joaquin Cabezas[1,2], Susana Llerena[1,2], Laura Rasines[2], Paula Iruzubieta[1,2], Emilio Fabrega[1,2,3], Javier Crespo[1,2,3]. *[1]Marques de Valdecilla University Hospital, Liver Unit, Santander., Spain; [2]IDIVAL, Santander., Spain; [3]Cantabria University, Santander., Spain*
Email: anpuente@humv.es

Background and aims: The potential influence of underlying ALD/NAFLD in fibrosis regression after SVR in HCV infection remains unclear. We aimed to assess the influence of metabolic syndrome (MetS) and alcohol consumption in fibrosis regression (evaluated by elastography, serological scores and biopsy) after 24 months of SVR. Also, we evaluated the relationship with serum and tissue expression of Lysyl oxidase-like-2.

Method: 271 patients treated with DAAs in our hospital from 2015 and who achieved SVR were included. A personal interview with AUDIT questionnaire, physical examination, blood tests, and Fibroscan® were made at baseline (B) and 24-months (24M) after SVR. Hemodynamic studies and transyugular liver biopsy were performed in 13 patients.

Results: At (B) 68 patients were F1 (25, 1%);59 patients were F2 (21, 7%);44 were F3 (16, %) and 100 were F4 (36, 9%).58.4% of patients have a body max index (BMI) ≥ 25 kg/m^2 and diabetes in 13, 1%. At 24M, although elastography improved in absolute value in 82% (n = 222), progressed in 49 cases (17.7%) and 42 remained in F4 (15.4%). At 24M, 48 patients met MetS criteria and patients with BMI ≥ 25 kg/m^2 increase to 59.5% p < 0.001. (B) and 24M BMI ≥ 25 kg/m^2 were risk factors for significant fibrosis or steatosis at 24M (p < 0.05), and progression on liver stiffness (p < 0, 001, Chi^2) as well as B and 24M MetS: OR 4.1IC (1.4-11.7) p = 0.008; and OR 5.4 IC (1.9-15.4) p = 0, 001, respectively. We found a significative correlation of elastography with insulin r = 0.356 and HOMA r = 0.385 p < 0.0001; LDL-cholesterol r = -0.122 p = 0.05, and serological scores APRI r = -0, 165 p < 0, 006; FORNs r-0, 287 p < 0, 0001 and HEPAMET r = 0, 508 p < 0, 001. In multivariable regression analysis, HOMA was the only one that remained significative r = 2.090 p = 0.025. We found correlation among ΔFibroscan, ΔAPRI, ΔForns and Δweight (p < 0.05). We didńt find differences regarding alcohol. 13 liver procedures were performed in cirrhotic patients with mean HVPG 3.7mmHg ± 1.14mmHg. However, we dindńt find a good correlation between Fibroscan® and liver biopsy. There is a great disparity of values (only 6 patients have concordance between them). No patient with METAVIR F1 has a Fibroscan® < 7Kpa and there are 4 patients with > 9Kpa that doń have a compatible biopsy (METAVIR 1 and 2). Interestingly, 3 patients with MetS and non-invasive scores of NALFD, had F3-NASH biopsy. We found statistically significant decrease in LOXL-2 levels at 24M respect B 891.80 ± 1616pg/ml vs 328.0 ± 1415.03pg/ml p < 0.001, with twice serum expression in patients with elastography > 9kPa (p = 0.046). We didńt find correlation with tissue expression or HOMA (p = 0.09).

Conclusion: Regression of elastography is reached in 82%of patients, correlated with serological values of LOXL-2, but not histologically in the subgroup of cirrhotic patients. Metabolic factors and alcohol doń seem to influence the regression of fibrosis in the medium term.

SAT-257

Incidence and predictors of liver outcomes in chronic hepatitis C patients: Comparison of an American and a Chinese cohort

Huiying Rao[1], Huixin Liu[2], Elizabeth Wu[3], Ming Yang[1], Bo Feng[1], Andy Lin[4], Ran Fei[1], Robert Fontana[3], Anna Lok[3], Lai Wei[1]. *[1]Peking University People's Hospital, Peking University Hepatology Institute, Peking University Health Science Center, Beijing, China; [2]Peking University People's Hospital, Department of Clinical Epidemiology and Biostatistics, Beijing, China; [3]University of Michigan, Department of Internal Medicine, Division of Gastroenterology and Hepatology, Ann Arbor, United States; [4]University of Michigan, The Molecular and Behavioral Neuroscience Institute, Ann Arbor, United States*
Email: weelai@163.com

Background and aims: The prevalence of HCV infection in China is estimated to be 0.7% but outcomes of chronic HCV in China are not well-reported. We compared clinical outcomes among adult chronic HCV patients in the US and China and factors predictive of outcomes.

Method: Prospective study of 2 cohorts of HBsAg-, HCV RNA+ patients recruited in 1 site in the US and 2 sites in China. Data on risk factors and medical history were collected using standardized questionnaire; diagnosis of cirrhosis and HCC was based on predefined criteria. Composite liver outcomes of liver-related deaths, HCC, decompensation, or liver transplant were analyzed using multivariate Cox regression with competing risks and SVR as a time-dependent covariate. Patients were censored at the time of liver transplant or HCC diagnosis.

Results: 795 US and 854 Chinese patients followed for a median of 3.06 and 3.99 years, respectively were analyzed. US patients were significantly more likely to be men (57.4% vs. 48.2%), older (mean 55 vs. 52 years), obese, diabetic, current or past use of alcohol, cigarettes, and coffee, and also had a significantly lower prevalence of anti-HBc (31.2% vs. 46.4%). At enrollment, a significantly higher percent of US patients had cirrhosis (45.4% vs. 16.2%). During follow-up, a similar percent of US and Chinese patients achieved SVR (53.7% vs. 50.6%).

The 5-year cumulative incidence of composite liver outcomes was significantly higher in US than in Chinese patients (25.5% vs. 6.6%, p < 0.0001). Stratification by fibrosis severity at enrollment showed this difference persisted in the subgroup without cirrhosis but not in the subgroup with cirrhosis (Figure). Multivariate analysis showed that baseline liver disease severity, age, and absence of SVR were significant predictors of composite liver outcomes but study site was not. Hazard ratio for outcomes among patients with SVR was 0.32 (95%CI 0.22-0.46) for US and 0.09 (95%CI 0.03-0.28) for Chinese patients.

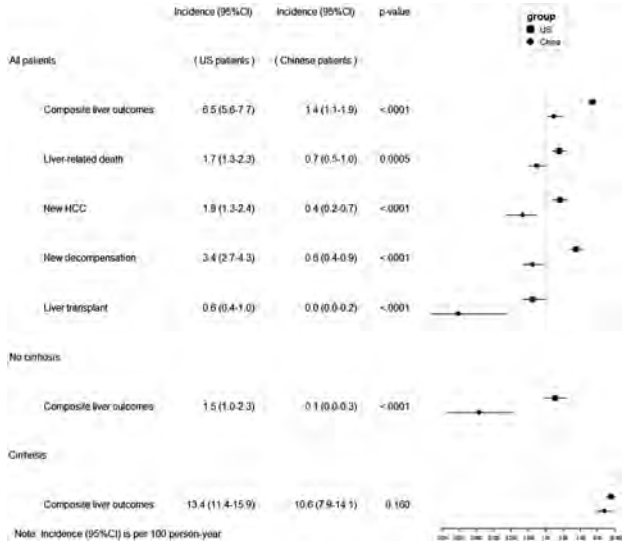

Figure: Incidence of composite liver outcomes in US and Chinese hepatitis C patients

Conclusion: In this parallel cohort study of HCV patients, the incidence of clinical outcomes was significantly higher in the US than in the Chinese patients due to a higher percent of US patients with cirrhosis at enrollment. Achievement of SVR markedly decreased the risk of outcomes in both cohorts. These data strengthen the WHO pledge to eliminate HCV worldwide by 2030 and demonstrate that improved diagnosis and access to treatment can help reduce morbidity and mortality of HCV in both the US and China.

SAT-258

Indocyanine green retention test predicts the risk of portal hypertension-related events after direct-acting antiviral therapy in compensated advanced chronic liver disease patients

Federico Ravaioli[1,2], Elton Dajti[1], Patrizia Simoni[1], Alberto Porro[1], Giovanni Marasco[1], Vanessa Alemanni[1], Mariarosa Tamé[1], Marco Montagnani[1], Stefano Brillanti[1,3], Antonio Colecchia[1,4], Davide Festi[1], Giuseppe Mazzella[1], Francesco Azzaroli[1]. *[1]University of Bologna, Gastroenterology and Hepatology Unit -Department of Medical and Surgical Sciences (DIMEC), Bologna, Italy; [2]Newcastle University, Institute of Cellular Medicine (ICM), Newcastle upon Tyne, United Kingdom; [3]University of Siena, Research center for the study of hepatitis, Siena, Italy; [4] Borgo Trento University Hospital, Gastroenterology Unit, Verona, Italy*
Email: francesco.azzaroli@unibo.it

Background and aims: Achieving a Sustained Viral Response (SVR) after treatment with direct-acting antivirals (DAAs) in patients with compensated advanced chronic liver disease (cACLD) HCV-related leads to an improvement in liver function, liver fibrosis and portal hypertension (PH). Currently, the long-term impact in terms of PH-driven complications is still under investigation. Indocyanine green retention test (ICG-r15') is a non-invasive liver test (NIT) correlated with PH and proposed as a predictor of hepatic decompensation in patients with active HCV infection. Thus, we aimed to investigate the changes of ICG-r15' after DAA therapy and evaluate its prognostic role in the development of PH-related events despite successful viral elimination.

Method: We prospectively followed 119 cACLD patients treated with DAAs in our tertiary centre with paired and available ICG-r15' and LSM both before and 6 months after treatment. According to the Baveno VI Criteria, cACLD and clinically significant PH (CSPH) were defined by pre-treatment values of LSM > 10 kPa and LSM ≥ 21 kPa, respectively. Hepatic decompensation (HD), Hepatocellular carcinoma, portal venous thrombosis, liver transplantation and death were considered as PH-related events. The Kaplan-Meier method was used to estimate the HD development during the follow-up. Time-dependent Cox regression models for HD and PH-related events after SVR were applied to account for changes in ICG-r15' and LSM after DAA therapy.

Results: The median follow-up was 26 (15-36) months. ICG-r15' significantly decreased from 17.3% at before treatment to 12.2% at 6 months follow-up. The cumulative incidence rate of PH-related events at 1 year and after 2 years of follow-up were 170.8 (104.7-278.9), 49.5 (15.9-153.3) per 100-Person Years, respectively. The incidence rate significantly differed when compared by previous HD, CSPH status and history of HCC. At the multivariate analysis, previous HD (HR, 6.313; 95%CI 2.201-18.108) and higher ICG-r15' values (HR, 1.025, 95%CI 1.004-1.047) were independently associated with a higher risk of PH-related events development after DAAs treatment. ICG-r15' ≥ 18.5 was significantly associated with a higher risk of PH-related events both at univariate and multivariate analysis.

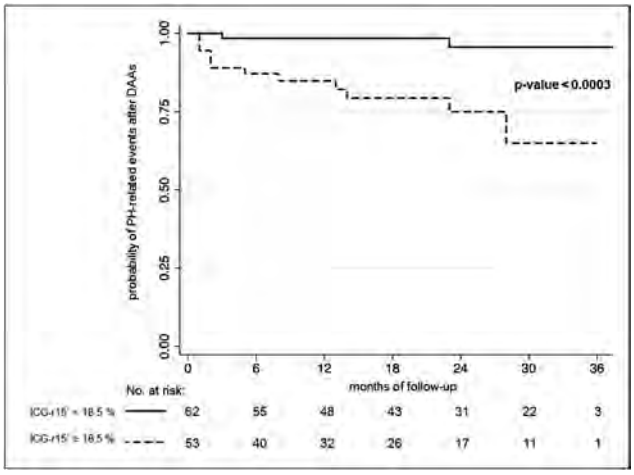

Figure: Kaplan Meier survival curve after DAAs treatment for PH-related events by ICG-r15' cut-off (18.5%) after time-dependent Cox predictive modelling.

Conclusion: ICG-r15', reflecting both liver function and PH, is demonstrated as an accurate predictor of PH-related events after DAAs treatment in HCV patients with cACLD. This predictive tool could help the clinicians to identify the right follow-up timing of ACLD patients after treatment.

SAT-259

Achieving accelerated elimination of hepatitis C virus infection by 2025: A case study in France

Victor De Ledinghen[1], Bureau christophe[2], Yuri Sanchez[3], Fabrice Ruggeri[4], Pierre-Henri Delaage[4], Homie Razavi[5]. *[1]CHU de Bordeaux, Bordeaux, France; [2]CHU de Toulouse, Toulouse, France; [3]AbbVie Inc., North Chicago, United States; [4]AbbVie France Ltd., Rungis, France; [5]Center for Disease Analysis, Lafayette, United States*
Email: victor.deledinghen@chu-bordeaux.fr

Background and aims: With the introduction of curative therapies for hepatitis C virus (HCV) infection and removal of restrictions on antiviral treatment by fibrosis score, France is on track to achieve

the World Health Organization's (WHO) 2030 targets for HCV elimination. To inform the path towards accelerated elimination, this analysis evaluates the clinical and economic impact of HCV elimination in France by 2025.

Method: A Markov disease progression model was developed to assess the impact of expanding HCV diagnosis and treatment, populated with demographic and epidemiological inputs for France. Historical incidence of HCV was calibrated to match 110, 000 chronically-infected adults (with 40, 000 diagnosed) in 2018. Future incidence was assumed to be proportional to prevalence. Two scenarios were compared: maintaining 15, 000 annual treatments and 4.1 million annual HCV antibody screens ("status quo"), and "accelerated elimination" requiring 13, 700 diagnoses and 18, 650 treatments annually over 2019-2025. Clinical outcomes included cases of decompensated cirrhosis (DC), hepatocellular carcinoma (HC), liver transplants (LTs) and liver-related deaths (LRDs). Economic outcomes included costs of hepatic and extrahepatic complications, screening and treatment, and incremental cost per quality-adjusted life year (ICER; €/QALY).

Results: Compared to the status quo, accelerated elimination in France require screening of two times more people annually, or 28 million additional HCV antibody screens over 2019-2025. This would avert 2, 913 new HCV infections, 32 DC cases, 67 HC cases, 6 LTs, and 50 LRDs while incurring €1, 153 million in additional healthcare costs over 2019-2025 (ICER of €119, 599/QALY). By 2030, the clinical and economic benefits of accelerated elimination would grow and yield cost savings of €159 million (ICER of -€9, 479/QALY).

	Status quo	Accelerated elimination by 2025
Clinical outcomes over 2019-2025, incident cases		
HCV infection	17, 281	14, 368
Decompensated cirrhosis	76	44
Hepatocellular carcinoma	163	95
Liver transplant	15	9
Liver-related deaths	120	70
Economic outcomes over 2019-2025, million €		
Screening	403	754
Antiviral treatment	2, 273	3, 259
Liver-related complications	123	96
Extra-hepatic manifestations	593	436
Total costs	3, 391	4, 545

Conclusion: While France is on track to eliminate HCV as a public health threat by 2030, an expansion of screening to 28 million more people would be necessary to accelerate elimination by 2025. This path would further reduce the clinical and economic burden of HCV and be cost-saving by 2030.

SAT-260

Global timing of hepatitis C virus elimination: estimating the year countries will achieve the World Health Organization elimination targets

Homie Razavi[1], Yuri Sanchez[2], Andreas Pangerl[2], Markus Cornberg[3].
[1]*Center for Disease Analysis, Lafayette, United States;* [2]*AbbVie Inc., North Chicago, United States;* [3]*Medizinische Hochschule Hannover, Department of Gastroenterology, Hepatology and Endocrinology, Hannover, Germany*
Email: hrazavi@cdafound.org

Background and aims: The introduction of highly efficacious therapies for hepatitis C virus (HCV) infection has made the elimination of HCV an attainable goal. This study assessed the progress made in 45 high-income countries and territories towards meeting the 2030 HCV elimination targets by the World Health Organization (WHO) for diagnosis, treatment, incidence, and mortality from chronic HCV infection.

Method: A Markov model was developed to forecast the annual HCV-infected population by stage of liver disease, sex, and age. For each country and territory, the model was populated with reported demographic and epidemiological inputs, and historical incidence was calibrated to reported overall, as well as sex- and age group-specific, prevalence of chronic HCV. Future incidence was assumed to be a linear function of prevalence except when treatment restrictions were in place. With restrictions, incidence was a linear function of the F0 prevalent population. The 2017 levels of diagnosis and treatment were assumed constant over the future. Modelled outcomes were analysed to determine which year countries were projected to meet the four components of the WHO HCV elimination targets for 90% reduction in incidence, 65% reduction in liver-related deaths, 90% diagnosis and 80% of the eligible HCV population treated. The earliest year in which all four targets were met was defined as the year of elimination.

Results: Of 45 high-income countries and territories analysed, only seven (Australia, France, Iceland, Spain, Switzerland, South Korea, and the United Kingdom) are on track towards meeting WHO's HCV elimination targets by 2030. Italy, Japan, and Malta can also reach the targets with expanded screening efforts. 30 countries are off-track by at least 20 years, as they are not projected to achieve HCV elimination before 2050. A 90% reduction in incidence was the most difficult target to achieve, followed by a 65% reduction in liver-related deaths (dependent of screening and treatment). Although many countries have expanded HCV treatment, few have national screening programs that can maintain sufficient number of patients to treat in the future.

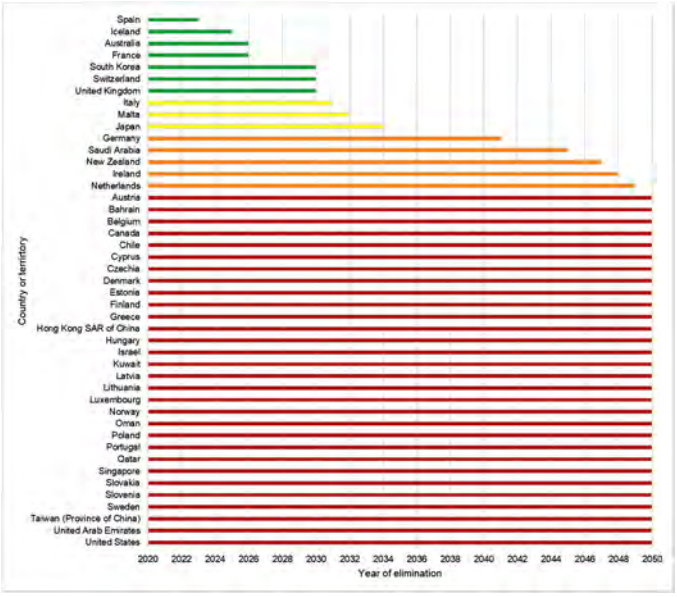

Figure: Year each country/region will meet all four World Health Organization (WHO) elimination targets

Conclusion: Even with the introduction of curative therapies, 84% of high-income countries are not on track to meet the WHO's 2030 targets that would eliminate HCV as a public health threat, and 66% are off-track by at least 20 years. Immediate action to improve HCV screening and treatment is needed globally to make WHO's HCV elimination targets attainable by 2030.

SAT-261

Elevated HCV reinfection rates after cure on spontaneous clearance among HIV-infected and uninfected men who have sex with men

Carmine Rossi[1], Zahid A Butt[1], Maryam Darvishian[1], Stanley Wong[1], Amanda Yu[1], Maria Alvarez[1], Naveed Janjua[1]. [1]*British Columbia Centre for Disease Control, Vancouver, Canada*
Email: carmine.rossi@mail.mcgill.ca

Background and aims: Increasing rates of hepatitis C virus (HCV) infection associated with ongoing risk activity have been reported after successful cure or viral clearance, particularly among HIV-infected men who have sex with men (MSM). There has been considerably less information on HCV reinfection risk factors in this population. We assessed factors associated with reinfection after treatment-induced or spontaneous clearance (SC) in both HIV-infected and uninfected MSM in British Columbia, Canada.
Method: We identified HIV-infected and uninfected MSM who achieved sustained virologic response (SVR) to HCV treatment or had SC with ≥ 1 subsequent HCV RNA measurement in the British Columbia Hepatitis Testers Cohort. Crude reinfection rates per 100 person-years (PYs) were calculated. Cox regression was used to model adjusted hazard ratios (HRs) and 95% confidence intervals (CI) for reinfection, overall, and by HIV status.
Results: We identified 1, 349 HCV-infected MSM with SVR (n = 856) and SC (n = 493), of which 349 (26%) were HIV-positive. HIV-infected MSM were more likely to have achieved viral clearance through SVR (76% vs. 59%), had histories of injection drug use (IDU; 41% vs. 21%), alcohol use (22% vs. 14%) and mental health disorders (47% vs. 28%), compared to HIV uninfected. A total of 98 reinfections were identified, yielding an overall reinfection rate of 1.9 per 100 PY (1.0 for SVR patients and 2.7 per 100 PY for SC). HIV-infected MSM had higher rates of reinfection (3.1 vs. 1.6 per 100 PY) than HIV uninfected individuals. In multivariable analysis, age < 35 years (HR 3.1, 95% CI: 1.2, 8.1), cure through SVR (HR 0.2, 95% CI: 0.1, 0.4), HIV infection (HR 2.0, 95% CI: 1.3, 3.1), problematic alcohol use (HR 2.0, 95% CI: 1.2, 3.3), IDU (HR 2.7, 95% CI: 1.6, 4.3) and mental health (MH) counseling (HR 0.2, 95% CI: 0.1, 0.4) were independently associated with reinfection, overall. Among HIV-infected, age < 35 years (HR 2.7, 95% CI: 1.0, 7.5) and MH counseling (HR 0.4, 95% CI: 0.1, 0.9) remained associated with reinfection, but IDU (HR 1.9, 95% CI: 0.8, 4.2) was less strongly associated. Among HIV uninfected, alcohol use (HR 3.0, 95% CI: 1.7, 5.7) and IDU (HR 2.7, 95% CI: 1.5, 4.9) remained the largest independent predictors of reinfection.
Conclusion: Rates of HCV reinfection remain elevated among HIV-infected and uninfected MSM. Ongoing substance use is driving reinfection among HIV-negative MSM, while sexual transmission may be more important among HIV-positive MSM.

SAT-262

Long-term liver function outcome and related risk factors in HCV cirrhotic patients treated with direct-acting antiviral therapy: Results from the Navigatore platform in Veneto-Italy

Francesco Paolo Russo[1], Martina Gambato[1], Sara Piovesan[2], Antonietta Romano[3], Salvatore Lobello[4], sandro Panese[5], Veronica Paon[6], Bertin Tosca[7], Valter Vincenzi[8], Irene Franceschet[5], Caterina Pozzan[5], Paolo Angeli[3], Liliana Chemello[3], Franco Noventa[2], Giada Carolo[6], Annamaria Cattelan[9], Patrizia Burra[1], Alfredo Alberti[2]. Email: francescopaolo.russo@unipd.it

Background and aims: high efficacy and safety of direct acting antivirals (DAAs) allowed to eradicate also patients with HCV-related advanced liver disease. We aimed to report long-term clinical outcomes from a large real-life multicenter cohort of HCV-infected cirrhotic patients.
Method: all cirrhotic patients starting a DAA regimen with at least 48 weeks (wks) follow-up were included in the study. Data were prospectively entered at sites into a centralized database. Primary outcomes were the modification of Child-Pugh score (CP) at 12 and 48wks after the end of therapy (EOT), and the related risk factors of CP improving or worsening. Multiple linear and logistic regression were used to evaluate the association between the variables considered and the clinical outcomes.
Results: A total of 2232 patients with cirrhosis due to HCV started DAA between January 2015 to September 2018. At baseline, 2046 patients (91.6%) were CPA and 186 patients (8.4%%) were CPB. At 12wks after EOT, 20.3% of patients (n = 452) improved at least 1 point of CP, 75% (n = 1674) remained stable and 4.7% (n = 106) showed liver function worsening. Similar results were showed at 48wks after EOT. At the Univariate analysis, factors associated with statistically significant worsening of CP were:- in CP5-patients: lower level of AST/albumin/PLT and higher level of INR/bilirubin/high stiffness, the presence of obesity, digestive bleeding before treatment (at 12wks after EOT), and HCV-genotype 3, lower level albumin, higher level of INR/bilirubin (at 48wks after EOT)-in CP > 5-patients: higher level of bilirubin (12wks after EOT) and higher level of INR and HCVG2 (48wks after EOT). At the multivariate analysis, baseline bilirubin < 2.5 mg/dL (OR = 0.47), INR < 1.5 (OR = 0.25), Platelets count > 100.000/mm3 (OR = 0.63), older age (OR = 0.98) and sustained virological response (SVR)12 (OR = 0.53), were protective factors of CP worsening at 12wks after EOT, while AST < 100 IU/L (OR = 1.71) was a predictive factor of CP worsening at 12 wks after EOT. Still, INR < 1.5, older age and SVR12 (OR = 0.48), were confirmed to be protective factors for CP worsening at 48wks after EOT. Finally, considering only patients who could improve CP (CP > 5), INR < 1.5 was the only predictive factor of CP improvement (OR = 2.9 12wks EOT and OR = 3.8 48wks EOT).
Conclusion: only 5% of HCV-infected cirrhotic patients showed a worsening of liver function at 12 and 48wks after EOT with DAAs. Liver function tests, coagulation parameters and SVR positively influenced the outcome after EOT.

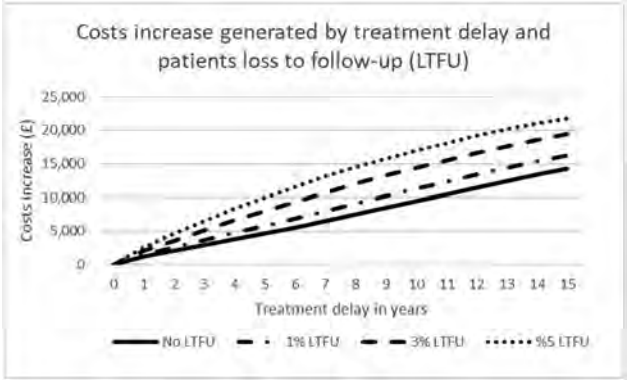
SAT-263

Immediate versus delayed hepatitis C treatment is cost-saving in the United Kingdom: A pan-genotypic cost-effectiveness analysis

John Dillon[1], Dominic Mitchell[2], Suchin Virabhak[2], Monika Hermansson[3], Svetlana Kalabina[3], Yuri Sanchez[4]. [1]*National Health Service (NHS), Tayside, United Kingdom;* [2]*Medicus Economics LLC, Boston, United States;* [3]*AbbVie Ltd, Maidenhead, United States;* [4]*AbbVie Inc., North Chicago, United States*
Email: j.dillon@nhs.net

Background and aims: Patients with hepatitis C virus (HCV) face increased healthcare costs due to hepatic and extrahepatic complications. While treatment has been shown to increase health benefits and reduce medical costs, it is often delayed for patients with early stages of liver disease. This study explored the clinical and economic burden of delaying treatment and the cost-effectiveness of immediate versus delayed treatment in the United Kingdom (UK).
Method: A Markov state transition model of the natural history of HCV was developed to forecast liver-related and economic outcomes over a lifetime from the UK National Health Service (NHS) perspective. Treatment attributes were based on clinical trials of glecaprevir (identified by AbbVie and Enanta) and pibrentasvir. Patient demographics as well as hepatic and extrahepatic costs were drawn from UK sources; transition probabilities and health state utilities were based on published literature. The analysis focused on the treatment of patients with HCV genotypes 1-6 and fibrosis stages

F0-F2 immediately versus later. In the base case, there was no patient loss to follow-up (LTFU) due to treatment delay. In scenario analyses, a proportion of the untreated but treatable cohort would be LTFU by 1%, 3% and 5% yearly. Health outcomes included lifetime risks of liver decompensation (DCC), hepatocellular carcinoma (HCC), liver transplantation (LT), and liver-related death (LrD). Other outcomes included total costs and quality-adjusted life years (QALYs) valued at £20, 000, and net monetary benefit (NMB), all discounted at 3.5% yearly. Regression analysis was performed to assess the impact of treatment delay and LFTU on NMB.
Results: Delaying treatment with glecaprevir/pibrentasvir increased long-term risks of DCC, HCC, LT, and LrD and total lifetime costs. For example, delaying treatment 5 years would cost £4, 666 more per patient vs immediate treatment, with 71% attributable nto extra-hepatic complications. Immediate treatment was a dominant strategy regardless of time of delay as it delivered more QALYs at lower costs. In regression analysis, NMB would decrease by £4, 236 (95% confidence interval: £4, 063-£4, 409) for every year treatment is delayed and by £3, 303 (£2, 888-£3, 717) per every 1% increase in LFTU.



Conclusion: Immediate versus delayed hepatitis C treatment decreased hepatic and extrahepatic costs and was a dominant strategy in the UK. Immediate treatment avoids the risk and burden of LFTU and maximizes the value of treatment to patients and payers.

SAT-264
Prediction of hepatocellular carcinoma development using liver stiffness after sustained virological responses by magnetic resonance elastography in patients with chronic hepatitis C
Nobuharu Tamaki[1], Mayu Higuchi[1], Masayuki Kurosaki[1], Shun Kaneko[1], Yutaka Yasui[1], Kaoru Tsuchiya[1], Hiroyuki Nakanishi[1], Jun Itakura[1], Namiki Izumi[1]. [1]*Musashino Red Cross Hospital, Department of Gastroenterology and Hepatology, Tokyo, Japan*
Email: tamaki@musashino.jrc.or.jp

Background and aims: It is unclear whether liver stiffness after sustained virological response (SVR) measured by magnetic resonance elastography (MRE) is useful for hepatocellular carcinoma (HCC) prediction. The aim of this study was to investigate the relationship between liver stiffness at 12 weeks after the end of treatment (SVR12) and subsequent HCC development.
Method: A total of 318 patients with chronic hepatitis C without history of HCC who achieved SVR through direct acting antivirals (DAAs) treatment and had been observed for more than 1 year were included. We initiated observation at the time of MRE measurement (SVR12), continued the observation for subsequent HCC development, and evaluated predictors for HCC development.
Results: Mean age 67.3 ± 10 years, 115 men (33%), 154 (48%) were FIB-4 > 3.25 at the time of DAAs start. 174 patients underwent liver biopsy before DAAs and 65 (37%) were METAVIR fibrosis stage 3/4. The mean observation period was 21.1 ± 6.7 months, and 23 patients developed HCC. For Receiver operating characteristic (ROC) analysis predicting HCC development within 2 years, 3.75 KPa was used as the cutoff value of liver stiffness. Comparing with liver stiffness and fibrosis stage or serum fibrosis markers, area under the ROC curve of liver stiffness, fibrosis stage at the DAA start, WFA+-M2BP at SVR12, and FIB-4 at SVR12 were 0.73, 0.61, 0.68, and 0.63, respectively and area under the ROC was highest in liver stiffness by MRE. The 1-year and 2-year HCC development rates were 6.9% and 13.6% for patients with liver stiffness ≥ 3.75 KPa and were 1.5% and 2.8% for patients with liver stiffness < 3.75 KPa ($p < 0.001$). Univariate analysis revealed that liver stiffness ≥ 3.75 KPa, age every 10 years, AFP ≥ 6.0 ng/ml, and presence of hypovascular nodule were associated with HCC development. In the multivariate analysis, liver stiffness ≥ 3.75 KPa [hazard ratio (HR), 2.97; 95% confidence interval (CI), 1.04-8.62], age every 10 years (HR, 1.97; 95% CI, 1.17-3.29), AFP ≥ 6.0 ng/ml (HR, 2.44; 95% CI, 1.03-5.78), and presence of hypovascular nodule (HR, 3.88; 95% CI, 1.36-11.1) were independent predictive factors of HCC development.
Conclusion: Liver stiffness measured by MRE at SVR12 in patients with chronic hepatitis C who achieved SVR following DAAs treatment is a predictive factor of HCC development. MRE was able to identify patients with high risks of HCC even after SVR was achieved.

SAT-265
Anti-VHC therapy does not increase de risk of developing splanchnic vein thrombosis in patients with cirrhosis
Fanny Turon[1,2], Claudia Berbel[1], Sabela Lens[1,2], Anna Baiges[1], José Ferrusquia[1], Marta Magaz[1], Zoe Mariño[1,2], Virginia Hernandez-Gea[1,2], Garcia Pagan Juan Carlos[1,2]. [1]*Hospital Clinic Barcelona. IDIBAPS. University of Barcelona., Barcelona Hepatic Hemodynamic Laboratory. Liver Unit, Barcelona, Spain;* [2]*CIBERehd., Barcelona, Spain*
Email: jcgarcia@clinic.cat

Background and aims: Splanchnic vein thrombosis (PVT) is a frequent event in the natural history of cirrhosis with an incidence of 4-16% per year. Several factors have been associated with its development such as portal velocity < 15 cm/s or advanced liver disease. Recently, it has been suggested that in patients with HCV cirrhosis, direct-acting antiviral (DAA) oral treatment-induced sustained virological response (SVR) may have an increased risk of PVT associated with a potential overcorrection of the coagulopathy after treatment. Thus, the aim of the study was to evaluate the incidence of PVT in patients with HCV-cirrhosis (active infection and DAA-induced SVR).
Method: 579 cirrhotic patients without PVT followed in our hospital were included: 210 with active HCV infection followed between Dec2010 and Apr2013 and 369 with DAA-induced SVR followed between Oct2012 and Dec2016. 74 patients from the active infection group received antiviral treatment before Apr2013 and were censored from the analysis on the day of its initiation and were not included thereafter in DAA-induced SVR group. All patients underwent an abdominal ultrasound every 6 months for PVT screening. In the DAA-induced SVR group, clinical and biochemical variables included in the analysis were those immediately prior to the start of DAA treatment. Competitive risk analysis was used for the statistical analysis.
Results: Of the 579 patients, 53% were men, mean age 61 ± 10 years, Child-Pugh A/B/C 83/15/2%, MELD 9 ± 3. At inclusion, 20% had presented ascites, 6% hepatic encephalopathy, 48% had esophageal varices (EV), 7% previous upper gastrointestinal bleeding (UGB), 25% were under β-blockers prophylaxis, 7% with previous endoscopic band ligation. The mean follow-up was 2.8 ± 1.2 years. 24 patients presented PVT during follow-up with an incidence of 1.5, 2.3 and 4.1% at 1, 2 and 3 years. Transplant-free survival was 97.4, 95.2 and 89.9% at 1, 2 and 3 years respectively. In a competitive risk analysis in a model adjusted for sex, Child-Pugh, creatinine, platelets, presence of EV, previous UGB, β-blocker treatment and active infection/DAA-induced

SVR, the only independent factor associated with the development of PVT was Child-Pugh (HR 1.37 [1.09-1.71; p = 0.005).
Conclusion: DAA-induced SVR does neither increase nor decrease the risk of PVT during follow-up in HCV cirrhosis. Therefore, despite achieving SVR, patients should be kept on PVT surveillance, especially patients with advance liver disease and deteriorated liver function.

SAT-266

High rates of early HCV reinfections after DAA therapy in active intravenous drug users attended at mobile harm reduction units

Jorge Valencia [1,2], Alejandro Alvaro-Meca[3], Guillermo Cuevas[4], Jesús Troya[4], Angela Morro[1], Jorge Gutiérrez[5], Ismael Escobar[6], Jorge Alvarez[2], Irene Cañamares[6], Pablo Ryan[4]. *[1]Mobile harm reduction Unit "SMASD", General Subdirectorate of Addiction Services, Madrid, Spain; [2]Mobile harm reduction Unit MADROÑO, Addiction Institute, Madrid, Spain; [3]Rey Juan Carlos University, Bioestatistical deparment, Madrid, Spain; [4]Infanta Leonor Hospital, Internal Medicine, Madrid, Spain; [5]NGO Madrid Positivo, Madrid, Spain; [6]Infanta Leonor Hospital, Pharmacy Service, Madrid,*
Email: jorge_vlr@yahoo.es

Background and aims: The WHO has recently called for hepatitis C virus (HCV) elimination and has identified injecting drug users (IDU) as a key population. Clinical trials of currently available all-oral regimens have demonstrated a high degree of efficacy in this population. Current HCV reinfections rates in IDU are < 6/100-person years (PY). There is an urgent need to confirm these data in clinical practice.
The aims of this study were to evaluate the efficacy of HCV therapy and the HCV reinfection rate in active drug users followed at low-threshold mobile harm reduction units (LTMHRU).
Method: We included active drug users (persons who smoked or injected heroin/cocaine in the last 6 months) who received HCV treatment and were attended at 2 LTMHRU in Madrid between Jan/2016 and Jul/2018. Sustained virological response (SVR12) was assessed 12 weeks after therapy. HCV reinfection incidence density was defined as the number of reinfections per 100-person years (PY) using person-time of observation and was stratified by drug consumption at initiation of HCV treatment. Cox proportional hazard regression analysis was used to assess factors associated with HCV reinfection.
Results: In the study period 165 drug users started HCV therapy. Intravenous drug use in the last 6 months was reported in 74% of the drug users. Of those who started therapy in abstinence, 65% relapsed drug consumption during follow-up. The overall SVR12 rate was 64.8% (107/165) (ITT, reinfection = failure) and 96.7% (117/121) (mITT). SVR12 was irrespective of the HIV and baseline active consumption status. There were 4 virological failures. The cohort at-risk for reinfection (n = 121) was composed of 44.2% HIV positive and 49.6% drug users who initiated HCV treatment in abstinence. Ten cases (10/121) of HCV reinfection (3 before EOT and 7 after SVR12) were identified and the median time to reinfection was 6.1 (IQR 0.42-1.8) months. Total follow-up time at-risk was 101.1-PY (median 0.6 years, IQR 0.3-1.3). The global reinfection incidence was 9.8 per 100-PY (95% CI 4.7, 18.2). Reinfection incidence was not statistical different according to HIV status: HIV positive [11.0 (95% CI 4.0; 23.9)] and HIV negative [8.6 (95% CI 2.3; 21.9)] per 100 PY; or baseline active consumption: no consumption [9.1 (95% CI 2.9; 21.3)] and consumption [10.8 (95% CI 3.5; 25.2)] per 100- PY; p 0.79. However, the reinfection incidence was higher amongst those who reported injected drug use in the previous six months: 16.7 (95%CI 8.0; 30.7) per 100-PY. In adjusted analysis, the unique factor associated with reinfection was injection drug use in the previous month at baseline (aHR 8.7, 95%CI 1.0-73.6; p 0.04).
Conclusion: HCV treatment was effective in active drug users attended at LTMHRU. We found a very high rate of early HCV reinfections in active IDU in this setting. Surveillance for reinfection at 6–month intervals should be implemented in this population.

SAT-267

Occult hepatitis C in immunocompetent patients who have achieved sustained viral response is associated with persistent histological abnormality

Yijin Wang[1], Huiying Rao[2], Xiumei Chi[3], Junqi Niu[3], Lai Wei[2], Jingmin Zhao[1]. *[1]Beijing 302 hospital, Beijing, China; [2]Peking University Hepatology Institute, Beijing, China; [3] The First Hospital of Jilin University, Changchun, China*
Email: jmzhao302@163.com

Background and aims: Whether achieving sustained virological response (SVR) in patients with HCV infection after Direct-acting antiviral agents (DAA) treatment means complete viral eliminationin is uncertain because occult HCV infection (OCI), defined by the presence of HCV RNA in liver tissues or PBMC whose serum is constantly negative for HCV RNA with or without presence of HCV antibodies, may occur. We thus investigated the prevalence and clinical relevance of OCI.
Method: Subjects from three tertiary hospitals who had achieved serum HCV clearance, including 60 of DAA induced SVR, 50 of peg-IFN plus ribavirin (PR) induced SVR, and 30 of spontaneous elimination (SE), were subjected to detect HCV RNA in hepatocytes by RNAscope in situ hybridization assay, and in PBMC by qPCR. All the subjects are immunocompetent. Paired liver biopsies of baseline and post-SVR were evaluated by Ishak scoring system.
Results: Fig.1A is an representative image of RNAscope assay for detecting HCV RNA in liver biopsy of an OCI patient before and after treatment. In total, OCI was detected in 16 subjects (11.4%): nine (15.0%) in the DAA-based group, five (10.0%) in the PR group, and two (6.7%) in the SE group (Fig.1B-E). HCV negative strand were detected in all PBMCs of patients with OCI. Intriguingly, the proportion of OCI was found higher in peg-IFN-free (solely DAA or DAA plus RBV) treated individuals than in patients who received PR treatment with or without combination of DAA (Fig. 1F). The occurrence of OCI is more frequent in patients with HCV genotype 3. No correlation between baseline viral load, interleukin-28B genotype, baseline transaminases, post-SVR transaminases and OCI were found. However, OCI was significantly linked with poor fibrosis status at post-SVR (Fig.2A-B). In addition, we found the fibrosis was significantly improved only in patients without OCI (p < 0.001), but not in OCI subjects (p = 0.385) after adjusted for fibrosis status at baseline, implying a role of OCI in persisting hepatic abnormality. Furthermore, we found only five of 14 (35.7%) OCI patients showed fibrosis regression at post-SVR and the remaining nine OCI patients exhibited either stabilization or worsening of liver fibrosis stage, whereas the frequency of fibrosis regression was 61.0% in non-OCI patients at post-SVR (p = 0.07). Together, these results revealed that patients with OCI reflected a trend towards persisting liver alteration. Importantly, we found HCV relapse in one of the OCI patients at 48 weeks after the end of PR treatment.
Conclusion: HCV RNA can persist in a certain of immunocompetent patients with DAA induced serum resolution of hepatitis C and associated with persistent hepatic abnormality. From a clinical perspective, our findings provide new insights into cure of HCV and could influence the following-up scenario after SVR.

SAT-268

Non-invasive prediction of gastroesophageal varies by serum wisteria floribunda agglutinin positive Mac-2 binding protein and FIB-4 index in chronic hepatitis C

Keiya Watakabe[1], Nobuharu Tamaki[1], Sakura Kirino[1], Leona Osawa[1], Wang Wan[1], Mao Okada[1], Takao Shimizu[1], Mayu Higuchi[1], Kenta Takaura[1], Shun Kaneko[1], Kaoru Tsuchiya[1], Hiroyuki Nakanishi[1], Jun Itakura[1], Masayuki Kurosaki[1], Namiki Izumi[1]. *[1]Musashino red cross hospital, musashino city, Tokyo, Japan*
Email: wkkya1234567@gmail.com

Background and aims: The aim of this study is to clarify the value of serum fibrosis marker for the non-invasive prediction of

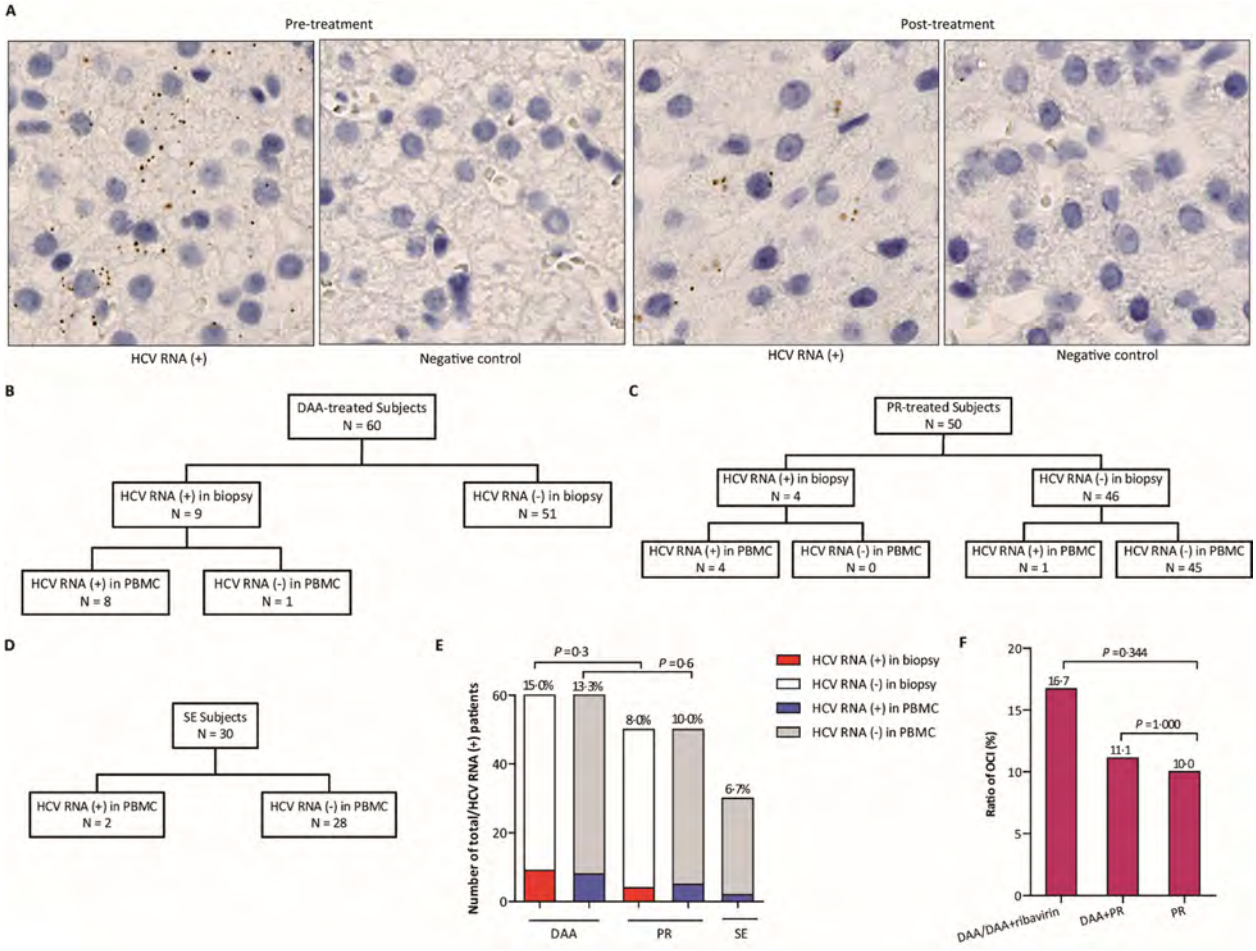


Figure 1: (abstract: SAT-267)

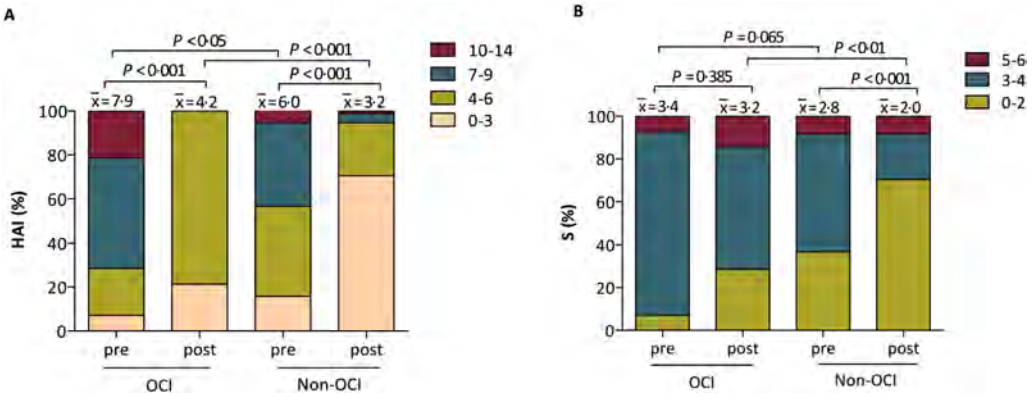

Figure 2: (abstract: SAT-267)

gastroesophageal varices (GEV) in patients with chronic hepatitis C and in those who achieved sustained virological responses (SVR) by direct acting antivirals (DAAs) therapy.

Method: This study involved 166 patients with chronic hepatitis C and 65 patients who achieved SVR by DAAs. Screening of GEV by endoscopy was performed and serum wisteria floribunda agglutinin positive Mac-2 binding protein (WFA+-M2BP), a novel serum biomarker which correlatie with liver fibrosis, was measured along with various laboratory data. The accuracy of serum markers for the prediction of the presence of GEV was examined.

Results: Among chronic hepatitis C, patients with GEV had significantly higher level of serum WFA+-M2BP (3.4 ± 3.0 vs. 10.2 ± 4.7, $p < 0.0001$) and FIB-4 index (4.9 ± 3.3 vs. 10.4 ± 7.2, $p < 0.0001$) compared to those without. The AUROC for the presence of GEV was 0.90 for WFA+-M2BP and 0.86 for FIB-4 index. By using the optimal cut off value of 6.0 for WFA+-M2BP and 6.0 for FIB-4 index, sensitivity and specificity for GEV prediction was 87% and 79% for WFA+-M2BP, and 72% and 79% for FIB-4 index, respectively. Serum WFA+-M2BP increased along with the grade of GEV: 3.4 ± 3.0 in no varices, 7.9 ± 5.1 in small varices, and 11.5 ± 4.1 in large varices ($p < 0.001$). Among

patients after SVR, patients with GEV had significantly higher level of serum WFA+-M2BP (1.6 ± 1.4 vs. 3.0 ± 1.6, p = 0.0007) and FIB-4 index (2.8 ± 1.8 vs. 5.9 ± 3.1, p < 0.0001) compared to those without. AUROC for the presence of GEV was 0.80 for WFA+-M2BP and 0.86 for FIB-4 index, and the optimal cut off value was 1.58 for WFA+-M2BP and 3.35 for FIB-4 index, which was lower compared to the optimal cut off value in chronic hepatitis C. Sensitivity and specificity and positive predictive value for GEV prediction was 76%, 84%, and 82%for WFA+-M2BP, and 82%, 84%, and 83% for FIB-4 index. The positive predictive value was 85% if WFA+-M2BP and FIB-4 index was combined.

Conclusion: Serum WFA+-M2BP and FIB-4 index had satisfactory accuracy to predict GEV, and may be utilized in clinical practice to define patients who need endoscopy. On the other hand, it is important to recognize that the optimal cut off values of these markers are different between patients with on-going hepatitis C infection and those who achieved SVR.

SAT-269

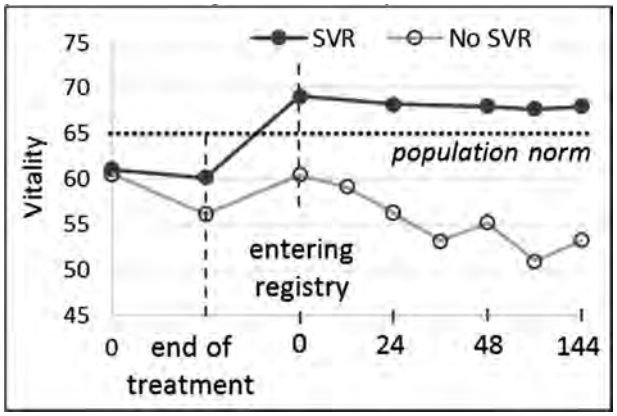
The sustained deleterious impact of viremia on patient reported outcomes in patients with chronic hepatitis C who don't achieve sustained virologic response

Zobair Younossi[1,2], Maria Stepanova[3], Andrei Racilla[3], Arian Afendy[3], Ira Jacobson[4], Andrew Muir[5], Stanislas Pol[6], Stefan Zeuzem[7], Eric Lawitz[8], Anuj Gaggar[9], Robert Myers[9], Issah Younossi[3], Fatema Nader[3]. *[1]Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, United States; [2]Center for Liver Diseases-, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, United States; [3]Center for Outcomes Research in Liver Disease, Washington DC, United States; [4]NYU Langone Health, New York, United States; [5]Duke Clinical Research Institute, Durham, United States; [6]Hopital Cochin, Universite Paris Descartes, Paris, France; [7]Universitatsklinikum, Frankfurt, Germany; [8]Texas Liver Institute, University of Texas, San Antonio, United States; [9]Gilead Sciences, Foster City, United States*
Email: zobair.younossi@inova.org

Background and aims: Although improvement of PROs in CHC patients who achieve SVR with direct-acting antivirals (DAAs) has been demonstrated, PROs of CHC patients who failed to achieve SVR with new DAAs have not been documented. AIM: Compare post-treatment PRO scores between CHC patients who did and did not achieve SVR after DAA treatment.

Method: Patients who had completed treatment in a clinical trial were prospectively enrolled in two registries based on treatment outcomes: the SVR Registry and Non-SVR Registry. PRO scores were prospectively collected using the Short Form-36 (SF-36) every 12-24 weeks.

Results: There were 4, 234 patients with SVR and 242 without SVR who were enrolled in these two registries and had pre-treatment PRO data: 54 ± 10 years old, 63% male, 83% white, 65% enrolled in the U.S., 17% with cirrhosis prior to treatment, 12% with coinfection with HIV, and 25% with history of depression. Upon registry enrollment, patients with SVR experienced significant improvement in all their PRO scores in comparison to their own pre-treatment baseline scores (all p < 0.0001) while there was no improvement in any PRO score (all one-sided p > 0.05) and, in fact, a significant decrement in General Health of SF-36 (mean −2.8 points, p = 0.008) in CHC patients without SVR. Furthermore, CHC patients without SVR experienced significant PRO decrements while followed on the registry (up to −7.0 points decrements in 4/8 SF-36 domains at registry week 12; up to −9.2 points in all 8 domains at week 24; up to −8.3 points in 5/8 domains at week 48, and up to −9.0 points in 4/8 domains at week 96 (all p < 0.05). In contrast, patients with SVR experienced sustained improvement of their PRO scores while on the registry (up to +7.0 points at registry week 24, up to +6.9 points at week 48, up to +6.1 points at week 96 (all p < 0.001) (Figure). In multivariate analysis, having achieved SVR was independently associated with superior scores in all SF-36 domains at all registry time points: beta from +4.8 to +14.9 points (all p ≤ 0.01). PRO scores were lower and their decrements were greater in cirrhotics without SVR than non-cirrhotic without SVR (p < 0.05).



Conclusion: These data clearly show the benefit of achieving SVR for patients' well-being which is contrasted to the deleterious impact of viremia (not achieving SVR). These data should inform payers and policy makers to remove any barriers to HCV treatment which could lead to the cure and reduce patients' suffering and PRO impairment.

NAFLD: Diagnostics and non-invasive assessment

SAT-271

Genetic risk factors for advanced alcoholic and non-alcoholic liver disease in the general population

Fredrik Åberg[1,2], Pauli Puukka[3], Perttu Sahlman[4], Markku Nissinen[4], Veikko Salomaa[3], Satu Männistö[3], Annamari Lundqvist[3], Markus Perola[3], Antti Jula[3], Martti Färkkilä[4]. *[1]Sahlgrenska University Hospital, Transplant Institute, Gothenburg, Sweden; [2]Helsinki University and Helsinki University Hospital, Transplantation and Liver Surgery Clinic, Helsinki, Finland; [3]National Institute for Health and Welfare, Helsinki and Turku, Finland; [4]Helsinki University and Helsinki University Hospital, Abdominal Center, Clinic of Gastroenterology, Helsinki, Finland*
Email: fredrik.aberg@helsinki.fi

Background and aims: Several genetic risk variants associated with liver disease have been identified, but their importance in the general population is uncertain. Recent EASL guidelines considered the study of susceptibility genes in alcoholic liver disease a research priority. We analyzed associations of selected genetic variants with incident advanced liver disease in the general population, and separately in non-alcoholic fatty liver disease (NAFLD) and alcohol risk users.

Method: We included individuals participating in Finnish health-examination surveys (FINRISK 1992-2012 or Health 2000) with available genome-wide SNP data. NAFLD was defined as a fatty-liver index > 60 and alcohol use < 30 g/day for men and < 20 g/day for women; alcohol risk use was defined as consumption exceeding these limits. Exclusions were known baseline liver disease or viral hepatitis. Data were linked with national registers for liver-related admissions, mortality, and liver cancer until 2013. Selected genetic variants with reported association with liver disease were individually entered into a Cox regression analysis adjusted for age and sex, with incident advanced liver disease (admission, death, cancer) as the outcome.

Results: The whole study population comprised 32, 939 subjects, 6397 of them with baseline NAFLD and 3336 with alcohol risk use. Carrier frequency of all tested genotypes were similar across these groups. In the whole cohort, PNPLA3 and TM6SF2 genotypes were significantly associated with incident advanced liver disease (Table). In NAFLD subjects, TM6SF2 and the Z allele of α1-antitrypsin (A1AT) deficiency were borderline significant. Among alcohol risk users, only PNPLA3 rs738409 was significant.

	All subjects	NAFLD	Alcohol risk users
Gene variant	**HR (95% CI)**	**HR (95% CI)**	**HR (95% CI)**
PNPLA3 rs738409	**1.56 (1.24-1.97)**	1.12 (0.75-1.68)	**1.62 (1.16-2.87)**
TM6SF2 rs58542926	**1.47 (1.07-2.01)**	**1.66 (0.99-2.77)**	1.39 (0.88-2.19)
MBOAT7 rs641738	1.13 (0.94-1.61)	1.29 (0.78-2.12)	1.01 (0.70-1.47)
HFE C282Y rs1800562	0.75 (0.45-1.27)	0.42 (0.13-1.32)	0.83 (0.40-1.69)
HFE H63D rs1799945	0.90 (0.66-1.22)	0.94 (0.56-1.59)	0.80 (0.52-1.23)
A1AT S-allele rs17580	0.27 (0.04-1.92)	too few events	too few events
A1AT Z-allele rs28929474	1.52 (0.90-2.55)	**2.13 (0.99-4.60)**	1.27 (0.56-2.88)

Conclusion: Carriers of the PNPLA3 variant have approximately 50-60% higher risk of incident advanced liver disease than non-carriers. TM6SF2 genotype was significant in all subjects and NAFLD. A1AT Z-allele may be relevant in NAFLD subjects. On a population level, none of the other genotypes tested showed significant impact on the risk for incident advanced liver disease.

SAT-272

A simple algorithm based on electronic medical records to identify NAFLD with advanced fibrosis in patients with Type 2 diabetes

Naim Alkhouri[1], Amandeep Singh[2], Mazen Noureddin[3]. [1]*Texas Liver Institute, San Antonio, TX, United States;* [2]*Cleveland Clinic, Cleveland, OH, United States;* [3]*Cedars Sinai Medical Center, Los Angeles, CA, United States*
Email: alkhouri@txliver.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) remains undiagnosed in the majority of patients even those with advanced fibrosis at highest risk for liver-related morbidity and mortality. With the anticipated approval of potent anti-inflammatory and anti-fibrotic medications, the major barrier to getting patients on effective treatment will be identifying appropriate patients with advanced disease that requires pharmacologic intervention. The aim of this study was to assess the utility of using simple steatosis and fibrosis scores to identify NAFLD-advanced fibrosis in patients with type 2 diabetes (T2DM) within a large electronic medical record (EMR) database.
Methods: All adult patients with a diagnosis of T2DM were identified from EMR using ICD-9 codes. Patients with other causes of chronic liver disease and those on steatogenic drugs were excluded. Baseline demographics, clinical characteristics, and laboratory data were collected. NAFLD was defined as hepatic steatosis index (HSI) > 36. Advanced fibrosis was defined as FIB-4 index > 2.67. A univariable and a multivariable logistic regression analysis were done to further assess which clinical factors are associated with advanced fibrosis. A p value < 0.05 was considered statistically significant.
Results: Of total of 121, 513 diabetic patients were included in the final analysis, 51% were male with a mean age of 62 years, 76% were White and 21% were Black. Overweight or obesity were present in 89% and the mean hemoglobin A1C was at 7.3 ± 4.3% with 26% of patients being on insulin. In total, 12.7% had chronic kidney disease and 64.6% had evidence of dyslipidemia. NAFLD based on HSI > 36 was present in 102, 628 patients or 84% of the total cohort and advanced fibrosis based on FIB-4 index > 2.67 was present in 9%. Factors associated with the presence of advanced fibrosis on multivariable analysis were chronic kidney disease, coronary artery disease, being on insulin, and not being on statins.
Conclusion: By using simple scores that rely on readily available clinical variables, patients with advanced fibrosis related to NAFLD can be identified easily. These strategies should be implemented as screening tools in large EMR databases to prioritize patients for referral and treatment of their liver disease.

SAT-273

Impact of age on routinely available non-invasive tests for the discrimination of advanced fibrosis due to NASH in the phase 3 STELLAR trials of the ASK1 inhibitor selonsertib

Email: stephen.djedjos@gilead.com

Background and aims: Routinely available non-invasive tests (NITs) have been shown to be able to identify patients with advanced fibrosis due to NASH, but their performance may vary by age. Our aim is to describe the performance of NITs across age groups using the baseline data from the Phase 3 STELLAR studies of the apoptosis-signal regulating kinase 1 (ASK1) inhibitor selonsertib (SEL).
Method: The STELLAR studies (NCT03053050 and NCT03053063) enrolled patients 18-70 years with bridging fibrosis (F3) or compensated cirrhosis (F4) due to NASH (NAFLD Activity Score [NAS] ≥ 3). Baseline liver biopsies were centrally read according to the NASH CRN fibrosis classification and non-invasive markers of fibrosis, including the NAFLD fibrosis score (NFS), Fibrosis-4 (FIB-4) index, Enhanced Liver Fibrosis (ELF) test, and liver stiffness (LS) by transient elastography (TE; FibroScan®) were measured. The performance of these tests to discriminate advanced (F3-F4) fibrosis in the full study population and in age strata (18-39, 40-64, and ≥ 65 years) was evaluated using AUROCs with 5-fold cross-validation repeated 100x.

Table: AUROCs (95% CI) of NITs to Discriminate Advanced Fibrosis (F3-F4) by Age Group

NIT	Total (n = 3202)	18-39 years (n = 190)	40-64 years (n = 2285)	≥ 65 years (n = 727)
NFS (n = 2417)	0.74 (0.74, 0.74)	0.74 (0.72, 0.74)	0.75 (0.75, 0.75)	0.68 (0.67, 0.68)
FIB-4 (n = 3123)	0.78 (0.78, 0.78)	0.69 (0.68, 0.70)	0.78 (0.78, 0.78)	0.74 (0.74, 0.75)
ELF (n = 3173)	0.80 (0.80, 0.80)	0.74 (0.73, 0.75)	0.79 (0.79, 0.79)	0.76 (0.76, 0.77)
LS by TE (n = 1765)	0.80 (0.79, 0.80)	0.74 (0.73, 0.75)	0.82 (0.81, 0.82)	0.59 (0.53, 0.69)

Results: A total of 3202 patients with evaluable liver histology were screened (median age, 59 years), including 190 aged 18-39 years, 2285 aged 40-64 years, and 727 older than 65 years. The prevalence of advanced fibrosis was71% overall, and varied substantially by age category (18-39: 45%; 40-64: 70%; ≥ 65 years: 80%; p < 0.0001). AUROCs for NITs to discriminate advanced fibrosis were generally similar across age groups except for somewhat lower performance (AUROC < 0.7) for FIB-4 in the 18-39 year old group, and NFS and LS by

TE in subjects ≥ 65 years (**Table**). In general, optimal thresholds for sensitivity and specificity across the total population demonstrated reduced sensitivity in younger patients and reduced specificity in older patients.

Conclusion: In these large, global phase 3 trials of SEL, routinely available NITs demonstrated acceptable diagnostic performance for the discrimination of advanced fibrosis due to NASH, but age-specific thresholds in younger or older patients may be required to optimize sensitivity and specificity.

SAT-274

Repeatability and reproducibility of multiparametric magnetic resonance imaging of the liver in children

Daniel Halliday[1], Hayley Simpson[1], Andrea Borghetto[1], Henry Wilman[1], Velicia Bachtiar[1], Matt Kelly[1]. [1]*Perspectum Diagnostics, Oxford, United Kingdom*
Email: velicia.bachtiar@perspectum-diagnostics.com

Background and aims: Hepatic multiparametric MRI, Liver*MultiScan*™, for quantitative analysis of Proton Density Fat Fraction (PDFF) and iron-corrected T1 (cT1) has been shown to have excellent repeatability and reproducibility in adults. Non-invasive MR-based biomarkers of liver inflammation and fibrosis has shown considerable utility in clinical trials and will have important implications on the delivery of paediatric investigation plans. We test the repeatability and reproducibility of the Liver*MultiScan*™ protocol to measure PDFF and cT1 across field strengths in a cohort of healthy children.

Method: cT1, T2* and Proton Density Fat Fraction (PDFF) maps were acquired from 33 healthy children volunteers (aged 6-18 years, mean 11; 16 male) without a reported history of liver disease. Each participant completed four same-day acquisitions of the Liver*MultiScan*™ protocol that comprised of a scan-rescan on a 1.5 T (Aera, E11C, MyoMaps) and a 3 T (Skyra, E11C, MyoMaps) Siemens scanner (Siemens Healthineers). Participants left the scanner after each scan and the order of scanner was counterbalanced.

Results: There was high reproducibility across different scanner models and field strengths for both cT1 (CoV 2.90%; bias 24.8 ms, 95% LoA of −23.8 ms to 73.4 ms) and PDFF (CoV 22.7%; bias 0.271%, 95% LoA of −1.35% to 1.90%). Bland-Altman analysis of the intra-rater differences also showed good repeatability for cT1 at 3 T (Cov 4.37%; bias 0.0712 ms, 95% LoA of −3.67 ms to 3.82 ms) and 1.5 T (Cov 2.23%; bias −16.9 ms, 95% LoA of −67.7 ms to 34.0 ms). Similar findings were shown in PDFF at 3 T (Cov 15.7%; bias 0.147%, 95% LoA of −1.43% to 1.72%) and 1.5 T (Cov 11.6%; bias 0.0443 ms, 95% LoA of −0.838% to 0.927%).

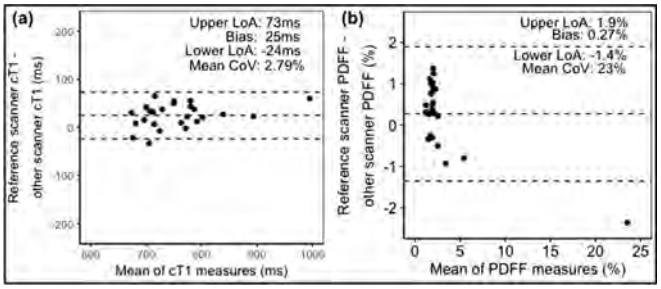

Figure: Bland-Altman plots from in-vivo measurements in children across field strength for (a) cT1 and (b) PDFF.

Conclusion: We demonstrate that multiparametric MRI is a non-invasive, repeatable, and reproducible method for quantifying liver tissue characteristics in children. This has future implications on the clinical utility of non-invasive methods in monitoring of liver disease in children and the delivery of paediatric investigation plans in clinical trials.

Email: guido.baselli@unimi.it

Background and aims: Efforts to manage non-alcoholic fatty liver disease (NAFLD) are limited by the absence of accurate non-invasive biomarkers. The rs738409 C > G polymorphism encoding for the I148M variant in Patatin-like phospholipase domain-containing 3 (*PNPLA3*) is the main genetic determinant of NAFLD variability. Aim of this study was to identify novel NAFLD biomarkers and to explore how the presence of *PNPLA3* I148M variant impacts on hepatic gene expression in obese patients at risk of NAFLD.

Method: Transcriptomic analyses were conducted in 125 liver-biopsied obese individuals. "Severe NAFLD" was defined by the presence of steatohepatits, NAFLD activity score ≥ 4, or fibrosis stage ≥ 2. RNA was sequenced using an HiSeq 4000. Reads were aligned and counted by STAR and RSEM. Differential gene and pathways expression were assessed by DESeq2 and GSEA. Plasma IL32 was measured in 71 obese patients by ELISA.

Results: Presence of *PNPLA3* I148M variant was the main feature associated with the two main components of hepatic transcriptome variability and was linked with overexpression of pathways related to inflammation and carcinogenesis. Consistently with impaired lipid turnover in intracellular droplets, the presence of *PNPLA3* I148M variant was also associated with downregulation of lipid metabolism. In patients with severe NAFLD, inflammatory and lipid metabolism pathways were upregulated. At the single gene level, in the severe NAFLD group Interleukin-32 (IL32) was the most robustly upregulated gene (log_2 fold change = 1.36 ± 0.21, adjusted $p = 1*10^{-6}$), and its expression correlated with steatosis severity. Remarkably, the association of IL32 transcript levels with NAFLD was more marked in *PNPLA3* I148M variant carriers.

Plasma IL32 levels were strongly correlated with hepatic gene expression and were associated to both NAFLD and severe NAFLD independently of serum aminotrasferases ($p < 0.01$ both). A combined score encompassing evaluation of IL32-ALT-AST showed a better performance than ALT-AST alone in NAFLD diagnosis (AUC = 0.85 vs. 0.72, p = 0.01). The IL32-ALT-AST classifier tended to perform better in *PNPLA3* I148M variant carriers (AUC = 0.92 vs 0.78, p = 0.06).

Conclusion: These results give insight into the liver transcriptional response associated with NAFLD in obese individuals, underscoring the role of *PNPLA3* I148M variant as a major determinant of transcriptome variability. Moreover, we highlight IL32 as a novel potential biomarker for early NAFLD diagnosis, showing high accuracy in *PNPLA3* I148M variant carriers.

SAT-276

Point shear wave elastography by ElastPQ accurately stages hepatic fibrosis in patients with NAFLD: A prospective, multicentric study

David JM Bauer[1], Dr. Vladimir Matic[2], Dr. Ruxandra Mare PhD[3], Dr. Laura Maiocchi[4], David Chromy[1], Theresa Bucsics[1], Sanda Mustapic[2], Ioan Sporea[3], Giovanna Ferraioli[4], Thomas Reiberger[1], Ivica Grgurevic[2]. *[1]Medical University of Vienna, Dept. of Gastroenterology and Hepatology, Vienna, Austria; [2]University Hospital Dubrava, University of Zagreb School of Medicine, Department of Gastroenterology, Hepatology and Clinical Nutrition, Zagreb, Croatia; [3]Victor Babes University of Medicine and Pharmacy, Dept. of Gastroenterology and Hepatology, Timișoara, Romania; [4]University of Pavia, Department of Diagnostic, Paediatric, Clinical and Surgical Science, Pavia, Italy*
Email: david.bauer@meduniwien.ac.at

Background and aims: We face a global epidemic of non-alcoholic fatty liver disease (NAFLD). Vibration-controlled transient elastography (VCTE) represents an accurate non-invasive screening tool for significant fibrosis. Limited evidence for the clinical applicability of point shear wave elastography (pSWE) techniques in NAFLD available.

Method: In this prospective, multicentric study (Vienna, Pavia, Timisoara, Zagreb) we performed liver stiffness measurements (LSM) both by VCTE and by pSWE (ElastPQ®, Philips) in NAFLD patients. Paired LSM were assessed for Pearson correlation and Lin's concordance correlation coefficient (CCC). Diagnostic performance was assessed using VCTE as a reference standard and calculating the area under receiver operator characteristics curves (AUROC) for pSWE. Optimal cutoffs for significant fibrosis (≥ F2) and cirrhosis (F4) were evaluated based on the Youden index. Patients with VCTE = 75kPa were excluded for assessment of linear correlation and CCC.

Results: 280 paired measurements were obtained. While 216 meet the reliability criteria-defined as (VCTE IQR/Median ≤ 30% and ElastPQ IQR/Median ≤ 30%) OR (VCTE ≤ 7kPa AND ElastPQ ≤ 7kPa), n = 6 additional patients with ascites and VCTE = 75kPa but discordantly low (< 1kPa) or high (> 150kPa) ElastPQ results had to be excluded despite meeting reliability criteria.

Among a final cohort of n = 210 patients, median age (IQR) and BMI (IQR) were 59 (18) years and 28.9 (7.0) kg/m^2, respectively. Most patients were male (132, 62.9%), 51 (24.3%) patients had significant

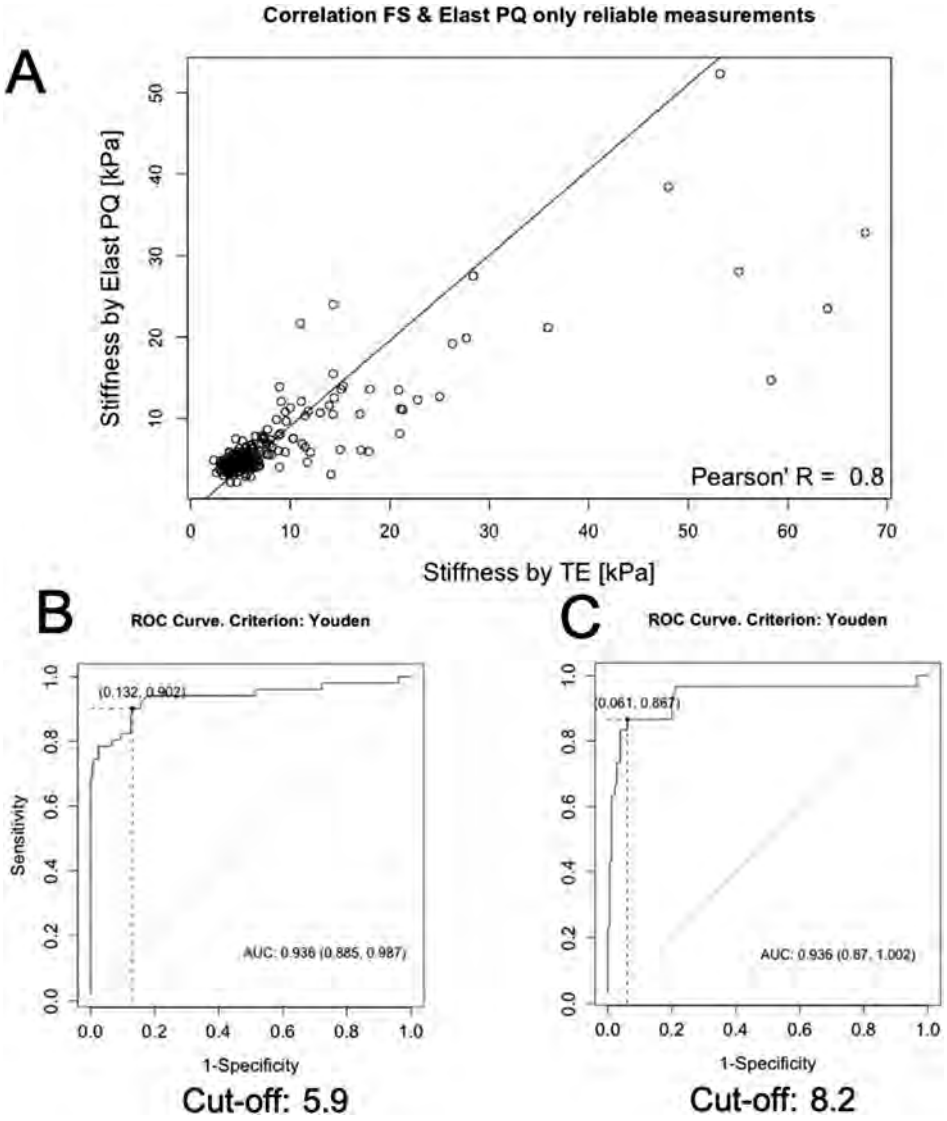

Figure 1: (abstract: SAT-276): A) Correlation of all reliable paired measurements. B) ROC Curve of optimal Youden cut-off for significant fibrosis. C) ROC Curve of optimal Youden cut-off for severe fibrosis

fibrosis (≥ F2, VCTE ≥ 8.5 kPa), while 30 (14.3%) had cirrhosis (F4, VTCE ≥ 12.5kPa). Overall the Pearson correlation between reliable measurements of VCTE and ElastPQ was r = 0.84. The overall CCC was 0.72. We determined an optimal ElastPQ cut-off for significant fibrosis at 6.0 kPa (≥ F2 AUROC 0.936, Se = 0.901, Sp = 0.869) and for cirrhosis at 8.2 kPa (F4 AUROC: 0.94, Se = 0.86, Sp = 0.94). Cutoffs for ruling-in NAFLD-F2 fibrosis and NAFLD-F4-cirrhosis were determined at > 7.5 kPa (PPV: 91%, Se = 0.784, Sp = 0.974,) and at > 10.1 (PPV: 0.78%, Se = 0.833, Sp = 0.956), respectively.

Conclusion: ElastPQ showed an excellent correlation and a high level of concordance with VCTE for staging fibrosis in NAFLD patients. While ElastPQ is very accurate in diagnosing fibrosis and cirrhosis, its concordance with VCTE in advanced liver disease, needs further investigation. Specific ElastPQ cut-offs for NAFLD-associated, significant fibrosis (≥ F2) and cirrhosis (F4) were determined at > 7.5 kPa and > 10.1 kPa, respectively.

SAT-277

Screening diabetic patients at risk for complications of non-alcoholic fatty liver disease: Prospective evaluation of national and international guideline recommendations

Valentin Blank[1,2], Volker Keim[1], David Petroff[2,3], Maria Heni[1], Thomas Berg[1], Yvonne Bausback[4], Arne Dietrich[2,5], Anke Toenjes[6], Martin Bauer[7], Beer Sebastian[1], Marcus Hollenbach[1], Yvonne Kupplich[8], Matthias Blüher[2,6], Udo Thrandorf[9], Johannes Wiegand[1], Thomas Karlas[1]. *[1]University Hospital Leipzig, Division of Gastroenterology, Leipzig, Germany; [2]Integrated Research and Treatment Center AdiposityDiseases Leipzig, Leipzig, Germany; [3]University of Leipzig, Clinical Trial Centre, Leipzig, Germany; [4]University Hospital Leipzig, Division of Angiology, Leipzig, Germany; [5]University Hospital Leipzig, Division of Visceral, Transplantation, Thorax and Vascular Surgery, Section of Bariatric Surgery, Leipzig, Germany; [6]University Hospital Leipzig, Division of Endocrinology and Nephrology,*

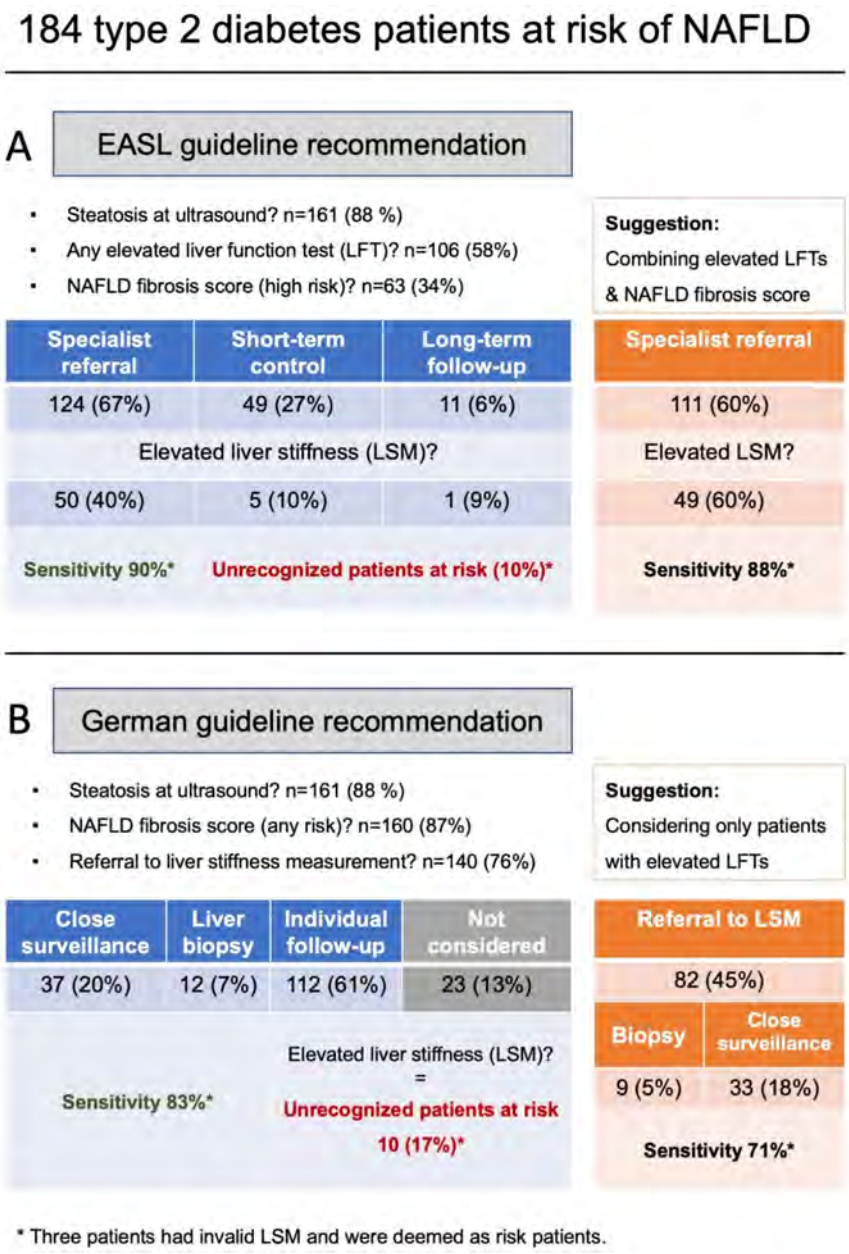

Figure: (abstract: SAT-277)

Leipzig, Germany; [7]General practitioner practice, Leipzig, Germany; [8]General practitioner practice, Leipzig, Germany; [9]General practitioner practice, Leipzig, Germany
Email: thomas.karlas@medizin.uni-leipzig.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the leading cause of liver-related morbidity and mortality in patients with type 2 diabetes mellitus (T2DM). The high prevalence demands efficient screening strategies to identify patients with advanced liver fibrosis at high risk for complications. Non-invasive fibrosis markers such as liver stiffness measurement (LSM) and serum-based fibrosis scores can guide risk stratification and referral decisions and have recently been implemented in (inter)national guideline recommendations. However, the efficacy of these diagnostic pathways is a matter of ongoing debate.
Method: T2DM patients were invited for NAFLD screening at an academic liver center. Participants were thoroughly evaluated for presence and severity of liver disease including anthropometry, abdominal ultrasound, LSM with transient elastography (TE; M or XL probe as appropriate) and NAFLD fibrosis score (NFS). Patients were then assigned to risk groups according to the current recommendations of EASL-EASD-EASO (E-E-E) and German (DGVS) NAFLD guidelines. Elevated LSM (cut-off 7.9/7.2 kPa for M/XL probe) served as reference for fibrosis risk.
Results: 203 patients with T2DM were recruited, 19 were excluded due to relevant alcohol consumption. The remaining 184 patients (58% female, median age 65 years) showed a high prevalence of obesity (median BMI 31.6 kg/m²: 28% overweight, 60% obese). Hepatic steatosis was observed in 161 (88%) cases. 56 (30%) had elevated LSM.
E-E-E and DGVS recommendations resulted in a high referral rate for hepatological assessment (67% and 76%, respectively; Figure A and B). The E-E-E algorithm identified 90% of cases with increased LSM. DGVS recommendations (sensitivity 83%) did not consider 23 patients without steatosis, of whom 9 (39%) had increased LSM. Additional NFS (E-E-E) or liver function tests (DGVS) based decision steps reduced referral rate (45%) and sensitivity (71%) of the DGVS recommendation, but only moderately influenced the E-E-E efficacy.
Conclusion: Guideline based NAFLD screening of T2DM patients revealed a high prevalence of fibrosis risk and excluded only a minority of patients from referral for further hepatologic assessment. The E-E-E algorithm had a higher sensitivity and a lower referral rate compared to the German DGVS recommendations. Comprehensive NAFLD screening requires optimized risk assessment strategies and reimbursement of non-invasive fibrosis tests.

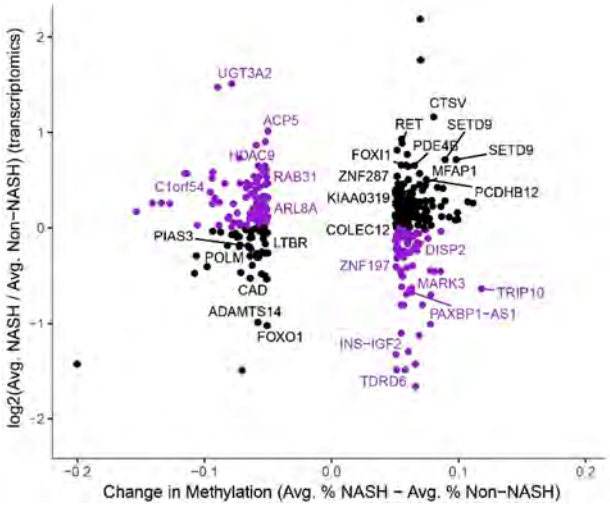
Email: noemi.cabre@urv.cat

Background and aims: Non-alcoholic steatohepatitis (NASH) in patients with obesity-associated metabolic disorders is a serious and underdiagnosed condition. The lack of non-invasive markers for its diagnosis and follow-up hampers clinical practice and development of novel treatments. Diseased livers undergo abnormal gene expression, and epigenetic mechanisms of gene regulation play a key role in establishing disease gene programs. DNA methylation changes at cytosine residues followed by guanine (CpGs) reprogram the genome at the structural level, coordinating with transcription factors to alter gene expression on a global scale (promoter methylation increase is associated with decreased transcription and vice versa). To identify potential therapeutic strategies for NASH, and to better understand mechanisms of disease, we measured DNA methylation changes directly involved in the gene reprograming that takes place in obese NASH patients.
Method: Patients undergoing laparoscopic sleeve gastrectomy were recruited as a model of obesity-induced NASH in an observational and cross-sectional study. Patient liver samples underwent histological evaluation and clinical stratification based on NASH score. Based on this classification, we systematically measured liver DNA methylation and mRNA expression profiles in NASH and Non-NASH patients (n = 16 each) using the Illumina Infinium Human MethylationEPIC BeadChip and Agilent SurePrint G3 Human Gene Expression 8×60 K v2 platform, respectively.
Results: We identified 2508 differentially methylated CpG sites between NASH and Non-NASH patients, 1640 of which lie within genes. Of those within promoters (TSS1500 or TSS200), we identified 13 genes with significant ($p < 0.05$) negative correlation between promoter DNA methylation and mRNA expression. These genes are involved in processes such as RET signalling (INS-IGF2, MARK3, TRIP10), immunity (DISP2, ARL8A, ZNF197) and gene regulation (HDAC9, RAB31, TDRD6).



Conclusion: Our results reveal 13 genes for stratification of NASH status in obese patients. The detected CpGs in the promoters of these genes are undergoing parallel mechanistic investigation in a separate validation cohort. Manipulation of these CpGs may serve as a locus-specific therapeutic strategy in obese NASH patients. In addition to CpG editing at specific loci, mechanistic study of our candidate genes may open avenues for epigenetic intervention at a broader level.

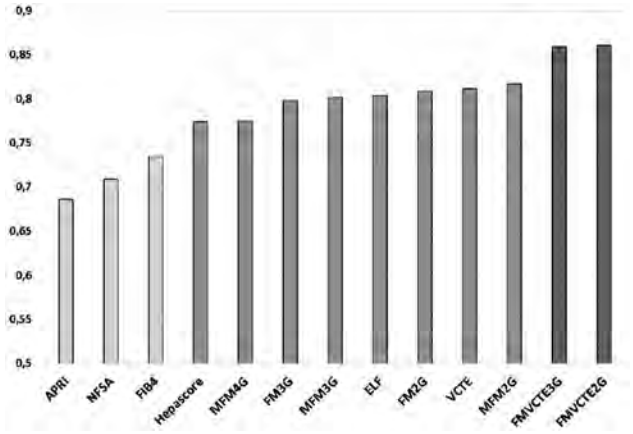
Email: paul.cales@univ-angers.fr

Background and aims: Classical blood tests are monotargeted (usually significant fibrosis) and include indirect (simple tests) and/or direct fibrosis markers (specialized tests). Recently, it has been

shown that non-invasive fibrosis tests developed for chronic viral hepatitis had good accuracy in NAFLD. New tests, like multi-targeted blood test (Hepatol Commun 2018;2:455) or test combining blood markers and liver stiffness measurement (LSM), have shown excellent accuracy in chronic viral hepatis. Thus, our aim was to compare all these types of tests in NAFLD.

Method: 410 patients with NAFLD were included in 2 centers. Their characteristics were: age: 56.5 ± 12.1 yrs, 61.5% males, diabetes: 52.9%, BMI: 32.4 ± 5.7 kg/m², liver biopsy: 29 ± 11 mm, NAS: 3.7 ± 1.6, F Kleiner stages: 0: 8.8%, 1: 22.2%, 2: 27.8%, 3:34.1%, 4: 7.1%. 13 tests were included in 4 categories: specialized blood tests (including direct fibrosis markers): Hepascore (HS), ELF, single-targeted FibroMeterV2G (FM2G including A2M and hyaluronate), FM3G, multi-targeted FM2G (MFM2G), MFM3G (without hyaluronate); LSM by VCTE (Fibroscan); combined tests: FMVCTE2G, FMVCTE3G; simple blood tests: APRI, Fib4, NFSA, MFM4G (multi-targeted FibroMeter without hyaluronate and A2M). Main outcome was advanced fibrosis (F3 + 4).

Results: Spearman's correlation coefficient between tests and Kleiner F ranged from 0.347 (APRI) to 0.672 (FMVCTE2G). AUROcs for advanced fibrosis were by growing order (Figure): APRI: 0.686, NFSA: 0.709, Fib4: 0.735, HS: 0.774, MFM4G: 0.775, FM3G: 0.798, MFM3G: 0.802, ELF: 0.804, FM2G: 0.809, VCTE: 0.812, MFM2G: 0.817, FMVCTE3G: 0.859, FMVCTE2G: 0.861. According to significant differences (by Delong test), tests were merged in 3 sets. 1/Simple blood tests: most (APRI, Fib4, NFSA) were significantly inferior to the 2nd set (except Fib4 vs HS). 2/Direct tests (blood tests and VCTE) + MFM4G; VCTE was not significantly different from other direct blood tests; MFM2G was the only test significantly superior to some other direct blood tests (HS, FM3G). 3/Combined tests: both FMVCTE were the only tests significantly superior to other tests; FMVCTE3G was not significantly different from FMVCTE2G (p = 0.219). We calculated test zones with 90% sensitivity or specificity for advanced fibrosis with grey zone between them. For example, grey zone was reduced from 56.1% for NFSA to 30.0% for FMVCTE2G which was significantly lower than in other tests (p < 0.001, except for FMVCTE3G). AUROCs for cirrhosis ranged from APRI: 0.703 to FMVCTE2G: 0.923.



Conclusion: A multitargeted simple blood test (MFM4G) is as accurate as a monotargeted direct blood test. Among direct blood tests, the most accurate was the multitargeted test MFM2G. Finally, combined blood-elastography tests outperform all other non-invasive fibrosis tests in NAFLD.

SAT-280

Comparison of CAP, MRI-PDFF, Steatotest, FLI and HSI performances for diagnosing NAFLD and NASH in morbidly obese patients undergoing bariatric surgery

philippe garteiser[1,2], Laurent Castera[2,3], Muriel Coupaye[4], Sabrina Doblas[1], Daniella Calabrese[5], Séverine Ledoux[4], Pierre Bedossa[6,7], Marina Esposito-Farese[8], Fadia Dib[8], Simon Msika[5], Bernard van Beers[1,2], Pauline Jouet[9]. *[1]Hôpital Beaujon, Assistance Publique-Hôpitaux de Paris, Radiology, Clichy, France; [2] INSERM UMR 1149, CRI, University Paris Diderot, Paris, France; [3]Hopital Beaujon, Assistance Publique-Hôpitaux de Paris, Hepatolgy, clichy, France; [4]Hôpital Louis Mourier, Assistance Publique-Hôpitaux de Paris, Explorations fonctionnelles, Colombes, France; [5]Hôpital Louis Mourier, Assistance Publique-Hôpitaux de Paris, Surgery, Colombes, France; [6]Liverpat, Paris, France; [7]University of Newcastle, Newcastle, United Kingdom; [8]Hôpital Bichat, Assistance Publique-Hôpitaux de Paris, Clinical research Unit INSERM CIC-1425, Paris, France; [9]Hôpital Louis Mourier, Assistance Publique-Hôpitaux de Paris, Gastroenterology, Colombes, France*
Email: laurent.d.castera@gmail.com

Background and aims: Non-invasive Methods for diagnosing NAFLD and NASH have not been well studied in morbidly obese patients. The aim of the present study was to compare prospectively the performance of MRI-PDFF, CAP, Steatotest (ST), hepatic steatosis index (HSI) and fatty liver index (FLI) for diagnosing NAFLD (steatosis > 5%), grading steatosis and detecting non-alcoholic steatohepatitis (NASH) in morbidly obese patients undergoing bariatric surgery.

Method: Liver biopsy (central reading by PB) was used as reference for steatosis grading (absent, mild > 5%, moderate > 33%, and severe > 66%) and NASH diagnosis (FLIP algorithm). MRI-proton density fat fraction (PDFF) and T2* relaxation rate were measured in an open-bore, vertical field 1.0 T scanner. The controlled attenuation parameter (CAP) was measured using transient elastography (TE, FibroScan, Echosens, France), using the XL probe. Diagnostic performances were measured using area under ROC curve (AUC) and compared using the DeLong Methods.

Results: One hundred and fifty two patients underwent liver biopsy of whom 128 out of 130 had successful MRI (failure rate: 1.5%) and 112 out of 142 had successful CAP and TE (failure rate: 21%; TE vs MRI failure rates p < 0.0001). Finally, 97 patients (mean age 41 ± 10 yrs, female gender 86%, BMI 44.4 ± 5.4) had all tests without fail and available. Histology was as followed: steatosis absent 23; > 5%: 21; > 33% 25; > 66% 28; NASH 31%. Fibrosis: F0 48%; F1 40%; F2 10%; F3 2%. Comparative performances of the 5 Methods are shown in Table 1. MRI-PDFF had significantly better diagnostic accuracy than CAP for moderate (p < 0.003) and severe steatosis (p < 0.002) and NASH (p < 0.006), but not for mild steatosis. MRI-PDFF also outperformed the three biological scores for mild and moderate steatosis. Regarding severe steatosis, MRI-PDFF performed better than HSI and FLI but not better than ST. CAP performance did not differ from those of biological scores.

AUC (95% CI)	MRI-PDFF	CAP	SteatoTest	HSI	FLI
NAFLD (S > 5%)	0.97 (0.94-1.00)	0.82 (0.70-0.94)	0.77 (0.66-0.88)	0.74 (0.62-0.85)	0.74 (0.63-0.86)
S > 33%	0.97 (0.94-1.00)	0.78 (0.69-0.88)	0.77 (0.68-0.86)	0.72 (0.61-0.83)	0.68 (0.57-0.79)
S > 66%	0.93 (0.88-0.98)	0.75 (0.65-0.85)	0.81 (0.72-0.90)	0.72 (0.62-0.82)	0.70 (0.60-0.81)
NASH	0.82 (0.70-0.90)	0.68 (0.57-0.79)	NA	NA	NA

Conclusion: In morbidly obese patients undergoing bariatric surgery, MRI-PDFF is an accurate diagnostic method for grading steatosis and detecting NASH. CAP has performance similar to that of MRI-PDFF for

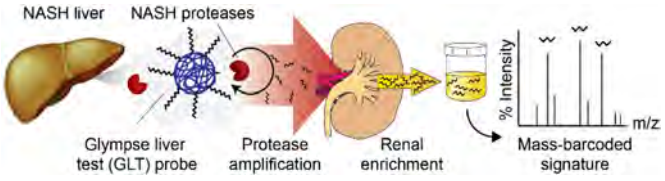
detecting mild steatosis and could be used as a first-line diagnostic Method for the diagnosis of NAFLD in these patients.

SAT-281

Protease activity sensors for non-invasive monitoring of NASH

Sophie Cazanave[1], Andrew Warren[1], Eric Huang[1], Gabe Kwong[1], Jay Luther[2], Kathleen Corey[2], Raymond Chung[2], Sangeeta Bhatia[1]. [1]*Glympse Bio, Inc, Cambridge, United States;* [2]*Massachusetts General Hospital, Harvard Medical School, Boston, United States*
Email: scazanave@glympsebio.com

Background and aims: NASH diagnosis is limited by a lack of validated, non-invasive tests. We have developed the Glympse Bio Liver Test (GLT), a multiplexed, injectable diagnostic of protease activity sensors that specifically detects the activity of proteases dysregulated in human fibrosis and NASH to monitor disease progression and regression.
Method: Protease expression was analyzed in liver biopsies from patients undergoing bariatric surgery (78 healthy, 90 NAFL, 144 NASH: 29 F0, 62 F1, 34 F2, 13 F3, 6 F4) using NanoString technology at the Massachusetts Institute of Technology. Peptides and protease sensors were synthesized by solid-phase peptide synthesis. NASH and NAFL were modeled using a choline-deficient high fat diet (CDAHFD) or a high fat diet (HFD) model, respectively, in C57BL/6 mice. Protease sensors were injected retro-orbitally; urine was collected 60-120 min post-injection and analysed by tandem mass spectrometry.
Results: We identified a specific liver protease signature that was upregulated in human NASH (or NASH-associated proteases), from which we selected a subset of 12 proteases in F2-4 (n = 53) vs F0-1 (n = 302) patients. These proteases are linked to relevant biological pathways in the disease (lipogenesis, inflammation and fibrosis) and individual proteases classified F2-4 from F0-1 disease with area under the receiver-operating characteristic curve (AUC) of up to 0.89 (median = 0.62); 12 NASH-associated proteases combined classified disease with AUC = 1.0/0.91. We next designed and synthesized a 19-member peptide substrate probe library to optimally detect the activity of NASH-associated proteases: the GLT. When testing GLT in a pre-clinical model of NASH (with 80% homology in protease signature with humans), we efficiently differentiated healthy (n = 87) or HFD mice (n = 23) from CDAHFD mice (n = 72) with training/validation AUC = 1.00/0.97. Also, GLT accurately identified regressing disease (n = 15) from stable/progressing NASH (n = 15) in mice by urinary fragment accumulation with training/validation AUC = 1.0/0.98. Finally, GLT performed consistently accurate measurements regardless of the circadian cycle or feeding/hydration status of the animals with training/validation AUC greater than 0.86/0.93.



Conclusion: GLT is an exogenously administered cocktail of multiplexed protease sensors that measures the activity of proteases in fibrosis and NASH and monitored NASH progression and regression *in vivo* with marked diagnostic accuracy.

SAT-282

Decrease in HbA1c accounts for the rapid decline in the measurement of liver stiffness by transient elastography in diabetic patients

Tugba Celebi[1], Nilay Daniş[2], Fulya Günsar[2], Galip Ersoz[2], Zeki Karasu[2], Ilker Turan[2], Omer Ozutemiz[2], Ulus Akarca[2]. [1]*Ege University, Medical School, Internal Medicine, Izmir, Turkey;* [2]*Ege University, Medical School, Gastroenterology, Izmir, Turkey*
Email: ulusakarca@gmail.com

Background and aims: Transient elastography (TE) is a reliable technique to estimate the fibrosis of the liver. However, it is intriguing that the measurements of liver stiffness (LS) may change over a short time period in patients with NAFLD. It can not be explained by an improvement in liver fibrosis. We aimed to determine the related parameters with the change of the measurements of LS by TE in diabetic patients over a 3 months period.
Method: Consecutively applied 200 diabetic patients who had been followed up in the outpatient clinic were invited to participate in the study. A hundred and seventeen patients signed the informed consent for the study. The patients with other liver diseases and those who consume alcohol > 20 g/day were excluded. Basal demographic, anthropometric data were recorded and liver biochemistry, CBC, HBA1c, blood insulin level were tested. LS was measured with Fibroscan®, Echosense, France. In accordance with previous studies, it was accepted that, F0 < 5.9 kPa, F1: 5.9-6.5, F2: 6.6-9.7, F3: 9.8-17.4, F4 ≥ 17.5. F3 and F4 were considered as advanced fibrosis. Abdominal ultrasound was used for detection of fatty liver. Anthropometric measurements, blood tests and LS were repeated 3 months later. Associations between basal parameters and LS were investigated. The related changes with the LS alterations were explored.
Results: Of 117 patients with DM, 68 were female, 49 male, mean age was 56 ± 10, mean duration of the illness was 9.2 ± 7.8 years, hypertension diagnosed 45%, peripheral neuropathy 15%. Fatty liver was detected in 80 patients (68%); grade 1: 31%, grade 2: 31%, grade 3: 7%. Metformin was used in 107, insulin in 52 patients. 61 patients took second or third antidiabetic medications. Mean BMI was 30.3 ± 5.3 kg/m^2, HbA1c: 7.7 ± 2.1%, LS: 7.2 ± 6.2 kPa. Among the basal parameters, age, BMI, waist circumference, AST, ALT, GGT, HbA1c, grades of the fatty liver, and insulin use were related to advanced fibrosis. In multivariate logistic regression analysis, BMI, AST, and GGT were found to be related to advanced fibrosis. A hundred patients came to the third-month visit. In these patients, LS decreased from 7.2 ± 6.2 to 6.6 ± 6.2 kPa (p = 0.003). Related parameters with LS decrease or increase at the third month were changes in GGT, ALP, fasted and postprandial blood sugar, and HbA1c levels. In multivariate analysis, the HbA1c change was found to be the single parameter which was related to LS change.
Conclusion: LS may significantly change within a short time in diabetic patients. LS reduction was associated with a better regulation of diabetes mellitus, but not associated with weight loss or reduction in transaminases. As the decline in glycated hemoglobin was related to the decline in LS, it may be speculated that glycated tissue proteins may be related to the liver stiffness.

SAT-283

Plasma acylcarnitines are biomarkers of magnetic resonance imaging-proton density fat fraction response in NASH patients treated with the ACC inhibitor GS-0976

Michael Charlton[1], Michelle Lai[2], Mazen Noureddin[3], Jacqueline M. Tarrant[4], Tao Hu[4], Guang Chen[4], Bryan Mccolgan[4], Chuhan Chung[4], Jay Chuang[4], Scott D. Patterson[4], Robert Myers[4], Parvez Mantry[5], Peter Ruane[6], Rohit Loomba[7]. [1]*University of Chicago, Chicago, United States;* [2]*Beth Israel Deaconess Medical Center, Boston, United States;* [3]*Cedars-Sinai Medical Center, New York, United States;* [4]*Gilead Sciences, Foster City, United States;* [5]*The Liver Institute at Methodist Dallas, Dallas, United States;* [6]*Ruane Clinical Research, Los Angelas, United States;* [7]*University of California San Diego, San Diego, United States*
Email: jacqueline.tarrant@gilead.com

Background and aims: MRI-PDFF is a reliable imaging modality for assessment of liver fat content and treatment response in NASH studies. However, due to its limited feasibility in clinical practice, simpler non-invasive biomarkers are needed to monitor treatment

response. In this study, we evaluated a novel, targeted panel of plasma AC, markers of fatty acid oxidation, as biomarkers of MRI-PDFF response in a Phase 2 study of the liver-targeted ACC inhibitor GS-0976.

Method: Using fasted plasma samples (baseline [BL], week 1 [W1], W4, and W12) from non-cirrhotic NASH subjects treated with GS-0976 20 mg (n = 49) or placebo (n = 26) orally once daily for 12 weeks (NCT02856555), 24 AC species were quantified with a targeted, LC-MS/MS assay (Metabolon, Morrisville, NC, USA). Changes in AC concentrations were compared according to MRI-PDFF response (MRI-R), defined as a ≥ 30% relative reduction in liver fat content between BL and W12. An optimal AC panel was selected using the Generalized, Unbiased, Interaction Detection and Estimation method, and the AUROC and 95% CI for discrimination of MRI-R were estimated using logistic ridge regression and 100x cross-validation.

Results: BL AC levels were balanced between GS-0976 and placebo groups (except AC5:0, p = 0.02) and did not differ significantly between groups over 12 weeks. Relative changes from BL in AC levels between MRI-R and MRI-non-responders (MRI-NR) in the GS-0976 group were significantly different at W4 and W12 for AC4:0, 12:0, 12:1, 14:0, 14:1, and 16:1 (**Figure**, all p < 0.05). With the exception of AC4:0, these AC increased significantly from BL (p < 0.05) among MRI-NR treated with GS-0976. Correlation of relative change between BL and W12 for AC and MRI-PDFF in the GS-0976 group were highest for AC4:0, 14:0, 14:1, and 16:1 (r = 0.34-0.45; all p < 0.03). For the discrimination of MRI-R among GS-0976-treated patients, the highest AUROCs for individual AC were observed for AC4:0 (AUROC 0.73), 14:0 (0.75), 14:1 (0.73), and 16:1 (0.72) at W12; similar findings were observed at W4. Using multivariate analysis, an optimized panel including 4 AC was derived that demonstrated good discrimination for MRI-R among GS-0976-treated patients (AUROC at W12: 0.77 [95% CI, 0.73, 0.79]).

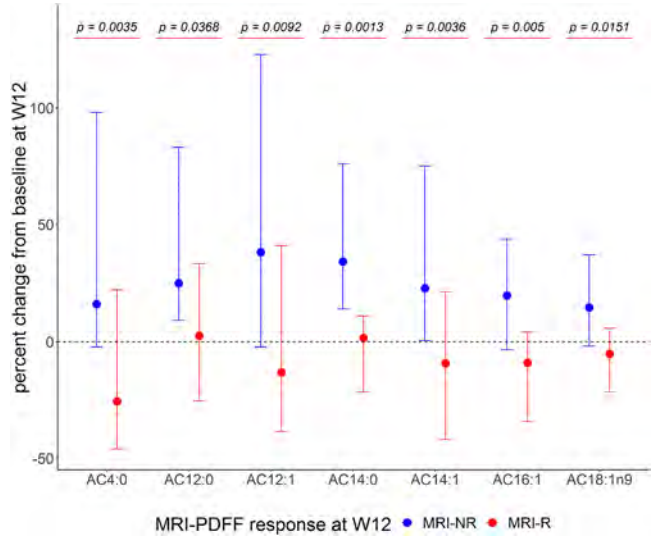


Figure: Relative (% median, IQR) changes from baseline to week 12 in acyl-carnitines among GS-0976-treated subjects according to MRI-PDFF response

Conclusion: Long-chain AC are promising early biomarkers of MRI-PDFF response to GS-0976 treatment in patients with NASH. These findings provide a mechanistic link between ACC inhibition with effects on liver fat content. This AC signature will be validated in future clinical studies of GS-0976 in NASH.

SAT-284

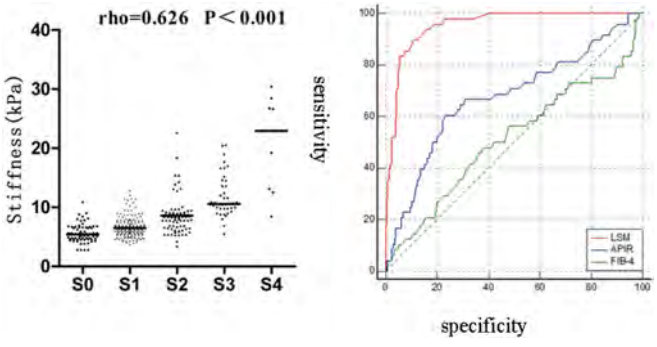
Diagnostic performance of transient elastography on liver fibrosis of patients with non-alcoholic fat hepatitis

Yi-Ming Fu[1], Dong Ji[1], Chun-yan Wang[1], guofeng chen[1]. [1]*The Fifth Medical Center of Chinese PLA General Hospital, Beijing, China*
Email: jidg302@126.com

Background and aims: Non -alcoholic fatty liver disease (NAFLD) is an important global public health problem in the 21st century. In the long course of NAFLD, non-alcoholic fat hepatitis (NASH) is a necessary stage of liver cirrhosis in NAFLD. If not timely intervention, it will gradually develop to liver cirrhosis, even liver cancer. Many studies have found that the early effective intervention can effectively control and reverse liver fibrosis. So early diagnosis and correct evaluation is important. This study was to assess the diagnostic performance of transient elastography (TE) on liver fibrosis of patients with NASH.

Method: All patients with NASH were selected from January 2006 to April 2018, were enrolled in the study, and liver stiffness measurement (LSM) by TE was performed within 3 days before liver biopsy. Clinical parameters and the pathological features were analyzed retrospectively. Non-invasive models (APRI and FIB-4) were calculated based on their own formula. The correlations between these 3 non-invasive approaches and liver fibrosis stages were analyzed with Spearman method, the diagnostic performances were analyzed with receiver operating characteristic (ROC).

Results: Of the 470 NASH patients, 346 were male (73.6%). The degree of hepatic fibrosis was detected by liver puncture. The number of patients with S0, S1, S2, S2, S3, S4 was 73, 253, 96, 40, 8 cases respectively. The median value of LSM in each group was 5.4, 6.5, 8.6, 10.7, 22.9 kPa, respectively. Spearman analysis showed that LSM and APRI was positively correlated with the stages of liver fibrosis, and the correlation coefficient were 0.626 and 0.342 (p < 0.001), There was no statistically significant correlation with FIB-4 (rho = -0.120, P > 0.05). ROC analysis showed that the diagnostic value of LSM for different stages of hepatic fibrosis was significantly higher than that of APRI. The AUROC of hepatic fibrosis S1, S2, S3 and S4 in LSM was 0.784, 0.857, 0.953 and 0.986 respectively. The corresponding optimal diagnostic bounds were 5.6, 7.7, 8.8 and 12.3 kPa, respectively.



Conclusion: The value of LSM is positively correlated with hepatic fibrosis stage of NASH and TE is a useful reference for diagnosing the degree of hepatic fibrosis in NASN.

SAT-285

Fibroscan-based score for detection of active nash and significant fibrosis is better than fib-4 in 361 chronic hepatitis B patients with non-alcoholic fatty liver disease

Xiaoling Chi[1], Meijie Shi[1], Huanming Xiao[1], Pengtao Zhao[1], Yubao Xie[1], Junmin Jiang[1], Gaoshu Cai[1], Minling Cao[1], Hongcai Liang[1], Yingxian Li[1], Huijun Chen[1], chaozhen zhang[1], sheng li[1], shuduo wu[1]. [1]*The Second Affiliated Hospital of Guangzhou University of Chinese Medicine, Guangzhou, China*
Email: chixiaolingqh@163.com

Background and aims: Chronic Hepatitis B (CHB) combined with Non-alcoholic Fatty Liver Disease (NAFLD) has become a hot research topic in recent years. Our previous study found that more CHB patients combined with Non-alcoholic steatohepatitis (NASH) showed severe fibrosis than those without NASH. Hence, it is particularly important to identify patients who are at high risk of significant disease in CHB-NAFLD patients. So we conducted this study to find a useful non-invasive marker for significant disease in CHB-NAFLD patients.
Method: Naïve-treatment CHB-NAFLD patients performed liver biopsy from April 2013 to October 2017 were enrolled in this study. The demographic, clinical, and pathological data were collected and analyzed to find out the risk factors for significant disease in CHB-NAFLD patients. Significant disease was defined as activity score (NAS) ≥ 4 and Fibrosis stage ≥ 2. Univariate analysis and Logistical regression analysis were used to find risk factors for significant disease. Area under receiver-operator curve (AUC) were used to determine the diagnostic accuracy of the non-invasive marker for significant disease.
Results: A total of 361 CHB-NAFLD patients were enrolled in this study and 139 (38.5%) of them were CHB-NASH patients. The univariate analysis showed that there was no significant difference in gender, age, serum ALT level, HBeAg positive rate and HBV-DNA level between the CHB-NAFLD patients with significant disease (NAS ≥ 4 + F ≥ 2) and those without significant disease. However, the CHB-NAFLD patients with significant disease had higher level of LSM, CAP, BMI, TG, GGT, ALP, glucose and IgG. Furthermore, the logistical regression analysis revealed that LSM and IgG were independent factors for significant disease in CHB-NAFLD patients. Therefore, a score model (Fibroscan-based score) based on the above two factors was established. This score model for active NASH and significant fibrosis resulted in good AUC (AUC = 0.841), which is better than that of FIB-4 (AUC = 0.623, P < 0.05).
Conclusion: The Fibroscan-based score could be used as a useful non-invasive marker for significant disease (NAS ≥ 4 + F ≥ 2) in CHB-NAFLD patients, who shoud be performed liver biopsy.

SAT-286
Application of guidelines for fatty liver in two prospective cohorts of human immunodeficiency virus positive patients

Sila Cocciolillo[1], Andrea Malagoli[2], Maria Osikowicz[1], Tom Pembroke[3], Marc Deschenes[1], Maged Ghali[1], Marina B. Klein[1], Giovanni Guaraldi[2], Giada Sebastiani[1]. [1]*Royal Victoria Hospital, McGill University Health Centre, Montreal, Canada;* [2]*University of Modena and Reggio Emilia, Modena, Italy;* [3]*School of Medicine, Cardiff University, Cardiff, United Kingdom*
Email: sila.coccio@gmail.com

Background and aims: People living with Human Immunodeficiency Virus (HIV) are at higher risk of non-alcoholic fatty liver disease (NAFLD) than the general population. Recent guidelines from the European Association for the Study of the Liver recommend a diagnostic algorithm to identify HIV-negative NAFLD patients at risk of progressive liver disease. This stepwise algorithm is based on non-invasive screening for NAFLD, followed by fibrosis assessment by the biomarker FIB-4 and ALT. We aimed to apply this algorithm to HIV mono-infected patients.
Method: This was a cross-sectional analysis of two prospective screening programs for NAFLD in HIV-infected persons: the LIVEr disease in HIV (LIVEHIV) Cohort and the Modena HIV Metabolic Clinic (MHMC) Cohort. HIV-infected adults without significant alcohol intake or viral hepatitis coinfection were included. NAFLD was diagnosed in the LIVEHIV Cohort if controlled attenuation parameter (CAP) was ≥ 248 dB/m; and in the MHMC Cohort if liver/spleen HU ratio on abdominal CT was < 1.1. In both cohorts, significant liver fibrosis was defined as FIB-4 > 2.67. Patients with either elevated ALT or NAFLD with significant liver fibrosis were considered at risk for progressive liver disease requiring specialist referral for hepatology consultation. Logistic regression analysis was used to identify predictors of progressive liver disease.
Results: We included 1.228 mono-infected patients (mean age 50, 73% males, time since HIV diagnosis 16 years, CD4 634 cells/mm3; 30% with BMI > 25 kg/m^2). Figure depicts the flowchart from the EASL guidelines applied to included patients. Overall, 31.8% had NAFLD and 25.2% were at risk of progressive liver disease. Among patients without NAFLD, 18.4% had elevated ALT and were considered at risk of progressive liver disease. After adjusting for BMI, hypertension, CD4 cell count and exposure to protease inhibitors, male sex (aOR 1.57, 95% CI 1.08-2.28), diabetes (aOR 1.52, 95% CI 1.04-2.24) and duration of HIV infection (aOR 1.26, 95% CI 1.02-1.58) were independent predictors of risk of progressive liver disease requiring specialist referral, while Black ethnicity was protective (aOR 0.22, 95% CI 0.09-0.52).
Conclusion: According to current NAFLD guidelines for HIV negative patients, a significant proportion of HIV mono-infected patients is at risk of progressive liver disease, requiring dedicated monitoring and referral for specialized care in hepatology.

Email: sjd@nordicbio.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a burgeoning problem for healthcare providers. Most NAFLD patients

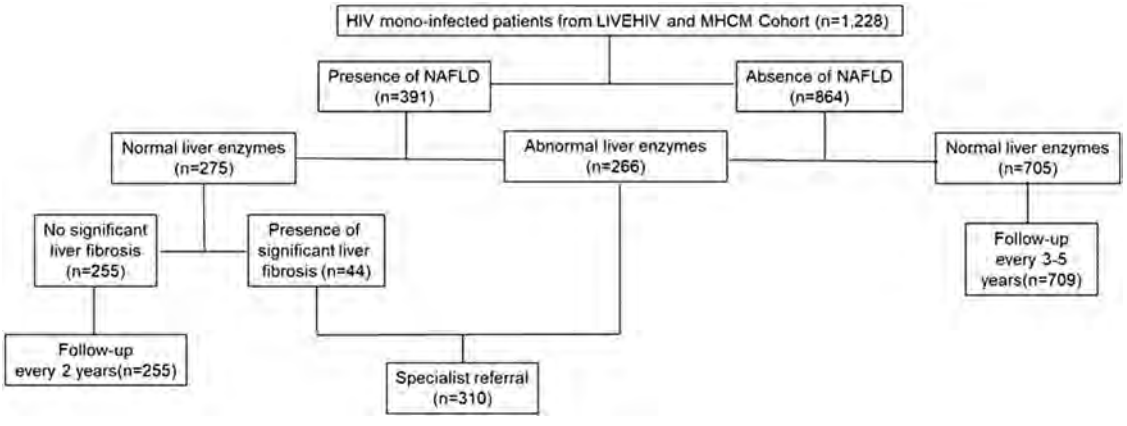

Figure: (abstract: SAT-286)

remain stable; however, those with the progressive phenotype, non-alcoholic steatohepatitis (NASH), are at a greater risk of progressing towards cirrhosis. The early identification of at-risk patients is paramount for timely intervention. We explored the ability of a new non-invasive algorithm based on serological collagen formation markers (PRO-C3 and PRO-C6) to identify subjects with NAFLD and highly active disease; NAFLD Activity Score (NAS) ≥ 5 and significant (F ≥ 2) or advanced fibrosis stage (F ≥ 3) per NASH Clinical Research Network (CRN) scoring in a post-hoc analysis of the Phase 2 CENTAUR study (NCT02217475). PRO-C3, a fibrogenesis marker, is associated with liver fibrosis severity and progression of disease. Endotrophin, a type VI collagen propeptide fragment is quantified by PRO-C6, is associated with metabolic dysfunction and insulin resistance.

Method: CENTAUR evaluated the efficacy and safety of cenicriviroc in adults with NASH (NAS ≥ 4 with ≥ 1 in each component of NAS) and liver fibrosis (NASH CRN Stages 1-3). PRO-C3 and PRO-C6 were assessed by ELISA in EDTA plasma collected at screening. A novel algorithm, developed by multivariate modelling, was applied to identify subjects with NAS ≥ 5 and F ≥ 2 or subjects with NAS ≥ 5 and F ≥ 3. ROC analysis was performed as a measure of diagnostic accuracy; optimal cut-off values for detection of subjects with NAS ≥ 5 and F ≥ 2/F ≥ 3 were identified. Diagnostic performance for the cut-offs (sensitivity, specificity, negative and positive predictive value) was determined.

Results: 406 NAFLD patients with non-missing values were included, 76% had NASH, 55% had F ≥ 2 and 32% had F ≥ 3. The non-invasive-NAS index (NI-NAS) included PRO-C3, PRO-C6, fasting blood glucose, AST and haemoglobin. The AUROC for the detection of subjects with NAS ≥ 5 and F ≥ 2 was 0.77 [0.73-0.82] and the AUROC for NAS ≥ 5 and F ≥ 3 was 0.77 [0.72-0.82]. The optimal cut-off for the identification of subjects with NAS ≥ 5 and F ≥ 2 was 4.89, sensitivity 68% and specificity 77% (PPV 65%, NPV 79%). The optimal cut-off for the identification of subjects with NAS ≥ 5 and F ≥ 3 was 4.95, sensitivity 74% and specificity 72% (PPV 45%, NPV 90%).

Conclusion: NI-NAS is a novel non-invasive serologic score that can aid in identification of NAFLD patients with highly active disease (NAS ≥ 5) and significant fibrosis (F ≥ 2) and patients with NAS ≥ 5 and F ≥ 3.

Email: sarah.shili@chu-bordeaux.fr

Background and aims: In Non-Alcoholic Fatty Liver Disease (NAFLD), fibrosis is the strongest prognostic factor and can be assessed by non-invasive methods. We evaluated the ability of Liver Stiffness Measurement (LSM) to predict overall survival and liver, cardiovascular and oncologic complications.

Method: We prospectively collected data on 2251 consecutive NAFLD patients (mean age 59 years, male 53%, mean BMI 28 kg/m²) in two centres of non-invasive diagnosis of liver fibrosis. At inclusion all patients had LSM, clinical and biological evaluation. During follow-up, we collected cardiovascular events, cancers, liver complications, liver transplantation, or death. Overall survival was the main end point used to assess the prognostic value of LSM. Survival curves according to LSM were first performed using Kaplan-Meier method for the primary end point, and Aalen-Johansen method for secondary

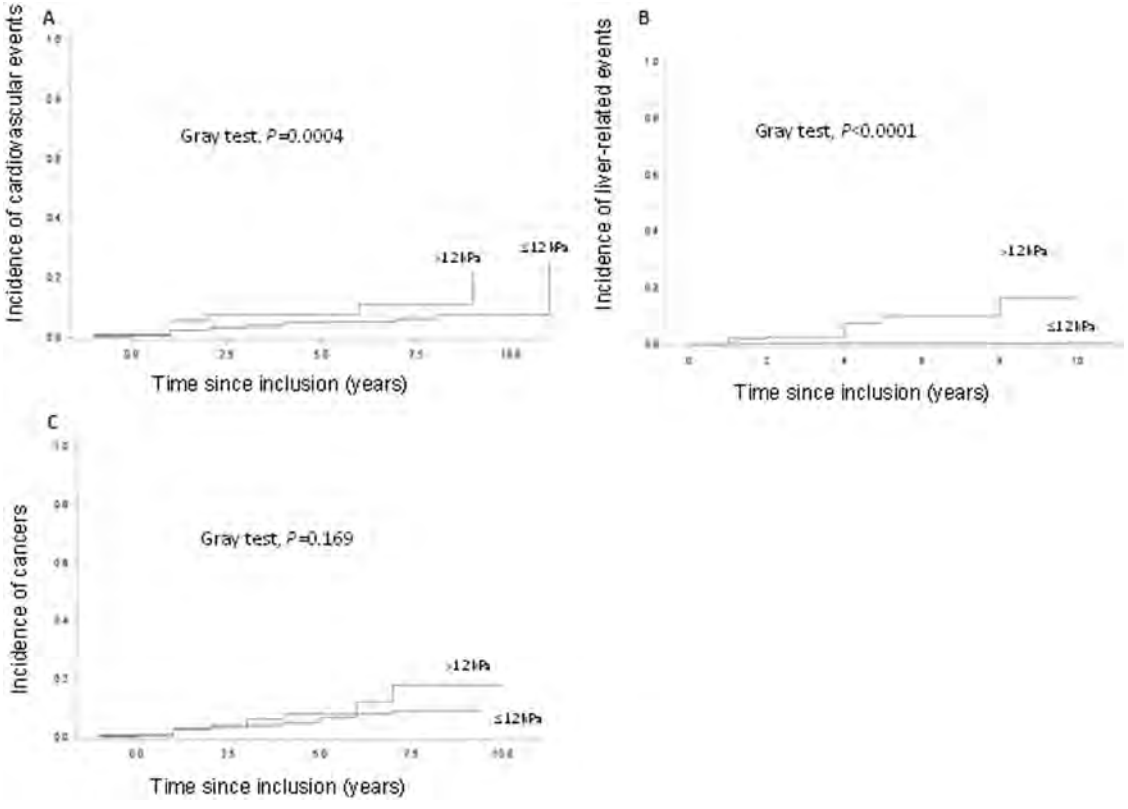

Figure: (abstract: SAT-288): Cumulative incidence of cardiovascular events (A), liver-related events (B), and cancers (C) according to LSM baseline value, taking into account competitive risks by Aalen-Johansen Method (n = 2245).

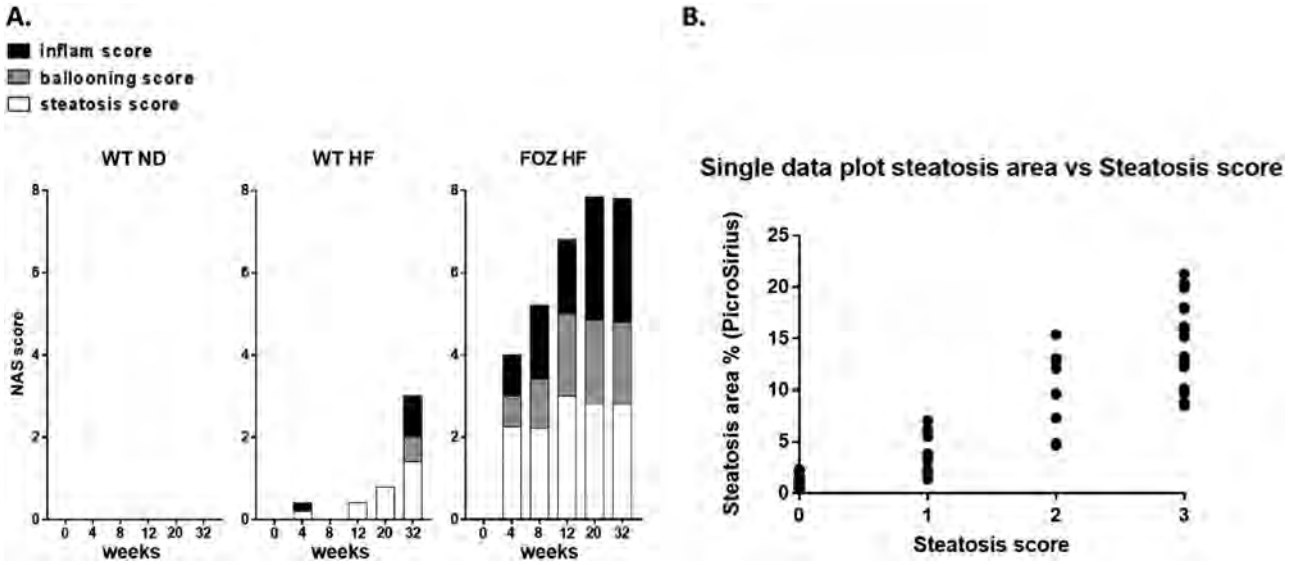

Figure: (abstract: SAT-289)

outcomes to take into account competitive risks. In a second step, a Cox proportional hazard model analysis was done to identify independent predictors of overall survival.

Results: Median follow-up was 27 months [IQR: 25-38]. 55 patients died and three patients had liver transplantation. Twenty-one patients (0.9%) had a liver event, 142 (6.3%) developed cancer (excluding HCC) and 151 (6.7%) had a cardiovascular event during follow-up. Overall survival significantly decreased as baseline LSM increased. Overall, 21 patients (0.9%) had a liver event, 142 (6.3%) developed cancer (excluding HCC) and 151 (6.7%) had a cardiovascular event during follow-up. By multivariable analysis, independent predictors of overall survival were: baseline LSM (adjusted HR (aHR) = 2.85 [1.65-4.92], $P = 0.0002$), age (aHR = 1.11 [1.08-1.13], $P < 0.0001$) and male sex (aHR = 2.05 [1.17-3.57], $P = 0.012$). Patients with elevated LSM presented significantly more cardiovascular and liver events but not other cancers. No cut-off below which HCC did not occur could be identified, but the incidence of HCC increased with baseline LSM (< 12 kPa: 0.32%; 12-18 kPa: 0.58%; 18-38 kPa 9.26% and > 38 kPa: 13.3%).

Conclusion: The prediction of survival, cardiovascular and liver complications should be based on initial evaluation of LSM. Thus, LSM might be a precious tool to decide of a medical treatment of NAFLD, and needs to be validated in clinical trials.

SAT-289

Follow-up of NAFLD/NASH progression using an automated histological image analysis

Maxime De Rudder[1], Nachit Maxime[1], Caroline Bouzin[2], Julé Yvon[3], Isabelle Leclerq[1]. [1]*Laboratory of Hepato-Gastroenterology, Institut de Recherche Expérimentale et Clinique, Université catholique de Louvain, Brussels, Belgium;* [2]*Imaging plateform 2IP, Institut de Recherche Expérimentale et Clinique, Université catholique de Louvain, Brussels, Belgium;* [3]*Biocellvia, Marseille, France*
Email: maxime.p.derudder@student.uclouvain.be

Background and aims: Pathologists assess NASH severity using semiquantitative scoring methods, such as NAS or SAF, which are linked to an inherent high variability. Histological scoring assessment provides discrete and not continuous values thus small variations may not translate into a different score. Here we performed a numerical quantification of NASH features, fully automatic, which is of particular interest for accurately monitoring evolution or regression upon therapy.

Method: We followed high fat diet fed foz/foz mice (FOZ HF) known to develop progressive NASH over 32 weeks. We compared them to chow-fed (Ctl) and high fat diet-fed wild type mice (WT HF) (n = 5/group/time point). Automated software image analysis was performed on digital images (20x) from entire liver sections stained with HandE or picrosirius red to quantify steatosis and fibrosis, and on serial F4/80 immunolabelled sections for quantifying inflammation. Data obtained from numerical analysis were compared with NAS score, biochemical quantification and gene expression.

Results: Ctl had normal liver histology at all time-points and WT HF mild steatosis (score 2 at wk32) without inflammation. FOZ HF exhibited macrovesicular steatosis stage 2 to 3 as from wk 4. Inflammation (mean score 1) and ballooning (mean score 1) were present at wk 4 and increased in severity with time such as NAS score was = 5 at wk 8, = 8 at wk 20. Automated assessment of macrovesicular area increased according to histological steatosis score (fig. B) and was strongly correlated with liver lipid content ($r_s = 0.83$, $p < 0.0001$). At each steatosis stage there was a large variation in the total lipid content evidenced by biochemical and macrovesicular area assessment (Fig. B).

The number of inflammatory foci (but not the inflammation score) and the surface of F4/80 crown-like structures, formed by active macrophages, positively correlated with F4/80 mRNA expression ($r_s = 0.68$, $p < 00001$ and $r_s = 0.6$, $p < 0.0001$, respectively). Ctl and WT HF had no fibrosis (sirius red positive area < 1%). In FOZ HF, the fibrogenic gene program was up regulated as from wk 8. A significant sirius red collagen deposits was visible at wk 20 (1.72 ± 0.12%) increasing at wk 32 (3.88 ± 0.29%).

Conclusion: Software-based fully-automated NASH represents a promising accurate and reliable quantitative analysis to rapidly monitor disease activity with high-throughput in large pre-clinical studies.

SAT-290

Association of liver inflammation and fibrosis score with non-invasive biomarkers in non-alcoholic fatty liver disease: Preliminary results from the MAST4HEALTH study

Email: dedousi@hua.gr

Background and aims: LiverMultiScan is a non-invasive diagnostic tool which uses multiparametric Magnetic Resonance Imaging to characterize liver tissue. It provides accurate measurements of % Proton Density Fat Fraction (PDFF) and tissue T1-relaxation time, corrected for liver iron (cT1), standardized as the Liver Inflammation and Fibrosis score (LIF). The aim herein was to elucidate the relationship between LiverMultiScan parameters and biochemical and anthropometric markers in a European NAFLD cohort recruited for the MAST4HEALTH study (http://www.mast4health.eu/en/).
Method: We recruited 110 overweight/obese patients (69% males) from three independent cohorts (Greece, Italy, Serbia). Serum lipids, liver enzymes, glucose, insulin and insulin resistance (HOMA-IR) were measured. Anthropometry was recorded. LIF and PDFF were calculated using LiverMultiScan. Our study group was stratified into 4 groups according to LIF (< 1, 1-1.99, 2-2.99, and ≥ 3) and differences between them were assessed. LIF was modeled via linear regression and PDFF via beta regression. Using a variable selection algorithm (*glmulti* R package), all candidate models for LIF and PDFF and the model-average importance of their predictors were assessed.
Results: Age, weight, BMI, HDL, LDL, triglycerides, glucose, ALT, PDFF and liver iron significantly differed between LIF subgroups. Weight, BMI, PDFF and ALT positively correlated with LIF (rho > 0.25; p < 0.01), while AST/ALT negatively correlated with LIF (rho < –0.25; p < 0.01). Based on multi-model inference, BMI (median = 33.4, IQR = 6.8) was the most important predictor for LIF (Figure1A), whereas BMI was the least relevant among the factors shaping PDFF. Instead, AST/ALT (median = 0.7, IQR = 0.3) and serum triglycerides were the factors most related to PDFF (Figure1B). BMI was the only predictor in the model best fitted for LIF (B = 0.04, p = 0.01). The best fitted model for PDFF incorporated triglycerides, glucose, AST/ALT (exp (B) = 1.003, 1.009, 0.396, respectively; p < 0.01) and distinguished patients according to treatment for hyperlipidemia.
Conclusion: In this preliminary survey conducted within the MAST4HEALTH project, the ratio AST/ALT and triglycerides levels were listed as the most important factors associated to PDFF. BMI was the most significant predictor of LIF, while showing least association with liver fat content. This striking contrast may be attributed to different patterns of fat deposition among the study participants.

SAT-291

Identifying NAFLD at the source: A novel approach to capturing non-alcoholic fatty liver disease in a diabetes practice

Srilakshmi Atluri[1], Christine Chen[2], Michael Ma[2], Daniel Pang[3], Tatyana Kushner[4], Ilan Weisberg[5], Amon Asgharpour[4], Amreen Dinani[4]. *[1]Mount Sinai St. Luke's, Internal Medicine, New York, United States; [2]Mount Sinai Beth Israel, Internal Medicine, New York, United States; [3]Mount Sinai Beth Israel, Clinical Trials Office, New York, United States; [4]Icahn School of Medicine at Mount Sinai, Division of Liver Diseases, New York, United States; [5]Mount Sinai Beth Israel, Department of Gastroenterology and Hepatology, New York, United States*
Email: amreen.dinani@mssm.edu

Background and aims: Vibration Controlled Transient Elastography (VCTE) is a non-invasive, well validated, and highly reproducible

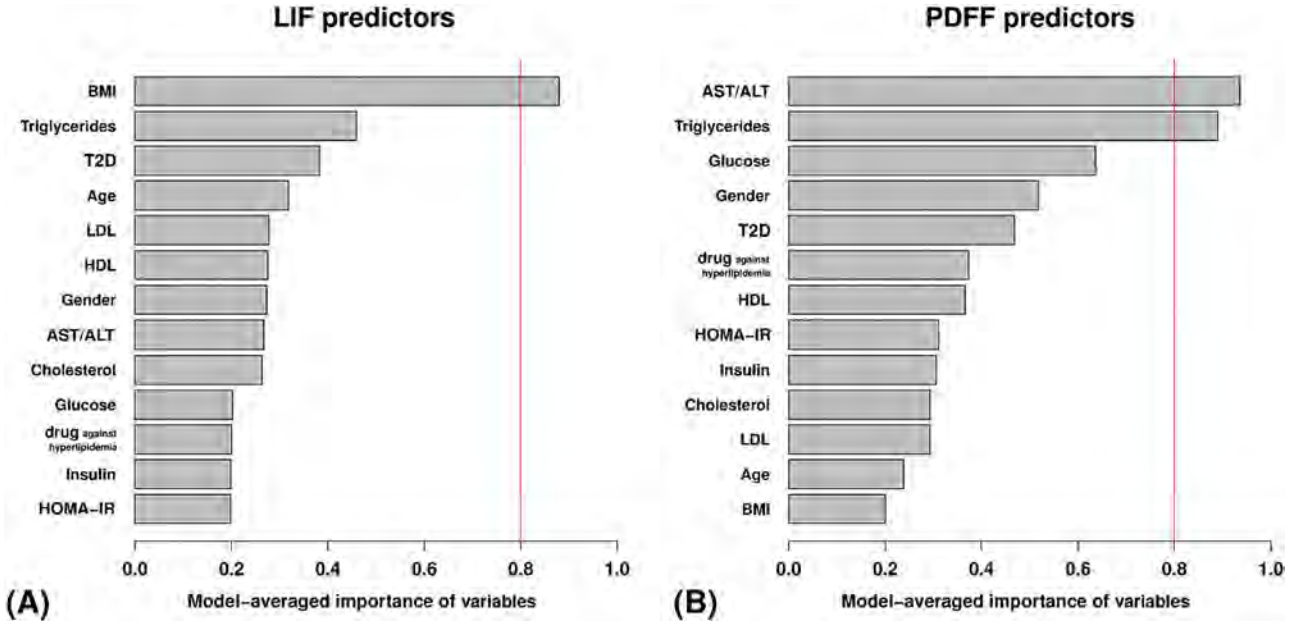

Figure: (abstract: SAT-290)

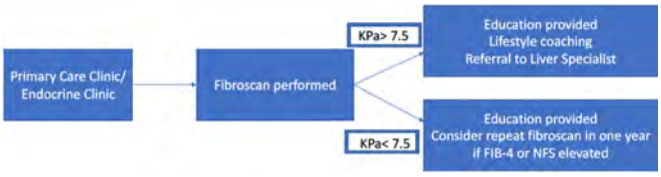
modality to diagnose NAFLD. Type 2 Diabetes (T2DM) is one of the leading risk factors for the development of NAFLD. Current guidelines recommend risk stratifying T2DM patients for NAFLD utilizing non-invasive tools to measure liver fibrosis. We screened T2DM patients for NAFLD utilizing VCTE after identifying them in two diabetes practices.

Method: T2DM patients > 18 years old were recruited prospectively during their diabetes clinic visits in a tertiary care healthcare system in NYC from September 2017 to September 2018. Features of the metabolic syndrome (MetS) were analyzed using the National Cholesterol Education Program-Adult Treatment Panel III (NCEP III) including waist circumference (with BMI as a surrogate), elevated triglycerides, reduced high-density lipoprotein (HDL) cholesterol, hypertension, and elevated fasting blood glucose. Having ≥ 3 of these features defined presence of the MetS. Informed written consent was obtained.

Results: A total of 89 patients (51% women, 12% African American, 6% Asian, 18% Caucasian, 44% Hispanic, 10% other), median age 60 (range 32-82) were analyzed. The median liver stiffness was 6.1 kPa (IQR; 2.4, 74.6) with a median controlled attenuation parameter of 296 dB/m (IQR: 100, 400). 51 (57%) patients had FIB-4 score ≤ 1.3, 23 (26%) had FIB-4 > 1.3 and < 2.67, and 3 (15%) had FIB-4 ≥ 2.67. Using NFS scores, 11 (12%) patients had NFS scores < −1.455, 47 (53%) had NFS ≥ -1.455 and ≤ 0.675, and 19 (21%) had NFS > 0.675. All patients had T2DM (89, 100%), 74 (83%) had hypertension, 50 (56%) had hypertriglyceridemia, 40 (45% had reduced HDL and 53 (60%) had a BMI > 30. 70 (82%) of the patients had at least three of these features indicating the presence of metabolic syndrome. Each additional feature of MetS had increased likelihood of KPA > 7.5 (Odd ratio 1.74 (95% CI 1.09, 2.79) for each increase in MetS). There were no statistically significant differences between ethnic groups for FIB-4, NFS or VCTE.



Conclusion: The latest NAFLD guidelines for risk-stratifying patients with type 2 diabetes via FIB-4, NFS or VCTE provide a non-invasive means for identifying patients with NAFLD and advanced fibrosis and are applicable to patients of different ethnicities. Screening for NAFLD in patients with T2DM during routine diabetes clinic visits is feasible, increases diagnoses of NAFLD and linkage to care.

SAT-292

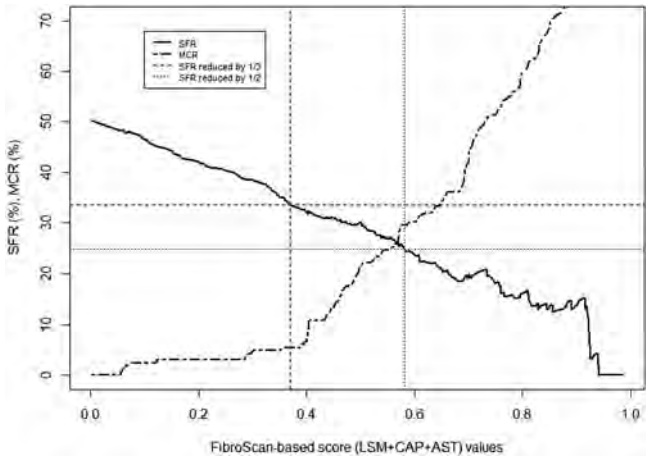
Effectively reducing screen failure rate in non-alcoholic fatty liver disease clinical trial using the FibroScan-based FAST score combining liver stiffness, controlled attenuation parameter and AST

Peter Eddowes[1,2], Michael Allison[3], Emmanouil Tsochatzis[4], Quentin Anstee[5], David Sheridan[6], Indra Neil Guha[2], Jeremy Cobbold[7], Valérie Paradis[8], Pierre Bedossa[5,9], Philip Newsome[1]. *[1]University of Birmingham, NIHR Birmingham Liver Biomedical Research Unit and Centre for Liver Research, Birmingham, United Kingdom; [2]Nottingham university hospital NHS trust and University of Nottingham, NIHR Nottingham biomedical research centre, Nottingham, United Kingdom; [3]Cambridge Biomedical Research Centre, Liver Unit, Cambridge, United Kingdom; [4]Royal Free Hospital, UCL Institute for Liver and Digestive Health, London, United Kingdom; [5]Newcastle University, Institute of cellular medicine-Faculty of Medical Sciences, Newcastle upon Tyne, United Kingdom; [6]Plymouth University, Institute of Translational and Stratified Medicine, Plymouth, United Kingdom; [7]Oxford University Hospitals NHS Trust, John Radcliffe Hospital, Department of Gastroenterology, Oxford, United Kingdom; [8] Beaujon Hospital Paris Diderot University, Department of Pathology, Physiology and Imaging, Clichy, United Kingdom; [9]Liverpat, Paris, France*
Email: peter.eddowes@nhs.net

Background and aims: Identifying patients with active NASH (NAS ≥ 4) and advanced fibrosis (F ≥ 2) is a key priority for clinical trials yet current strategies are associated with high screen failure rates. We set out to evaluate the screen failure and missed case rate of a FibroScan based score (TE/CAP/AST) in a UK setting.

Method: Patients were enrolled for undergo FibroScan examination within 2 weeks of a clinically indicated liver biopsy (LB) for suspected NAFLD. Recruitment took place (Mar 2014-Jan 2017) at seven UK centres. LB were scored by two expert pathologists in a blinded manner with consensus using the NASH CRN system and NASH using the FLIP definition. SFR was computed as being 1-positive predictive value for each value of the score. Similarly the missed case rate MCR was calculated as being 1-sensitivity. For each possible value of the score (ranging between 0 and 1), the corresponding SFR and MCR were plotted and used to define optimal cut-offs depending on the study objective. Cut-offs to reduce the SFR by a third and half were calculated as exploratory end points. For comparison SFR/MCR above the higher published cut-offs for Fib4 (3.25) and NFS (0.676) were also calculated.

Results: 335 patients were included in the analysis. AUROC of the FibroScan-based score to detect patients with NASH + NAS ≥ 4 + F ≥ 2 was 0.83 (0.77-0.87). Prevalence of NASH + NAS ≥ 4 + F ≥ 2 was 50% which would have been the SFR if no prior screening of patients was undertaken. Evolution of the SFR as a function of all possible values is shown on Figure 1, together with the evolution of the MCR. At a cut-off value of 0.37, SFR was reduced to 33% with an associated MCR of 5%. At a cut-off value of 0.58, the SFR was reduced to 25% and the MCR was 30%. Taking an in between cut-off value of 0.48 gave a SFR of 30% and an MCR of 17%. Using a 3.25 cutoff for Fib4 yields a SFR of 13% with MCR of 91%. Using a 0.676 cutoff for NFS yields a SFR of 28% with MCR of 86%.



Conclusion: The Fibroscan-based score identified optimal cut-offs to significantly reduce SFR with an acceptable MCR.

SAT-293

Combination of FibroScan and FibroMeter (FibroMeter VCTE) improves identification of patients with advanced fibrosis in patients with NAFLD

Peter Eddowes[1,2], Michael Allison[3], Emmanouil Tsochatzis[4], Quentin Anstee[5], David Sheridan[6], Indra Neil Guha[2], Jeremy Cobbold[7], Valérie Paradis[8], Pierre Bedossa[5,9], Philip Newsome[1]. *[1]University of Birmingham, NIHR Birmingham Liver Biomedical Research Unit and Centre for Liver Research, Birmingham, United Kingdom; [2]Nottingham university hospital NHS trust and University of Nottingham, NIHR Nottingham biomedical research centre, Nottingham, United Kingdom;*

Email: peter.eddowes@nhs.net

Background and aims: In non-alcoholic fatty liver disease (NAFLD) the presence of fibrosis is predictive of long-term complications. FibroMeter (FM)^{VCTE} is a patented blood test combining blood parameters and FibroScan Liver Stiffness Measurement (LSM) developed in hepatitis C patients which we set out to validate in patients with NAFLD to assess the presence of advanced fibrosis and cirrhosis (F ≥ 3).
Methods: Patients underwent FibroScan and blood collection (analyzed in central lab) within 2 weeks of a liver biopsy (LB) performed due to a clinical suspicion of NAFLD. LB were read in a blinded manner with consensus by two expert pathologists using the NASH CRN scoring system. Advanced fibrosis (F ≥ 3) was ruled out or in using published cutoffs (−1.455 and 0.676 for NFS, 1.30 and 3.25 for FIB4, 6.5 and 12.1 kPa for LSM and 0.385 and 0.715 for FM^{VCTE}). Sensitivity, positive predictive value (PPV) for the high cut-off and specificity (Sp), negative predictive value (NPV) for the low cut-off were calculated. Area under receiver operating characteristics curves (AUC) were assessed and compared using Delong's test.
Results: 356 patients were included. 43% were female, BMI was 34.4 ± 6.5 kg/m² and age 53 ± 12 years. Prevalence of F ≥ 3 was 36%, F4 was 9%. Performance of each test is shown in Table 1. For identifying F ≥ 3, FM^{VCTE} significantly outperformed other tests (AUC = 0.85 (0.81-0.89), P < 0.003). FIB4 had the best PPV = 0.82 with low Se = 0.14 whereas FM^{VCTE} had Se = 0.62 with a PPV = 0.74. FM^{VCTE} had the lowest patients in the grey zone (26%, P < 0.003) and identified 62% of F3/F4 patients vs 14% with FIB4 and 89% of F4 vs 25% with FIB4. For the diagnostic of cirrhosis, AUCs were: NFS 0.79 (0.70-0.87), FIB4 0.84 (0.77-0.90), LSM 0.88 (0.83-0.93) and FM^{VCTE} 0.91 (0.86-0.95). FM^{VCTE} outperformed other tests (p < 0.01).

Table 1:

	AUC (95% CI) for F ≥ 3	P value	Rule out F ≥ 3	Grey zone	Rule in F ≥ 3
*FibroScan **LSM***	0.79 (0.74-84)	$< 10^{-3}$	Sp = 0. 38 NPV = 0.89 N = 98 (28%) F < 3: 87 F = 3: 11 F = 4: 0	N = 152 (42%) F < 3: 110 F = 3: 38 F = 4: 4	Se = 0.59 PPV = 0.70 N = 106 (30%) F < 3: 30 F = 3: 48 F = 4: 28
FM^{VCTE}	0.85 (0.81-0.89)	Reference	Sp = 0.90 NPV = 0.92 N = 154 (43%) F < 3: 141 F = 3: 13 F = 4: 0	N = 93 (26%) F < 3: 57 F = 3: 32 F = 4: 4	Se = 0.62 PPV = 0.73 N = 109 (31%) F < 3: 29 F = 3: 52 F = 4: 28
FIB4	0.78 (0.73-0.83)	0.003	Sp = 0.73 NPV = 0.81 N = 204 (57%) F < 3: 166 F = 3: 33 F = 4: 5	N = 130 (37%) F < 3: 57 F = 3: 54 F = 4: 19	Se = 0.14 PPV = 0.82 N = 22 (6%) F < 3: 4 F = 3: 10 F = 4: 8
NFS	0.74 (0.69-0.80)	$< 10^{-4}$	Sp = 0.55 NPV = 0.85 N = 146 (41%) F < 3: 124 F = 3: 19 F = 4: 3	N = 167 (47%) F < 3: 88 F = 3: 65 F = 4: 14	Se = 0.22 PPV = 0.65 N = 43 (12%) F < 3: 15 F = 3: 13 F = 4: 15

Conclusions: FibroMeter^{VCTE} performs well in the identification of patients with advanced fibrosis without compromising sensitivity.

SAT-294

Automated quantitation of steatosis, inflammation, ballooning and fibrosis using machine learning in routine histological images of liver biopsies of patients with NAFLD

Roberta Forlano[1], Benjamin H. Mullish[1], Nikos Giannakeas[2], James Maurice[1], Markos Tsipouras[2], Alexandros Tzallas[3], Michael Yee[1], Josephine Lloyd[4], Robert D. Goldin[4], Mark Thursz[1], Pinelopi Manousou[1]. [1]1Liver Unit/Division of Integrative Systems Medicine and Digestive Disease, Imperial College London, London, United Kingdom; [2]Department of Computer Engineering, Technological Educational Institute, Greece, Greece; [3]Department of Informatics and Telecommunication Engineering, Greece, Greece; [4]Department for Cellular Pathology, Imperial College London, London, United Kingdom
Email: r.forlano@imperial.ac.uk

Background and aims: Histology is the standard to diagnose and stage Non-Alcoholic Fatty Liver Disease. Current scores display high intra and inter-observer variability. We developed an automated method based on machine learning for quantitation of fat, inflammation, ballooning and fibrosis using routine histological images of NAFLD.
Method: We evaluated liver biopsies with NAFLD. Biopsies stained with HandE and Sirius Red were scored for NASH CRN score and digitalized. Fat, inflammation, ballooning and fibrosis were annotated manually for machine learning. Inflammation and ballooning were identified after the analysis of the intensity the nuclei and the texture of the cytoplasm. Results expressed as % (areas divided by the whole biopsy area). Concordance between results and annotations was reported as Interclass Correlation Coefficient (ICC).
Results: We analysed 120 biopsies. As per scores, steatosis was mild in 33, moderate in 65 and severe in 22. Inflammation was 0 in 28, grade 1 in 72, grade 2 in 17 and grade 3 in 2. Ballooning was 0 in 38, 1 in 49 and 2 in 33. Fibrosis was F1-F2 in 47, F3 in 44 and F4 in 14.
As per quantitation, Fat% was 4.1% (IQR 2.1-6.4) in grade1, 11.2% (IQR 8.3-32.4) in grade2, 22.1% (IQR 16.6-44) in grade3. Inflammation% was 1.6% (IQR 0.7-1.9) in score0, 3.7% (IQR2.4-4) in score1, 7.7% (IQR 6.6-9.3) in score2, 9.7% (IQR 7.2-11.3) in score3. Ballooning% was 4.7% (IQR 3.2-6.7) in score0, 12.6% (IQR 10-12.8) in score1, 15.4% (IQR 12-21.9) in score2. CPA was 2.7% (IQR 1.9-4) in F1, 2.1% (IQR 1.3-3.8) in F2, 4.8% (IQR 2.5-8.05) in F3, 12.2% (IQR 6.8-17.2) in F4. ICC was excellent: 0.98 (95%CI = 0.96-0.99, p = 0.0001) for steatosis, 0.95 (95%CI = 0.89-0.98, p = 0.0001) for inflammation, 0.94 (95%CI = 0.87-0.98, p = 0.001) for ballooning and 0.92 (95%CI = 0.88-0.96, p = 0.001) for CPA.

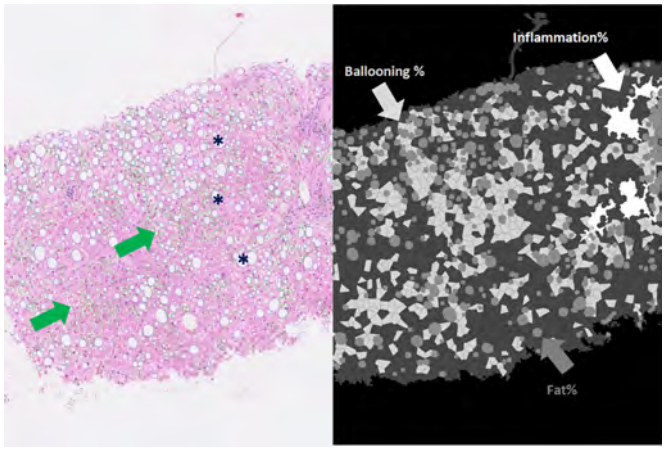

Figure: Fat% 27.7, Inflammation 2.1%, Ballooning 16.6%.

Conclusion: We developed a technique for objective quantitation of histological features in biopsies of NAFLD. This does not require sophisticated equipment and demonstrated reliable results. Given

the key role for histology in clinical trials, these techniques should be considered as end points.

SAT-295

Diagnostic accuracy of non-invasive Methods (NFS Score and FIB-4) for detecting advanced fibrosis: A validation study of NFS score and FIB-4 in a cohort of South Indian patients with NAFLD

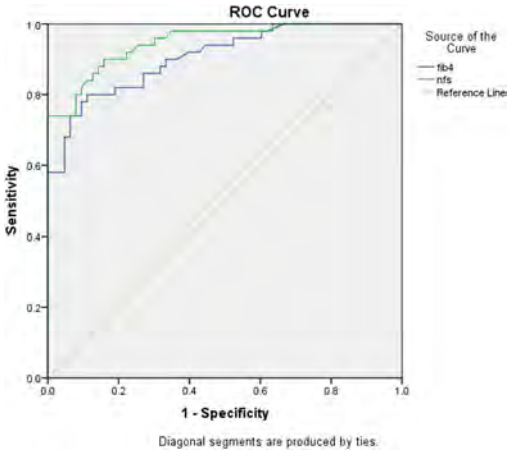
Charles Panackel[1], Mathew Jacob[1], Joe Francis[1], Kaiser Raja[1], Mallikarjun Sakpal[1], Naveen Ganjoo[1], Sonal Asthana[1], Rajiv Lochan[1], Rehan Saif[1], Jayanth Reddy[1], Ismail Siyad[2], Ganesh Ramesh[2], Rommel Sandhyav[1], Noushif m[1]. *[1]Aster Medcity, Aster Integrated Liver Care, Kochi, India; [2]Aster Medcity, Gastroenterology, Kochi, India*
Email: charlespanackel@hotmail.com

Background and aims: Presence of advanced fibrosis in Non-alcoholic fatty liver disease (NAFLD) increases the risk of HCC as well as liver related and cardiovascular mortality. Liver biopsy is the current goal standard for diagnosing fibrosis in NAFLD but has its own risks. Vibration controlled transient elastography (VCTE) is costly and not easily accessible to all. NAFLD fibrosis score (NFS) and FIB-4 are scoring systems validated in western population for diagnosing fibrosis in NAFLD.

Aim We aimed to assess the accuracy of NFS score and FIB-4 as non-invasive Methods for diagnosis of advanced liver fibrosis in a cohort of south Indian population with NAFLD.

Method: All patients with biopsy proven NAFLD who attended our liver clinic between 1st January 2016 and 30th June 2018 were enrolled. Diagnosis of NAFLD was based on histological criteria for NAFLD by non-alcoholic steatohepatitis clinical research network (NASH CRN). Stages 0-2 were considered as mild/moderate fibrosis and stages 3-4 as advanced fibrosis. NFS score and FIB-4 score were calculated for each patient using an online calculator. An NFS score greater than 0.676 and FIB-4 score more than 2.67 were taken as cut-off to predict advanced fibrosis based on data from previous studies. Statistical analysis was conducted using SPSS 19.0 software (SPSS, Inc., Chicago, IL).

Results: A total of 113 patients [Mean age 49.23 ± 12.07 years; Male: female = 62:51] were studied. Mean BMI was 26.41 ± 3.80 and 72 (63.7%) patients were obese (BMI > 25). 50 (44.24%) patients had advanced fibrosis on liver biopsy. DM was seen in 44 (38.9%) patients and was more common in patients with advanced fibrosis (66% versus 17.5%). Patients with advanced fibrosis were more likely to be older and males. Patients with advanced fibrosis had lower platelet count, higher AST, lower albumin and higher AST/ALT ratio). The NFS score > 0.676 had a sensitivity of 72%, specificity of 100%, PPV of 100%, NPV of 78.46% and accuracy of 86.14% to diagnose advanced fibrosis. FIB-4 > 2.67 had a sensitivity of 70%, specificity of 100%, PPV of 100%, NPV of 70% and accuracy of 82.35% to diagnose advanced fibrosis. Area under ROC curve was 0.948 for NFS and 0.908 for FIB-4 for diagnosing advanced fibrosis (Figure1).



Area Under the Curve

Test Result Variable (s)	Area	Std. Error[a]	Asymptotic Sig.[b]	Asymptotic 95% Confidence Interval	
				Lower Bound	Upper Bound
fib4	.906	.028	.000	.852	.960
Nfs	.948	.019	.000	.910	.986

The test result variable (s): fib4, nfs has at least one tie between the positive actual state group and the negative actual state group. Statistics may be biased.
a. Under the nonparametric assumption
b. Null hypothesis: true area = 0.5

Conclusion: The NFS and FIB-4 have good accuracy in diagnosing advanced fibrosis in NAFLD patients. These simple, non-invasive tests can substitute liver biopsy as well as guide further investigations and follow-up of patients with NAFLD.

SAT-296

Oxidized LDL is a distinctive biomarker of NASH independently of liver fibrosis in patients with NAFLD

Email: rociogallegoduran@gmail.com

Oxidized LDL is a distinctive biomarker of NASH independently of liver fibrosis in patients with NAFLD.

Background and aims: To determine the diagnostic capacity of oxidized LDL (oxLDL) in non-alcoholic fatty liver disease (NAFLD) and its role in the physiopathology of the disease.

Method: Multicenter study including 178 patients that underwent liver biopsy due to clinical suspicion of NAFLD: 164/178 (92%) were found to be compatible with NAFLD and 14/178 (8%) showed normal hepatic histology. Epidemiological, biochemical and anthropometrical variables were recorded. Non-alcoholic steatohepatitis (NASH) and liver fibrosis were evaluated by using SAF Score. Levels of oxLDL were measured by ELISA (Mercodia AB, Uppsala, Sweden) following manufacture's instructions.

Results: 53.4% of patients displayed NASH and fibrosis distribution was as follows: F0 27.4% (45/164), F1 37.2% (61/164), F2 25.6% (42/164), F3 6.7% (11/164) and F4 3% (5/164). oxLDL levels in healthy controls were 42.1 + 10.3 U/L. In NAFLD patients, oxLDL was found to be associated with NASH (55 + 15.8 *vs.* 45.1 + 13.7 U/L; p < 0.0001), but not with liver fibrosis (F0 50.7 + 14.8 *vs.* F1 52.7 + 16.5 *vs.* F2 48.6 + 13.8 *vs.* F3 54 + 20.5 *vs.* F4 39.4 + 8.5 U/L; p = 0.299).

Further, association between oxLDL and NASH was found to be maintained independently of obesity [(BMI > 30 kg/m^2 54.5 + 15.1 *vs.* 45.6 + 12.9 U/L; p = 0.0001) (BMI < 30 kg/m^2 65.6 + 27.2 *vs.* 43.8 + 14.3 U/L; p = 0.022)] and *diabetes mellitus* [(DM 55.8 + 15 *vs.* 43 + 12.1 U/L; p = 0.001) (non-DM 54.6 + 16.3 *vs.* 46.2 + 13.8 U/L; p = 0.003)]. In both mild fibrosis (F0-F1) and significant fibrosis (F2-F4), oxLDL levels were found to be significantly higher when displaying NASH

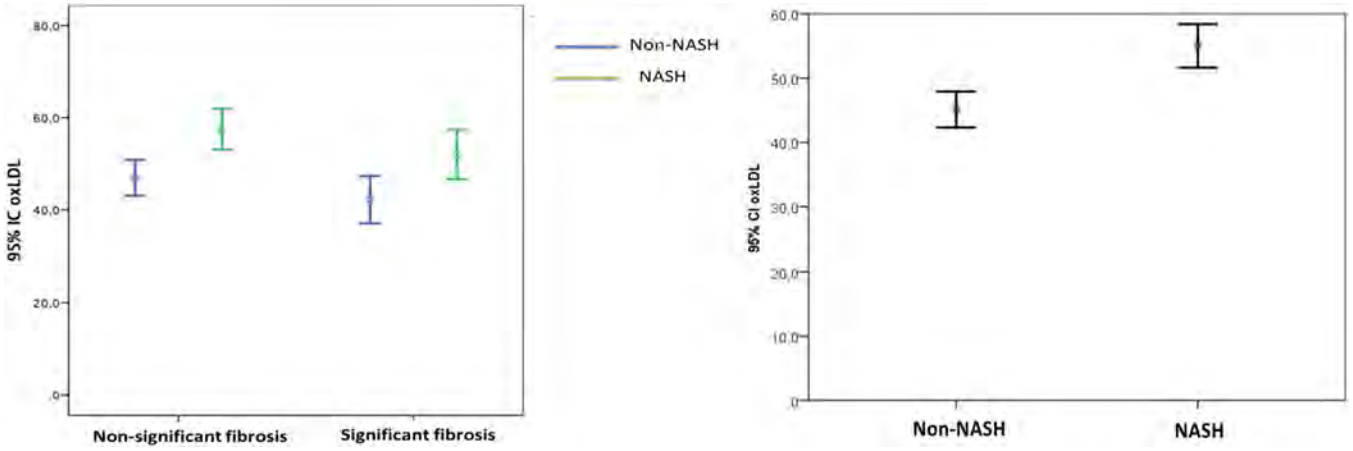

Figure: (abstract: SAT-296)

(Fig 1). BMI, GGT, albumin and total cholesterol were also associated to NASH presence. After multivariate analysis, oxLDL [OR 1.05 (CI95% 1.02-1.08); p = 0.001] and BMI [OR 1.08 (CI95% 1.03-1.13); p = 0.001] remained as independent variables associated to NASH.

Conclusion: oxLDL levels were associated to NASH but not to liver fibrosis. These data may reinforce the role of oxidative stress in NASH, independently of obesity and diabetes, and highlights the interesting role of this molecule linking NASH and cardiovascular risk.

SAT-297

Prediction of incident severe liver disease in the general population using non-invasive scoring systems

Hannes Hagström[1], Mats Talbäck[1], Anna Andreasson[2], Axel Carlsson[1], Göran Walldius[1], Niklas Hammar[1]. *[1]Karolinska Institutet, Stockholm, Sweden; [2]Stockholm University, Stockholm, Sweden*
Email: hannes.hagstrom@ki.se

Background and aims: Non-invasive scoring systems can be used to identify persons with a high risk of advanced liver fibrosis in NAFLD. Which score that best predict future liver-related events in the general population is largely unknown.

Method: We used data from the Swedish AMORIS cohort, generated in 1985-1996. The cohort consisted of > 800, 000 persons with laboratory data obtained from routine health check-ups and primary care. Body mass index (BMI) and diabetes status were ascertained by record linkage to national registers and research cohorts. We calculated the following five scores for persons free of baseline cirrhosis or alternative liver diseases than NAFLD: APRI (n = 172, 016), BARD (n = 79, 583), FIB-4 (n = 171, 460), Forns score (n = 164, 861) and the NAFLD fibrosis score (NFS, n = 18, 236). All five scores were possible to calculate in 18, 236 persons. We ascertained incident cases of severe liver disease, defined as diagnoses of cirrhosis, decompensated cirrhosis, hepatocellular carcinoma and/or death in liver disease by linkage to high-quality national registers, until 31 December 2011. Cox regression was used to estimate hazard ratios. ROC-curves and C-statistics were used to investigate which score that best predicted incident severe liver disease.

Results: During a mean follow-up period of 17 years, we found an increased incidence of severe liver disease in intermediary as well as high-risk groups compared to low-risk groups. Total number of outcomes, hazard ratios for intermediary and high-risk groups, AUROCs and C-statistics per score are presented in Table 1. Although the negative predictive value for severe liver disease for persons in the low-risk group was > 0.98 for all tested scores, most severe liver disease events occurred in persons with low risk of advanced fibrosis at baseline.

Conclusion: Currently available non-invasive scores predicted incident severe liver disease to a poor extent although subjects in the intermediate and high-risk groups had a clearly elevated risk. Persons with a low risk for having advanced fibrosis per these scores are at a low absolute risk for future cirrhosis, but better prognostic models are needed.

Scoring system	N exposed	N outcomes (%)	HR (95%CI)	AUROC	C-statistics
APRI, low	165, 253	1, 549 (0.94%)	(ref)	0.616	0.631
APRI, interm.	5, 968	265 (4.44%)	5.5 (4.9-6.3)		
APRI, high	795	99 (12.45%)	24.4 (19.9-29.9)		
BARD, low	24, 841	216 (0.87%)	(ref)	0.509	0.511
BARD, interm.	49, 543	329 (0.66%)	0.7 (0.6-0.9)		
BARD, high	5, 199	85 (1.63%)	1.4 (1.1-1.8)		
FIB-4, low	142, 494	1, 218 (0.85%)	(ref)	0.645	0.671
FIB-4, interm.	22, 916	427 (1.86%)	1.4 (1.3-1.6		
FIB-4, high	6, 050	255 (4.21%)	4.3 (3.7-5.0)

MR elastography based fibrosis correlates with clinical liver events in patients with non-alcoholic fatty liver disease: A multi-center study

Ma Ai Thanda Han[1], Jonathan Grotts[2], Rola Saouaf[3], Nabil Noureddin[4], Walid Ayoub[1], Andrea Scott[5], Mary Barbara[6], Matthew Tjahja[5], Toluwalase Okubote[5], Dr. Zeid Kayali[7], Edward Mena[8], Naim Alkhouri[5], Mazen Noureddin[9]. *[1]Cedars-Sinai Medical Center, Gastroenterology and Hepatology, Los Angeles, United States; [2]UCLA, Los Angeles, United States; [3]Cedars-Sinai Medical Center, Imaging, Los Angeles, United States; [4]University of Nevada, Internal Medicine, Las Vegas, United States; [5]Texas Liver Institute, Liver, San Antonio, United States; [6]UT Health, Liver, San Antonio, United States; [7]Inland Empire Liver Foundation, Riverrside, United States; [8]California Liver Research Center, Pensadena, United States; [9]Cedars-Sinai Medical Center, Fatty Liver Program, Division of Digestive and Liver Diseases, Los Angeles, United States*
Email: maaithandahan@gmail.com

Background and aims: Liver fibrosis assessed by liver biopsy has been shown to predict clinical liver events in patients with non-alcoholic fatty liver disease (NAFLD) and remains the gold standard in phase 3 trials. MR elastography (MRE) has been shown to be highly correlated with liver biopsy in assessing liver fibrosis and is currently used in phase 2 trials. Data to assess the correlation between MRE and clinical liver events are lacking. We investigated the correlation

between MRE and clinical liver events in a large cohort of NAFLD patients.

Method: This is a multi-center study of NAFLD patients from Texas and California. We investigated liver events in 3 groups of patients, one with MRE ≥ 2.5 kPa (correlated with NASH), one with MRE ≥ 3.62 kPa (advanced fibrosis) and one with MRE ≥ 4.7 kPa (correlated with cirrhosis). Fisher's exact test was used for testing association strength. Univariate logistic regression model was used to predict the events.

Results: Our cohort included 245 patients: 53% female; 47% T2DM; mean BMI 32.3 (6.2) kg/m^2, ALT 55.7 (48.4) U/L, AST 41.6 (29.3) U/L, and ALP 84.4 (33.5) U/L. Patients with MRE ≥ 2.5 kPa and MRE ≥ 3.62 were more likely to be diabetics, have higher ALT, AST and ALP, and lower platelets ($p < 0.05$ for all). NAFLD patients with MRE ≥ 2.5 kPa were more likely to have overall liver decompensation (7.4%% vs 0%; P = 0.003) and ascites (5.2% vs 0%; P = 0.018). Patients with MRE ≥ 3.62 kPa were more likely to have overall liver decompensation (19.2% vs 0%; P < 0.001), ascites (13.5% vs 0%; P < 0.001), hepatic encephalopathy (HE) (9.8% vs 0%; P < 0.001), esophageal variceal bleeding (EVB) (3.8% vs 0%; P = 0.045) and death (3.9% vs 0%; P = 0.043). Patients with MRE ≥ 4.7 kPa were more likely to have overall liver decompensation (26.7% vs 0.9%; P < 0.001), ascites (16.7% vs 0.9%; P < 0.001), HE (17.2% vs 0%; P < 0.001), EVB (6.7% vs 0%; P = 0.015) and death (6.9% vs 0%; P = 0.014). Association of advanced fibrosis estimated by MRE and incidence of clinical liver events using univariate logistic regression is shown in table.

Table:

Events	OR (95%CI)	P value
Decompensation	2.34 (1.64-3.34)	< 0.001
Ascites	1.83 (1.37-2.43)	< 0.001
HE	2.87 (1.62-5.07)	< 0.001
EVB	1.64 (1.18-2.29)	0.003
Mortality	2.47 (1.26-4.85)	< 0.001

Conclusion: MRE is a non-invasive biomarker that has been shown to correlate with histological fibrosis in NAFLD patients. This is the first study to show that MRE may predict clinical liver events and decompensation in NAFLD patients.

SAT-299

Assessment of NIS4 clinical utility for identification of patients with active NASH (NAS ≥ 4) and significant fibrosis (F ≥ 2) in patients at risk of NASH

Remy Hanf[1], Pierre Chaumat[1], Zouher Majd[1], Geneviève Cordonnier[1], John Brozek[1], Emilie Praca[1], Fouad Ben Sudrik[1], Prof. Pierre Bedossa[2], Prof. Quentin M. Anstee[3], Prof. Sven Francque[4], Prof. Stephen A. Harrison[5], Prof. Vlad Ratziu[6], Sophie Mégnien[7], Alice Roudot[1], Suneil Hosmane[7], Dean W. Hum[1], Arun J. Sanyal[8].

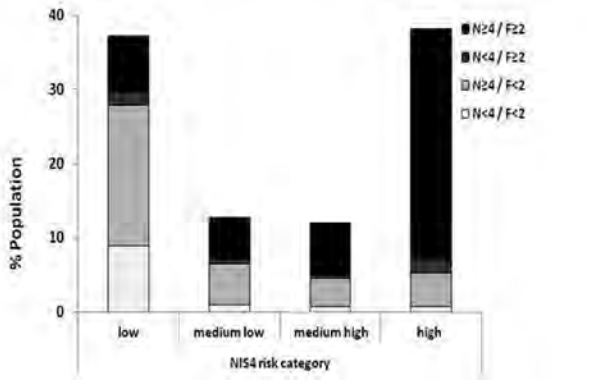
Email: remy.hanf@genfit.com

Background and aims: NASH is dramatically under-diagnosed largely because a liver biopsy is needed for diagnosis confirmation. Given the globel burden of NASH, development of new non-invasive tools are needed to identify millions of patients at higher risk of developping liver related outcomes. We recently described a new non-invasive score, NIS4. The aim of this study was to set-up clinically useful cut-offs for NIS4 to efficiently rule-out patients with no or mild disease and rule-in patients with active NASH and significant fibrosis (NAS ≥ 4 with F ≥ 2).

Method: 710 patients were screened for inclusion in GOLDEN and RESOLVE-IT trials. Blood samples and a liver biopsy were collected during the screening periods. Histological diagnosis and scoring were centralized. Each component of NIS4 (i.e. miR-34a, alpha2-macro-globuline, YKL-40 and HbA1c) were measured for calculation of NIS4. A ROC analysis was performed to determine the optimal cut-off for detection of patients with NAS ≥ 4 and F ≥ 2. We then set a low cut-off at 85% sensitivity (Sens) and a high cut-off at 85% specificity (Spec) defining 4 score ranges: low, low-medium, medium-high and high probability of having NAS ≥ 4 and F ≥ 2. Diagnostic metrics (Sens, Spec, negative predictive value and positive predictive value) were derived as well as the % of patients in the 4 score ranges.

Results: Ninety % of patients had signs of liver damage (elevated LFT's) and one or more cardio-metabolic risk factor. The cohort covered the complete histological spectrum of NAFLD (NAS = 0-8 and F = 0-4) and 51% had NAS ≥ 4 with F ≥ 2. The AUROC for detection of these patients was 0.83 [0.80-0.87] for NIS4 vs 0.75 [0.71-0.78] for FIB-4 ($p < 0.001$). At optimal cutoff of NIS4, Sens was 74% [69-78] and Spec was 75% [71-80]. At a low-cut-off set at 85% Sens, Spec was 61% [55-66] while NPV was 80%. 37% of patients (n = 264) had NIS4 values below the low cut-off (Figure1). The vast majority of patients with no or mild histological lesions (80%) were well classified in this low probability range. At high cut-off set at 85% Spec, Sens was 61% [55-66] for NIS4 while PPV was 81%. 38% of patients (n = 271) had NIS4 value above the high cut-off. In this range, almost all patients had histological lesions since 98% of patients had active NASH (NAS ≥ 4) and/or F ≥ 1.

Figure 1: Distribution of patients in NIS4 ranges



Conclusion: Using a large cohort of patients screened for suspicion of NASH, this study illustrates the clinical utility of NIS4 to eliminate patients at low probability of having active NASH and significant fibrosis and to accurately identify those at high probability of progressive disease who should be considered for therapeutic intervention.

SAT-300

Prospective liver biopsy-based prevalence of non-alcoholic fatty liver disease and steatohepatitis among a large middle-aged population utilizing FibroScan, LiverMultiscan and magnetic resonance elastography to guide liver biopsy

Stephen Harrison[1], Katharine Roberts[2], Christopher Lisanti[3], Ryan Schwope[3], Katherine Cebe[4], Valérie Paradis[5], Pierre Bedossa[6,7], James Aden[8], Jennifer Whitehead[2,3], Angelo Paredes[2]. *[1]Pinnacle Clinical Research, San Antonio, United States; [2]San Antonio Military Medical Center, Internal Medicine, Gastroenterology and Hepatology, San Antonio, United States; [3]San Antonio Military Medical Center, Radiology, San Antonio, United States; [4]San Antonio Military Medical*

Center, Pathology, San Antonio, United States; [5]Beaujon Hospital, APHP, Pathology, Beaujon, France; [6]Liverpat, Paris, France; [7]Institute of cellular medicine-Newcastle University, Newcastle upon Tyne, United Kingdom; [8]San Antonio Military Medical Center, San Antonio, United States
Email: stephenharrison87@gmail.com

Background and aims: NAFLD prevalence is estimated to be as high as 30-46% in the USA, while the prevalence of NASH is less well delineated. Large prospective studies are lacking correlating demographic, clinical and novel radiographic data to histopathology.
Method: Adult patients were prospectively enrolled predominantly at the time of referral for routine colon cancer screening. They were screened for evidence of NAFLD with FibroScan, LiverMultiScan (LMS), and MR elastography (MRE). A prior history of liver disease or alcohol ingestion greater than the accepted range for NAFLD was considered exclusionary. Patients exceeding pre-specified cut-off values on any imaging test were offered liver biopsy. Liver biopsies were read by two expert pathologists in double-blind with consensus using the Brunt criteria.
Results: 829 subjects were enrolled of which 532 completed all studies and are available for analysis (245 subjects completed liver biopsy; 287 subjects not eligible for liver biopsy based on negative imaging). Mean age: 56.0 ± 6.8 years; mean BMI: 30.6 ± 5.8 kg/m^2; 50.0% male; 14.1% diabetic. The prevalence of NAFLD (defined by a proton density fat fraction (PDFF) of > 5%) among those who completed all radiographic studies was 33.2% (Fig. 1). The prevalence of NASH was found to be 17.7%. PDFF values distributed as follows: 5-10%: 14.7%; 10.1-20%: 14.3%; > 20%: 4.2%. The prevalence of NAFLD/NASH among major ethnic groups were as follows: Hispanics (56.2%/33.1%), Caucasians (39.7%/20.7%), African-Americans (21.9%/4.2%). In the subgroup with biopsies: 22.4% normal, 39.2% Non-NASH NAFLD and 38.4% NASH. Among the NASH patients: 19.1% stage-0 (27.8% diabetic), 45.7% stage-1 (27.9% diabetic), 24.5% stage-2 (47.8% diabetic), and 10.6% stage-3 (70.0% diabetic). Patients with diabetes and NAFLD compared to non-NAFLD had higher FibroScan™ LSM (p = 0.0007), FibroScan™ CAP (p < 0.0001), steatosis grade (p < 0.0001), and fibrosis stage (p < 0.0001). Among those with NASH vs. non-NASH NAFLD mean: FibroScan™ LSM 7.5 ± 3.4 vs. 6.4 ± 2.6 kPa (p = 0.0292); LIF 2.5 ± 0.6 vs. 2.0 ± 0.7 (p < 0.0001); MRE 2.6 ± 0.7 vs. 2.3 ± 0.4 kPa (p = 0.0019), MRI cT1 920.1 ± 53.9 vs. 872.3 ± 55.5 (p < 0.0001).

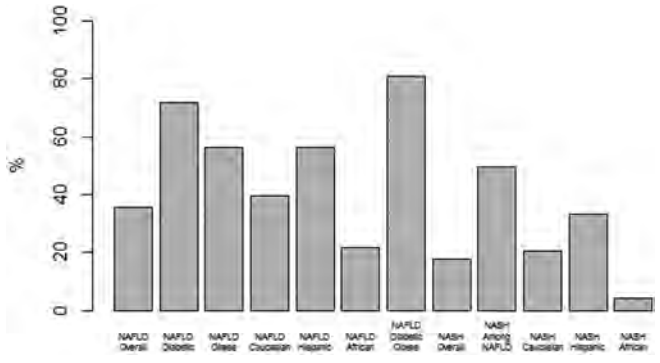


Figure: The prevalence of non-alcoholic fatty liver disease and non-alcoholic steatohepatitis using novel radiographic studies and liver biopsy. On the left is the overall NAFLD prevalence distributed by race and ethnicity.

Conclusion: In adult patients without previously known liver disease results from novel radiographic studies and prospective liver biopsy confirm the high prevalence of NAFLD and NASH in middle-aged Americans.

SAT-301

The FibroScan-based FAST score combining liver stiffness, controlled attenuation parameter and AST can efficiently screen for presence of at risk fibrotic NASH: Evaluation in an American cohort of patients screened for NAFLD

Stephen Harrison[1], Jennifer Whitehead[2], Valérie Paradis[3], Pierre Bedossa[4,5], Angelo Paredes[2]. *[1]University of Oxford, Radcliffe Department of Medicine, Oxford, United Kingdom; [2]Brooke Army Medical Center, Fort Sam Houston, United States; [3]Hôpital Beaujon, APHP, Pathology department, Clichy, France; [4]Liverpat, Paris, France; [5] Newcastle University, Institute of cellular medicine, Newcastle upon Tyne, United Kingdom*
Email: stephenharrison87@gmail.com

Background and aims: Given the increased need to identify NASH patients with fibrosis in drug development, Echosens has developed a score to identify patients with NASH + NAS ≥ 4 + F ≥ 2. The score combined the FibroScan liver stiffness measurement (LSM), controlled attenuation parameter (CAP) and AST. The objective was to assess its performance in a cohort of patients screened for NAFLD.
Methods: Patients were screened for NAFLD in one American center. Patients with MRI-PDFF ≥ 5% or liver inflammation and fibrosis score (LIF) ≥ 2 or FibroScan LSM ≥ 7kPa or MRE LSM ≥ 3kPa were advised to undergo a liver biopsy (LB). The performance of the score was assessed using area under the receiver operating characteristics (AUC).
Results: 510 patients were included in the analysis: 240 with LB and 270 with no LB (all 4 liver imaging modalities "normal" (below the predefined cutoffs)). 50% of were female, median age was 56 [IQR = 10] years and BMI was 30.3 [7.3] kg/m^2. At LB, 37 (15%) patients had at F ≥ 2, 91 (38%) had NASH and 27 (11%) had a NASH + NAS ≥ 4 + F ≥ 2. Of note, 7 (3%) had F ≥ 2 but no NASH and 3 (1%) had NASH, F ≥ 2 and NAS = 3.
Cutoffs value for a sensitivity (Se) and specificity (Sp) ≥ 0.90 and associated diagnostic metrics are provided in Table 1. AUC for the score to detect NASH + NAS ≥ 4 + F ≥ 2 was 0.88 (0.81-0.94) and significantly outperforming FibroScan LSM (0.77 (0.68-0.86), p = 0.006), CAP (0.71 (0.63-0.80), p < 10-3) and AST (0.76 (0.66-0.86), p = 0.004) alone.
Using the lower cutoff, 97 patients (19% of the population) would have been sent for referral. Among those patients, 26% were NASH + NAS ≥ 4 + F ≥ 2, 69% weren't and 5% had normal imaging modalities. Using the higher cutoff, 38 patients (7% of the population) would have been sent for referral. Among those patients 42% were NASH + NAS ≥ 4 + F ≥ 2, 55% weren't and 3% had normal imaging modalities.
With the hypothesis that patients with normal imaging were not NASH + NAS ≥ 4 + F ≥ 2, prevalence of NASH + NAS ≥ 4 + F ≥ 2 would drop to 5%. Corresponding positive and negative value (PPV/NPV) of the score would be 0.26/99.5 for the lower cutoff and 0.42/97.7 for the higher cutoff.

Table 1:

	Cut-off for Se ≥ 0.90		Cut-off for Sp ≥ 0.90	
In patients with LB	0.205 Se = 0.93/Sp = 0.69 PPV = 0.27/NPV = 0.99		0.425 Se = 0.63/Sp = 0.90 PPV = 0.45/NPV = 0.95	
In all patients	score LSM + CAP + AST < 0.205	score LSM + CAP + AST ≥ 0.205	score LSM + CAP + AST < 0.425	score LSM + CAP + AST ≥ 0.425
Not NASH + NAS ≥ 4 + F ≥ 2 at LB	146	67	192	21
NASH + NAS ≥ 4 + F ≥ 2 at LB	2	25	11	16
Unknown (no LB)	265	5	269	1

Conclusion: A simple score based on FibroScan LSM, CAP and AST can be used to efficiently identify patients eligible for for potential pharmacologic therapy.

SAT-302

Predicting the severity of hepatic steatosis and fibrosis by transient elastography and MRI-based techniques in adults patients with suspected NAFLD

Stephen Harrison[1], Katharine Roberts[2], Christopher Lisanti[3], Ryan Schwope[3], Katherine Cebe[4], James Aden[5], Valérie Paradis[6], Pierre Bedossa[7,8], Jennifer Whitehead[2,3], Angelo Paredes[2]. *[1]Pinnacle Clinical Research, San Antonio, United States; [2]San Antonio Military Medical Center, Internal Medicine, Gastroenterology and Hepatology, San Antonio, United States; [3]San Antonio Military Medical Center, Radiology, San Antonio, United States; [4]San Antonio Military Medical Center, Pathology, San Antonio, United States; [5]San Antonio Military Medical Center, Biomedical Statistics-Institute for Surgical Research, San Antonio, United States; [6]Beaujon Hospital, APHP, Pathology, Beaujon, France; [7]Liverpat, Paris, France; [8]Institute of cellular medicine-Newcastle University, Newcastle upon Tyne, United Kingdom*
Email: stephenharrison87@gmail.com

Background and aims: This ongoing prospective study aimed at evaluating the diagnostic performance of FibroScan- (FS) and magnetic resonance imaging (MRI)-based techniques in predicting the degree of hepatic steatosis, inflammation and fibrosis compared to liver biopsy (LB) in patients with suspected NAFD.
Method: Patients referred for a routine colon cancer screening with no prior history of liver disease or alcohol abuse offered participation in the study. Screening for NAFLD was performed using 5 modalities. 2 FibroScan® (FS) modalities: liver stiffness measurement (FS-LSM) and Controlled Attenuation Parameter (FS-CAP) and 3 MRI-based imaging-based modalities: MR Elastography (MRE-LSM), proton density fat fraction (MRI-PDFF) and liver inflammation fibrosis score (LMS-LIF, Liver MultiScan®). Patients with FS-LSM ≥ 7 kPa, MRE-LSM ≥ 3 kPa, PDFF ≥ 5%, or LIF ≥ 2 were proposed a LB. LB were assessed by two expert pathologists in a double-blind manner with consensus, using the NASH CRN scoring system. Diagnostic performances were assessed using area under receiver operating curve (AUROC). Spearman correlation coefficients were also assessed between modalities.
Results: To date, 829 patients have been screened, of which 232 underwent LB. 22.8% were S0, 37.5% S1, 22.8% S2 and 16.8% S3 steatosis. 53.9% were F0, 30.2% F1, 12.1% F2 and 3.9% F3. 37.9% of patients had NASH. For the prediction of steatosis, respective AUROCs for FS-CAP and MRI-PDFF relative to LB were 0.84 [0.78;0.90] vs 0.93 [0.89;0.97] for S ≥ 1, 0.80 [0.75;0.86] vs 0.96 [0.94;0.98] for S ≥ 2, and 0.76 [0.69;0.83] vs 0.92 [0.88;0.95] for S ≥ 3. For the prediction of fibrosis, respective AUROCs for FS-LSM, and MRE-LSM relative to LB were 0.60 [0.53; 0.68] vs 0.64 [0.57;0.71] for F ≥ 1, 0.78 [0.70;0.86] vs 0.83 [0.75;0.90] for F ≥ 2 and 0.91 [0.86;0.96] vs 0.97 [0.92;1.00] for F ≥ 3. FS-based modalities and MRI-based imaging modalities were available in 595 patients. Correlations coefficients between FS-LSM/MRE-LSM and FS-CAP/MRI-PDFF were.45 and 0.66 respectively. Performance of FS-LSM to predict MRE-LSM ≥ 3 kPa (prevalence 5%) was 0.76 [0.66;0.86]. Performance of CAP to predict MRI-PDFF ≥ 5% (prevalence 37%) was 0.86 [0.83;0.89].
Conclusion: Both FS-CAP/MRI-PDFF and FS-LSM/MRE are very good modalities to non-invasively assess liver fat and liver fibrosis in NAFLD respectively, with a modest advantage for MRI-based imaging modalities for assessment of high grades of steatosis.

SAT-303

Liver fibrosis together with PNPLA3 p.I148M variant affects quality of life in patients with non-alcoholic fatty liver disease: prospective liver stiffness-based study

Lena Heintz[1], Robert Holz[1], Susanne N Weber[1], Frank Lammert[1], Marcin Krawczyk[1,2]. *[1]Saarland University Hospital, Department of Internal Medicine II, Homburg, Germany; [2]Medical University of Warsaw, Laboratory of Metabolic Liver Diseases, Department of General, Transplant and Liver Surgery, Warsaw, Poland*
Email: lena.heintz@uks.eu

Background and aims: Non-alcoholic fatty liver disease (NAFLD) belongs to the most common liver diseases, and the *PNPLA3* gene variant p.I148M is associated with higher hepatic fat contents and liver fibrosis. Here, we investigate if hepatic fibrosis and steatosis as well as the *PNPLA3* variant affect Health-related Quality of Life (HRQoL) in patients with fatty liver diseases.
Method: Prospectively, we recruited individuals with NAFLD/diabetes at our center. All patients filled the battery of HrQoL questionnaires, i.e. SF36, STADI, FIS, PHQ9, and RIS (Regensburg Insomnia Scale). Hepatic steatosis and fibrosis were assessed non-invasively by controlled attenuated parameter (CAP) and liver stiffness measurement (LSM). Patients were stratified using CAP ≥ 248 dB/m, LSM ≥ 9.2 kPa and LSM ≥ 13.0 kPa as cut-offs for significant steatosis, fibrosis and cirrhosis, respectively. The variant *PNPLA3* p.I148M was genotyped using a specific TaqMan assay.
Results: Among 107 patients (57 women, age 60 ± 13 years) 76% presented with significant steatosis, 23% of these showed at least significant fibrosis and 13% cirrhosis. LSM correlated significantly (all $p < 0.05$) with several QoL aspects: physical functioning (SFpfi), physical component summary (SFPCS), anxiety and depression at present (STADI states) and as personal characteristic (STADI traits). Patients with significant fibrosis scored worse in physical scales and often showed characteristics of major depressive disorder (according to PHQ9) (all $p < 0.05$). The differences in HRQoL were most pronounced in patients with cirrhosis, who scored worst in physical and mental health scores. Notably, the *PNPLA3* polymorphism significantly affected patients' quality of life: Carriers of the prosteatotic *PNPLA3* variant were characterized by higher level of physical fatigue (FIS), reported impaired physical functioning in everyday life and during physical activity, felt more often affected by physical pain (Sfpain) and scored worse in SFPCS (all $p < 0.05$).
Conclusion: LSM allows the detection of patients with NAFLD who have impaired life quality, including depressive states. Since not only HRQoL but also treatment success might be affected, special attention should be paid to identify depressive comorbidities in patients with fatty liver. Finally, the *PNPLA3* gene variant might represent the first genetic marker for worse HRQoL in the context of NAFLD.

SAT-304

The association between visceral fat and evolution of patients with non-alcoholic fatty liver disease

Marta Hernández Conde[1], Elba Llop[1], Beatriz Tormo[1], Javier Abad Guerra[1], Christie Perello[1], Marta López-Gómez[1], Luis Rodríguez[1], José Luis Martínez Porras[1], Natalia Fernández Puga[1], Carlos Ferre[1], José Luis Calleja Panero[1]. *[1]Hospital Universitario Puerta de Hierro Majadahonda, Madrid, Spain*
Email: marta.hernandez.conde@gmail.com

Background and aims: Obesity is a risk factor for non-alcoholic fatty liver disease (NAFLD). However, patients with body mass index (BMI) > 30Kg/m^2 and NAFLD do not always develop advanced fibrosis (AF). The distribution of body fat predicts the risk of AF in patients with NAFLD. This study investigated the association between visceral fat (VF) and the severity of NAFLD.
Method: In this cross-sectional study, 345 patients with liver steatosis detected by ultrasound were included. 36 patients with alcohol consumption > 20gr/day, other liver comorbidities, prior bariatric or ileal surgery, ingestion of drugs known to produce hepatic

steatosis or with malignancy were excluded. All patients underwent an anthropometric evaluation, blood tests and bioimpedance (TANITA DC430PMA). AF was defined by a NAFLD fibrosis score (NFS) > 0.675 and Fibroscan® > 8.7Kpa. Histological diagnosis was obtained in 80 patients

Results: Between September 2017 and August 2018, 309 patients were collected for the study (63.83% male, age 57 years (SD10.4), Metabolic syndrome (MetS) 52.1% and Obesity 53.1%). 32 (10.4%) patients had AF. Age (66 vs. 56 years; p < 0.01), BMI (35 vs 30.8 Kg/m^2; p < 0.01), waist circumference (WC) (118.1 vs. 106.3 cm; p < 0.01), VF (19 vs. 13; p < 0.01), bilirubin (1 vs. 0.7 mg/dl; p < 0.01), FA (95.3 vs. 81IU/L; p = 0.02) and MetS (78.1 vs. 49.1%; p < 0.01) were related to AF. In the multivariate analysis bilirubin (OR 4.7, 95%CI 1.9-11.8; p < 0.01) and VF (OR 1.3, 95%CI 1.2-1.4; p < 0.01) were related to AF. The optimal cutoff point for VF in terms of AF prediction is 16 (Youdeńs index = 0.74) (Se 69% and Sp 78%) and an AUROC of 0.8 (95CI0.7-0.9) (Figure1).

In the cohort of patients confirmed by liver biopsy, 30 (37.2%) patients had AF. Age (63 vs. 53years; p < 0.01), VF (18 vs. 14; p = 0.02), Fibroscan® (23.2 vs 9.2Kpa; p < 0.01), platelets (158.8 vs. 222.2 10F3/microL; p < 0.01) and MetS (100 vs. 55.2%; p < 0.01) were related to AF. The risk of AF was higher in patients with higher VF (OR 1.2, 95%CI 1.1-1.3; p = 0.02) and the optimal cutoff point for VF to predict AF is 14 (Youdeńs index = 0.8) (Se 92% and Sp 61%) and an AUROC of 0.8 (95CI 0.7-0.9)

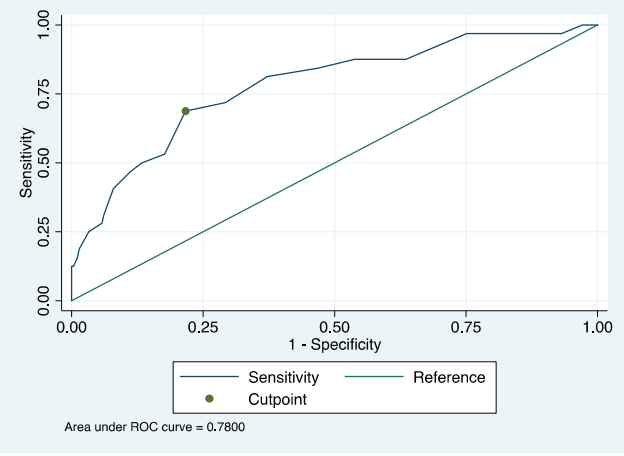

Figure: ROC curve between VF and AF (n = 309)

Conclusion: VF is independently associated with AF in patients with NAFLD. VF is a surrogate marker of visceral obesity and should be measured in all patients with high BMI and NAFLD to predict AF.

SAT-305

Alignment between physician-estimated versus objectively derived fibrosis scores in non-alcoholic steatohepatitis: Real-world evidence suggests clinicians underestimate disease severity in secondary care

Quentin Anstee[1,2], Niall Lynch[3], Adrien Hauvespre[3], Juliana Bottomley[3], Claudia Knight[4], Nathan Williams[4], James Piercy[4], Victoria Higgins[4]. [1]*Newcastle University, Institute of Cellular Medicine, Newcastle upon Tyne, United Kingdom;* [2]*The Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, United Kingdom;* [3]*Gilead Sciences, Uxbridge, United Kingdom;* [4]*Adelphi Real World, Bollington, United Kingdom*
Email: nathan.williams@adelphigroup.com

Background and aims: In a real-world setting, physicians do not always have access to or wish to subject patients to the invasive reference standard liver biopsy (LB) diagnostic tool for Non-Alcoholic Steatohepatitis (NASH). Alternative non-invasive tests (NIT) are often relied upon and clinical severity assessment subsequently assigned. This analysis aims to establish the degree of alignment in the real-world with severity staging when comparing physician estimated fibrosis scores to published fibrosis reference points, irrespective of the diagnostic pathway the specialist used to diagnose NASH.

Method: Data were derived from the 2018 5EU Adelphi NASH Disease Specific Programme, a real-world, cross-sectional survey. Physicians completed questionnaires describing five consecutive NASH patients. Diagnosis was via LB or NIT assessment. Physicians reported diagnostic test, stated fibrosis score and Fibroscan reporting. Patients were grouped by fibrosis stage: F0-F2 vs. F3-F4 (Advanced Fibrosis NASH [AF-NASH]). Fibroscan assessment was applied as recommended in two previous studies via both specificity and sensitivity approaches.

Results: 370 physicians (35% hepatologists, 38% gastroenterologists, 27% diabetologists) provided data on 1, 844 NASH patients. Of these, 1, 175 had both a physician-reported fibrosis score and Fibroscan result. Physician-stated fibrosis scores yielded 22% AF-NASH patients. The 1st studies' sensitivity yielded higher proportion of AF-NASH patients vs. specificity (79% vs 61%) as did the 2nd (69% vs 46%). Applying these criteria, NASH patients can have their fibrosis score underestimated by their physician in the real-world (1st study: Specificity 29%, Sensitivity 40%; 2nd study: Specificity 21%, Sensitivity 33%). Of note, the 1st study does state using values with a higher specificity produces more false positive results and conversely a higher sensitivity will produce more false negatives.

Conclusion: In a real-world setting, specialists do not always correctly estimate a NASH patient's fibrosis stage when compared to established Fibroscan reference points. As many as one in four patients may be assigned an incorrect, lower fibrosis score. Underestimation of fibrosis score could result in incorrect patient management and treatment approaches. Further education could help provide physicians with the tools to correctly assign fibrosis classification and enhance optimal patient management approaches.

SAT-306

Autotaxin is a valuable biomarker for predicting liver fibrosis in patients with non-alcoholic fatty liver disease

Yasushi Honda[1], Kento Imajo[1], Takashi Kobayashi[1], Takaomi Kessoku[1], Yuji Ogawa[1], Masato Yoneda[1], Satoru Saito[1], Atsushi Nakajima[1].
[1]*Yokohama City University Graduate School of Medicine, Gastroenterology and Hepatology, Yokohama, Japan*
Email: y-honda@umin.ac.jp

Background and aims: Serum autotaxin (ATX) has been reported as a novel fibrosis marker in various chronic liver diseases. In this study we investigated the clinical characteristics of ATX and the diagnostic performance of ATX for liver fibrosis in large cohort sizes of NAFLD subjects.

Method: We compared the usefulness of ATX and other fibrosis markers (hyaluronic acid, type IV collagen 7S, Fibrosis-4 index, and aspartate aminotransferase to platelet ratio index) in 307 biopsy proven NAFLD subjects. In 145 NAFLD subjects, we compared the diagnostic performance of ATX with that of non-invasive imaging methods (vibration-controlled transient elastography (VCTE) and magnetic resonance elastography (MRE)).

Results: There were 307 biopsy proven NAFLD subjects; median age 51.8 ± 14.9 years; 173 males, 134 females. Fibrosis stage was stage 0 for 33 cases (10.7%), stage 1 for 154 cases (50.2%), stage 2 for 52 cases (16.9%), stage 3 for 59 cases (19.2%), stage 4 for 9 cases (3%). Median serum ATX levels in all NAFLD subjects were 0.81 ± 0.32 mg/L. Serum ATX levels in male subjects were significantly lower than in female subjects (0.67 ± 0.21 vs 0.97 ± 0.36, respectively; p = < 0.0001). Serum ATX levels were significantly correlated with fibrosis stage in both male and female NAFLD subjects (Figure). In male NAFLD subjects, the area under the receiver operating characteristic (AUROC) value of ATX for diagnosis of ≧stage 1 was 0.65 and other AUROC values were more than 0.75. In female NAFLD subjects, the AUROC values were all more than 0.81 and that for diagnosis of ≧stage 1 was

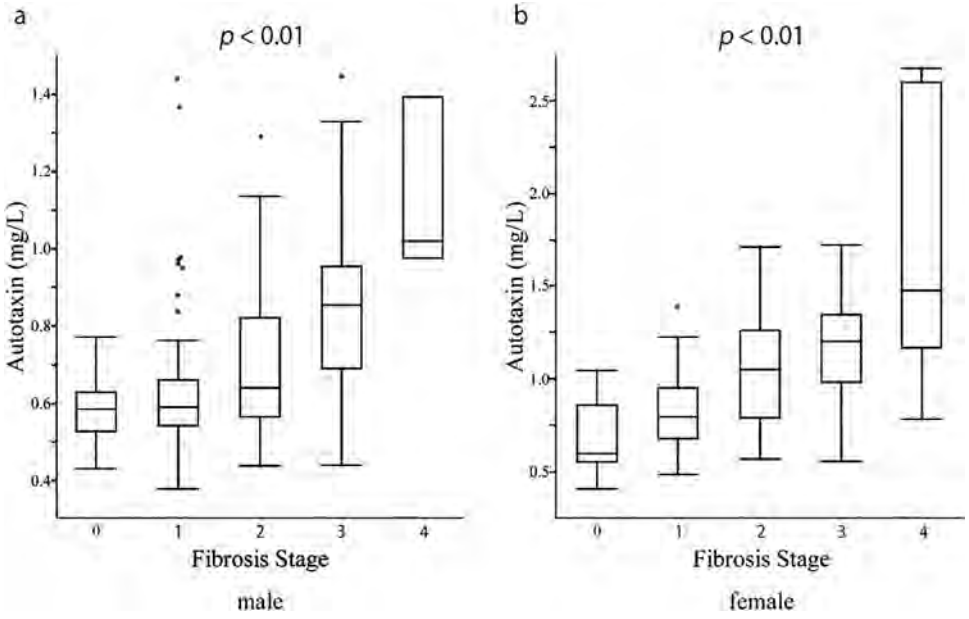

Figure: (abstract: SAT-306)

highest compared with other fibrosis makers. Sensitivities of ATX were highest in diagnosis of ≧stage 2 and ≧stage 3 in both male and female NAFLD subjects. In the comparison between ATX and non-invasive imaging methods, the AUROC levels of MRE were highest in all fibrosis stages.

Conclusion: Serum ATX levels were significantly correlated with fibrosis stage in NAFLD subjects. The diagnostic accuracy of ATX for liver fibrosis was found to be lower than that of MRE, however the diagnostic performance of ATX were comparable with that of other fibrosis markers excluding type IV collagen 7S and sensitivities of ATX in diagnosis of ≧stage 2 and ≧stage 3 were highest. It is supposed that ATX is useful for the selection of patients requiring further examination for liver fibrosis. Further studies must be conducted to explore the usefulness of ATX in NAFLD subjects.

SAT-307

A direct comparative study among magnetic resonance elastography, vibration controlled transient elastography and shear wave elastography in patients with non-alcoholic fatty liver disease

Kento Imajo[1], Yuji Ogawa[1], Yasushi Honda[1], Takaomi Kessoku[1], Masato Yoneda[1], Hiroyuki Kirikoshi[1], Satoru Saito[1], Atsushi Nakajima[1].
[1]*Yokohama City University School of Medicine, Yokohama, Japan*
Email: kento318@yokohama-cu.ac.jp

Background and aims: Non-invasive Methods have been evaluated for the assessment of liver fibrosis in patients with non-alcoholic fatty liver disease (NAFLD). We previously indicated that magnetic resonance elastography (MRE) had higher diagnostic accuracy than vibration-controlled transient elastography (VCTE) in the assessment of each liver fibrosis stage (Gastroenterology 2016). In present study, the diagnostic ability of MRE, VCTE and shear wave elastography (SWE) for liver fibrosis were compared directly in patients with NAFLD.

Method: We performed a cross-sectional study of 119 patients with NAFLD (identified by liver biopsy; mean body mass index, 27.9 kg/m^2). All study subjects were evaluated by MRE using 3.0-T imagers (GE Healthcare), VCTE with the M or XL probe (Fibroscan: EchoSens) and SWE using LOGIQ S8 FS (GE Healthcare). In addition, we aimed to investigate the inter and intraobserver variability of MRE, VCTE and SWE to assess liver fibrosis. Inter and intraobserver variability was assessed by using kappa (κ) statistics.

Results: A rate of reliable measurements of MRE, VCTE and SWE were 98.3%, 93.2% and 86.5%, respectively. The diagnostic accuracy of MRE, VCTE and SWE in detecting liver fibrosis in patients with NAFLD (n = 108) in which all MRE, VCTE and SWE could be performed successfully, are directly compared. MRE, VCTE and SWE identified patients with fibrosis stage > 1, > 2, > 3 and > 4 with an area under the receiver operating characteristic (AUROC) curve value of 0.99 or 0.98 or 0.90, 0.87 or 0.86 or 0.86, 0.87 or 0.85 or 0.86 and 0.90 or 0.85 or 0.88, respectively. The interobserver agreements of MRE, VCTE and SWE were 92%, 85% and 74%, respectively. The intraobserver

Figure: (abstract: SAT-307)

agreement was of MRE, VCTE and SWE was 93%, 88% and 80%, respectively.
Conclusion: MRE had high diagnostic accuracy in the assessment of each liver fibrosis stage relative to VCTE and SWE. In addition, intra and interobserver variability of MRE in evaluation of liver stiffness was excellent compared with VCTE and SWE.
MRE vs VCTE vs SWE

SAT-308

The optimal cut-off points of FIB-4 index for predicting the incidences of HCC and extra-hepatic malignancies in biopsy-proven Japanese NAFLD patients

Takanori Ito[1], Masatoshi Ishigami[1], Yoji Ishizu[1], Teiji Kuzuya[1], Takashi Honda[1], Mitsuhiro Fujishiro[1]. *[1]Nagoya University Graduate School of Medicine, Department of Gastroenterology and Hepatology, Nagoya, Japan*
Email: tahkun56@gmail.com

Background and aims: The utility of the FIB-4 index, a non-invasive fibrosis marker, used instead of liver biopsy have been reported for predicting the hepatic fibrosis and prognosis in patients with chronic liver diseases. The cut-off points of the FIB-4 index to exclude and diagnose advanced fibrosis in non-alcoholic fatty liver disease (NAFLD) were reported as 1.30 and 2.67, respectively. However, it remains unclear whether these cut-off points of the FIB-4 index are suitable for assessing the outcomes in NAFLD patients, including extra-hepatic carcinogenesis. We therefore aimed to clarify the prognosis in biopsy-proven NAFLD patients based on the FIB-4 index.
Method: A total of 312 patients with Japanese NAFLD diagnosed by liver biopsy were enrolled. We investigated the factors associated with the incidences of hepatic/extra-hepatic malignancies.
Results: The cumulative incidental numbers of hepatocellular carcinoma (HCC) and extra-hepatic malignancies were 11 (3.5%) and 21 (6.7%) during follow-up period (median 7.2 years), respectively. When patients were categorized into three groups based on FIB-4 index; < 1.30 (low, n = 145), 1.30-2.67 (intermediate, n = 100), and ≥ 2.67 (high, n = 67), high FIB-4 group was at the highest risk for HCC (low vs intermediate, P = 0.040; intermediate vs high, P < 0.001). On the other hand, intermediate and high FIB-4 index groups had higher incidental rate of extra-hepatic malignancies compared with low FIB-4 group (p < 0.01). However, there was no significant difference between intermediate and high FIB-4 groups (p = 0.853). Risk factors significantly associated with hepatocarcinogenesis and extra-hepatic carcinogenesis in multivariate analysis were following: liver fibrosis (F3-4) (hazard ratio [HR] 10.539, 95% confidence interval [CI] 2.009-55.286, P = 0.005) and FIB-4 index ≥ 2.67 (HR 3.373, 95% CI 0.803-14.173, P = 0.097) for HCC, and liver inflammation (A2-3) (HR 2.611, 95% CI 1.003-6.797), FIB-4 index > 1.3 and < 2.67 (HR 4.132, 95% CI 1.142-14.949, P = 0.031), and FIB-4 index ≥ 2.67 (HR 3.127, 95% CI 0.770-12.696, P = 0.111) for extra-hepatic malignancies.
Conclusion: Both 1.30 and 2.67 as cut-off points of the FIB-4 index could predict hepatocarcinogenesis with good discriminative ability. Conversely, lower cut-off value of FIB-4 index (1.30), not 2.67, was suitable to predict the incidence of extra-hepatic malignancies. In addition, hepatic inflammation preceding severe fibrosis may be a surrogate marker for the earlier prediction of extra-hepatic carcinogenesis in NAFLD patients.

SAT-309

Prevalence of NAFLD and metabolic syndrome in rural and regional Victoria, Australia

William Kemp[1,2], Ammar Majeed[1,2], Dunya Tomic[3], David Simmons[4], Kristen Glenister[5], Lisa Bourke[4], Sian Wright[4], Stuart Roberts[1,2]. *[1]Alfred Hospital, Gastroenterology Department, Melbourne, Australia; [2]Monash University, Central Clinical School, Melbourne, Australia; [3]Monash University, Medicine, Melbourne, Australia; [4]University of Melbourne, Rural Health, Shepparton, Australia; [5]University of Melbourne, Rural Health, Wangaratta, Australia*
Email: w.kemp@alfred.org.au

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most prevalent liver disease in Western communities. Epidemiological data is limited in Australia and frequently extrapolated from overseas studies and culturally distinct ethnic groups. Moreover, there is a paucity of data on the prevalence of NAFLD in rural and regional communities that have poorer health outcomes than metropolitan regions. Thus, we examined the prevalence of NAFLD using non-invasive techniques in rural and regional communities in Victoria, Australia.
Method: We conducted a cross-sectional epidemiological study across four towns in the Goulburn Valley, Victoria, Australia (200 km from Melbourne) as part of a larger population health study-The Crossroads 2 Project. Households were randomly selected from the local government rate payer lists and one adult from each household was randomly selected and invited to a screening clinic. Comprehensive demographic and health related data were obtained. Abnormal ALT was determined as > 1.5 x ULN adjusted for gender (Male < 30U/L and Female < 20U/L). Steatosis was defined as CAp > 250 dB/m. FibroScan® 402 or 530 compact was used. Patients were grouped according to liver stiffness measurement (LSM) < 7.0 kPa, 7.0 ≤ LSM < 12.5 kPa and LSM ≥ 12.5 kPa. Metabolic syndrome was defined according to ATPIII criteria.
Results: A total of 748 participants (Male = 45%, Age 59.6 ± 16 yrs, range 18-92 yrs) completed the clinical assessment. The mean BMI was 28.9 ± 6 kg/m^2 and only 26% had a BMI < 25 kg/m^2. The metabolic syndrome was present in 26% and diabetes mellitus in 10%. Excluding those with an alternative cause for liver disease (n = 57; Alcohol n = 49, HCV Ab + ve n = 8), ALT > 1.5 x ULN consistent with NAFLD was detected in 97/677 (14%). 405 underwent successful assessment with FibroScan (XL probe n = 192) with the mean LSM = 5.7 kPa. LSM ≥ 12.5 kPa or 12.5 > LSM ≥ 7.0 kPa was seen in 9 (2%) and 60 (15%) subjects respectively. The CAP score was available in 79 subjects and was > 250 dB/m in 63%. Severe fibrosis (F3/F4) was suggested in 5% (28/600) by NFS > 0.675 and 2% by FIB4 > 3.25. There was no difference in age or BMI across the LSM groups, but ALT was associated with higher LSM (p < 0.001).
Conclusion: This cross-sectional study in regional Victoria demonstrates high rates of obesity (74%) and the metabolic syndrome (26%). Furthermore there are high rates of hepatic steatosis as determined by CAP (63%). Non-invasive tests indicate advanced fibrosis (F3/4) present in 2-5%. These findings highlight a potential significant burden of metabolic liver disease in rural and regional Victoria.

SAT-310

Real-world evaluation of NASH in US clinical practice: Underutilization of liver biopsy and liver imaging

Michelle Lai[1], Scott Milligan[2], Nicole Wick[2], Zobair Younossi[3,4], Nezam Afdhal[1]. *[1]Beth Israel Deaconess Medical Center, Boston, United States; [2]Trio Health Analytics, La Jolla, United States; [3]Center for Liver Diseases, Inova Fairfax Hospital, Department of Medicine, Falls Church, United States; [4]Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, United States*
Email: scott.milligan@triohealth.com

Background and aims: NASH requires histologic diagnosis by liver biopsy and the new drug development for NASH requires primary histologic end points (NASH resolution or fibrosis improvement). Hepatology clinical care has moved away from liver biopsy to utilizing non-invasive markers for clinical decision making. The aim of this study was to evaluate the use of liver biopsy and liver imaging in patients with clinical diagnosis of NASH in real world clinical care.
Method: Data were obtained by Trio Health from a national proprietary EMR database containing demographic, medication, lab, diagnosis, and procedure information from academic, hospital, and community care centers in the US. For this study, data were

limited to adult patients from 19 healthcare organizations followed for 3 years (ending in Oct 2018). NAFLD was defined as ICD10 codes K75.81 or K76 and NASH as K75.81. In addition, patients at NASH risk and meeting criteria for evaluation with potential liver biopsy were defined as AGE > 50 years, ALT > 40 U/L + [Type II Diabetes (T2DM) or BMI > 30 kg/m^2] without viral hepatitis or evidence of alcohol abuse/complications. Imaging and liver biopsy were assigned using CPT and ICD-10 codes.

Results: Of the 2, 792, 087 adult patients in the study, 207, 632 (7%) met the predefined criteria of either NASH diagnosis by ICD-10 (N = 8, 010) or at risk of NASH (N = 199, 622). NASH risk was seen in 38% of those diagnosed with NASH (3, 031/8, 010) and 14% with NAFLD (19, 734/137, 495). Despite fulfilling NASH risk criteria, liver biopsy was obtained in only 1-5% of subjects. In contrast, imaging was performed 13-45% of subjects (Table).

Table:

Group	NASH Risk Criteria	Patients	Liver Biopsy	Imaging
NAFLD-K75.81 or K76	All patients-no filters for risk	137495	3327/ 137495 (2%)	31978/ 137495 (23%)
	Age > 50 + ALT > 40 + [BMI > 30 or T2DM]	19734	1027/ 19734 (5%)	8588/ 19734 (44%)
NASH-K75.81 only	All patients-no filters for risk	8010	328/8010 (4%)	2262/ 8010 (28%)
	Age > 50 + ALT > 40 + [BMI > 30 or T2DM]	3031	148/3031 (5%)	1034/ 3031 (34%)
NAFLD-K76 only	Age > 50 + ALT > 40 + [BMI > 30 or T2DM]	16703	879/ 16703 (5%)	7554/ 16703 (45%)
Non-NASH by diagnostic code. Positive risk factors	Age > 50 + ALT > 40 + [BMI > 30 or T2DM]	199622	1492/ 199622 (1%)	26496/ 199622 (13%)

Conclusion: Utilizing well accepted coding and risk factors for NASH, there is almost no utilization of liver biopsy in clinical care in the US with almost a 10-fold higher use of imaging. Novel NASH treatments will either require development of non-invasive diagnostic and outcome surrogates or change current clinical practice in the US.

SAT-311

The PDGFR-beta containing PRTA-score is a novel non-invasive diagnostic algorithm for significant liver fibrosis in patients with viral, alcoholic, and metabolic liver disease

Joeri Lambrecht[1], Stefaan Verhulst[1], Inge Mannaerts[1], jan-peter sowa[2], jan best[2], Ali Canbay[2], hendrik reynaert[1,3], Leo A. van Grunsven[1]. *[1]Vrije Universiteit Brussel, Department of Basic Biomedical Sciences-Liver Cell Biology Laboratory, Brussels, Belgium; [2]University Hospital Magdeburg, Department of Gastroenterology, Hepatology and Infectious Diseases, Magdeburg, Germany; [3]Algemeen Stedelijk Ziekenhuis Aalst, Department of Gastroenterology and Hepatology, Aalst, Belgium*
Email: Joeri.Lambrecht@vub.be

Background and aims: Diagnosis of liver fibrosis onset and regression remains a controversial subject in the current clinical setting, as the gold standard remains the invasive liver biopsy. Multiple novel non-invasive markers have been proposed but lack sufficient sensitivity and specificity for diagnosis of early stage liver fibrosis. Platelet Derived Growth Factor Receptor beta (PDGFRβ) has been associated to hepatic stellate cell activation and has been the target of multiple therapeutic studies. However, little is known concerning its use as a diagnostic agent. In this study, we analysed the diagnostic potential of PDGFRβ for liver fibrosis in a heterogenous patient population.

Method: The study cohort consisted of 148 patients with liver fibrosis/cirrhosis due to various causes of liver injury (metabolic, alcoholic, viral), and 14 healthy individuals as control population. A validation cohort of 57 patients with metabolic liver disease, who underwent liver biopsy to stage fibrosis, were gathered. Circulating soluble PDGFRβ (sPDGFRβ) levels were determined using a commercial ELISA kit. The diagnostic performance of sPDGFRβ as individual parameter, or in combination with other biochemical and metabolic factors was evaluated, and values were compared to those obtained by the clinical diagnostic algorithms Fib-4, APRI, and AST/ALT ratio.

Results: In the total patient population, sPDGFRβ levels were progressively augmented with increasing fibrosis stage. Circulating sPDGFRβ levels were elevated ($p < 0.0001$) in patients with significant fibrosis ($F \geq 2$), compared to no or mild fibrosis (F0/1), with a discriminative capacity, as quantified by AUC, of 0.7303, which was shown to be higher for this cohort than the AUCs of Fib-4, APRI, and AST/ALT ratio. The accuracy of sPDGFRβ could be increased by combining it with albumin levels and platelet counts into a novel diagnostic algorithm, which we termed the PRTA-score. Using a cut-off value of 7.804; a sensitivity of 77.11% and a specificity of 73.17% could be obtained for the diagnosis of significant fibrosis ($F \geq 2$). AUC values for the prediction of advanced liver fibrosis ($F \geq 3$) and cirrhosis ($F = 4$) were respectively 0.7470 and 0.7995; values which are slightly better, or comparable to Fib-4, APRI, and AST/ALT ratio. The diagnostic value of sPDGFRβ levels and the PRTA score were confirmed in an independent patient cohort, suffering from metabolic liver disease, which were staged for fibrosis by liver biopsy.

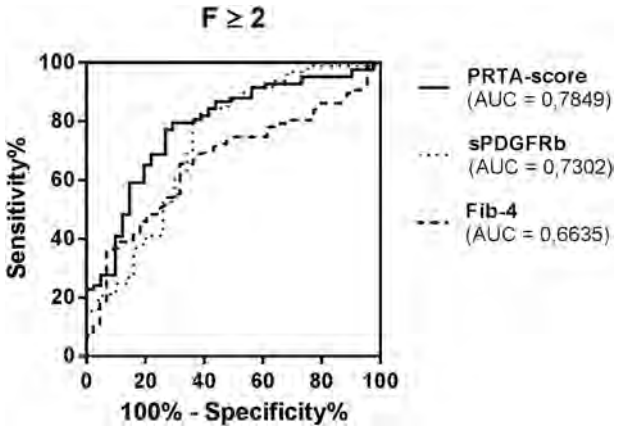

Figure: Comparison of performance of sPDGFRβ, PRTA-score and Fib-4 in the diagnosis of significant liver fibrosis

Conclusion: We put forth the PRTA score as an easy applicable, low cost and accurate scoring for significant liver fibrosis. With validation in larger patient cohorts, this serological test could become an important tool in future non-invasive clinical assessment of liver fibrosis.

SAT-312

Serial liver stiffness and controlled attenuation parameter measurements by transient elastography in patients with type 2 diabetes: A prospective cohort study

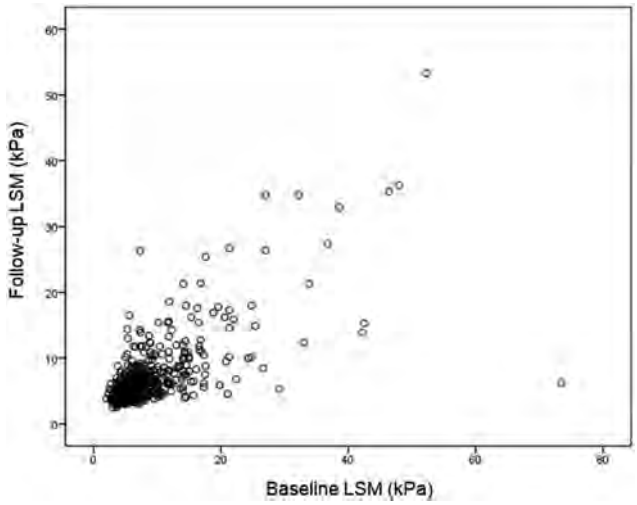
Hye Won Lee[1], Raymond Kwok[1], Grace Wong[1], Henry Chan[1], Juliana Chan[1], Alice Pik-Shan Kong[1], Vincent Wai-Sun Wong[1]. *[1]The Chinese University of Hong Kong, Department of Medicine and Therapeutics, Shatin, Hong Kong*
Email: wongv@cuhk.edu.hk

Background and aims: Type 2 diabetes is an important risk factor for non-alcoholic fatty liver disease (NAFLD) and advanced fibrosis. Current European guidelines recommend repeating non-invasive

tests of fibrosis in NAFLD patients at 3-yearly intervals, but data are largely lacking. Here we report the changes in the controlled attenuation parameter (CAP) and liver stiffness measurement (LSM) by transient elastography (TE) in patients with type 2 diabetes at 3 years.

Method: We recruited patients with type 2 diabetes from a complication screening facility in Hong Kong in 2013-2014 and repeated the assessment in 2016-2018. The primary end point was the proportion of patients who progressed to compensated advanced chronic liver disease (cACLD) by the Baveno VI criteria (< 10 kPa: unlikely cACLD; ≥ 15 kPa: probable cCALD). The secondary end point was the proportion of patients who experienced a change in the CAP.

Results: A total of 612 diabetic patients with valid LSM (mean age, 61.3 ± 10.8 years; 343 males [56.0%]) were included in this study (573 also had valid CAP). There was a history of hypertension, ischaemic heart disease, and stroke in 53.8% (n = 330), 15.2% (n = 93), and 5.5% (n = 34) of the patients, respectively. Overall, there was moderate correlation between baseline and follow-up LSM (r = 0.689, P < 0.001; Figure). At baseline, 557 (90.9%) patients had an LSM < 15 kPa (487 [79.6%] < 10 kPa), and 15 (2.7%) had follow-up LSM ≥ 15 kPa. Among the remaining 55 (9.0%) patients with LSM ≥ 15 kPa at baseline, 31 (56.4%) had follow-up LSM < 15 kPa (18 [32.7%] < 10 kPa). Among 198/573 (34.6%) patients with CAp < 248 dB/m at baseline, 103 (52.0%) had CAP increased to ≥ 248 dB/m (55 [27.8%] ≥ 280 dB/m suggestive of severe steatosis). Among the 375/573 (61.3%) patients with a CAP ≥ 248 dB/m at baseline, CAP decreased to < 248 dB/m in 49 (13.1%) patients.



Conclusion: The prevalence and incidence of NAFLD in patients with type 2 diabetes are high. While cACLD is common in this population, the incidence of cACLD is relatively low. Our results support one-off fibrosis testing in diabetic patients but not routine 3-yearly assessments in all patients.

SAT-313

Exosomal miRNA analysis for classifying severity of disease in biopsy-proven NAFLD patients

Young-Sun Lee[1], Sung Won Chang[1], Ha Seok Lee[1], Sehwa Kim[1], Haein Bak[1], Min-jin Lee[1], Young Kul Jung[1], Ji Hoon Kim[1], Yeon Seok Seo[1], Hyung Joon Yim[1], Jong Eun Yeon[1], Soon Ho Um[1], Kwan Soo Byun[1]. [1]*Korea university, Seoul, Korea, Rep. of South*
Email: jeyyeon@hotmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is becoming leading cause of chronic liver disease. Although determining the exact mechanisms that lead to NAFLD and NASH is important for disease identification, factors that regulate disease progression are largely unknown. In this study, we analyzed serum exosomal miRNA from biopsy-proven NAFLD patients and compared miRNA expression according to disease severity.

Method: Sera were collected from 41 patients with biopsy-proven NAFLD without other chronic liver disease from November 2016 to January 2018. Sera were stored at −20°C and thawed for isolation of the exosome. Exosomes were isolated from sera using an exosome isolation kit. Total RNA was extracted from exosomes and microarray was performed.

Results: Mean age and BMI were 53.5 ± 12.3 years and 29.9 ± 4.6 kg/m^2, respectively. Female was dominant (n = 34, 82.9%). In microarray analysis, total 2, 578 miRNAs were identified. We classified patients into non-significant fibrosis group (F0-2, n = 25) and significant fibrosis group (F3-4, n = 16). 40 miRNAs expression were significantly increased in advanced fibrosis group comparing with non-advanced fibrosis group. (Figure) Among them, miRNA4668 and miRNA3613 were increased more than 8 times in advanced fibrosis group comparing with non-advanced fibrosis group. Whereas 22 miRNAs expression were significantly increased in non-advanced fibrosis group comparing with advanced fibrosis group. When patients were classified into NASH group (n = 19) and non-NASH group (n = 22), 4 miRNAs showed higher expression comparing with NAFL group, whereas 1 miRNAs showed lower expression in NASH group comparing with NAFL group. In comparison between severe inflammation group (grade 2, 3, n = 25) and mid inflammation group (grade 0, 1, n = 16), severe inflammation group showed higher expression of 1 miRNA and lower expression of 9 miRNAs comparing with mid inflammation group.

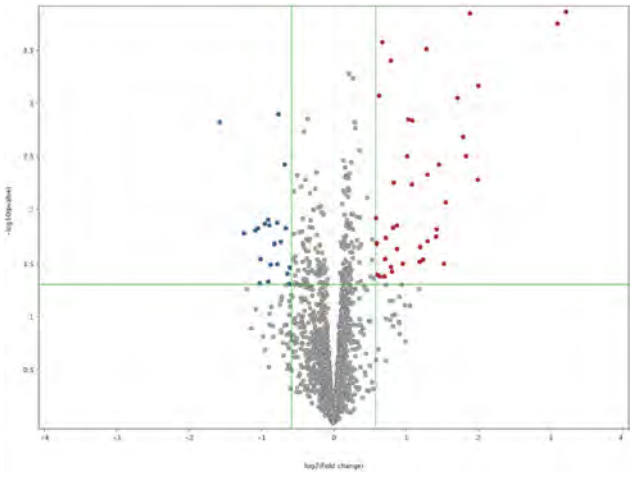


Figure: Volcano plot. F 0, 1, 2 (Blue) versus F3, 4 (Red)

Conclusion: miRNA expression analysis showed significant differences according to status of fibrosis, NASH, and inflammation. These results mean miRNA expression might be important factor for disease progression in NALFD patients. Further validation studies are needed to identify the role of miRNA in disease progression of NAFLD.

Email: rosalombardi@hotmail.it

Background and aims: Type 2 diabetes mellitus (T2DM) is a risk factor for the onset and progression of non-alcoholic fatty liver disease (NAFLD) to liver fibrosis, but this issue is often neglected. Liver biopsy is the gold standard for staging NAFLD, but it is not routinely applicable to wide cohorts of T2DM patients. We aimed at estimating non-invasively prevalence and predictors of NAFLD and fibrosis in a multi-center cohort of T2DM patients.
Method: Three-hundred nineteen T2DM patients attending the diabetes outpatient clinic in five Italian centres were enrolled. Secondary causes of liver disease were excluded. All patients underwent liver ultrasound (steatosis grading 1-3) and FibroScan®. Controlled attenuation parameter (CAP) ≥ 248 Db/m and liver stiffness measurement (LSM) ≥ 8.7 kPa for M probe and ≥ 7.2 kPa for XL probe defined steatosis and advanced fibrosis, respectively.
Results: Among the 319 T2DM patients included (mean age 69 ± 9 years; 49% males; mean HbA1c 7 ± 1.1%), hypertension was present in 78%, dyslipidemia in 84% (mostly treated with statins) and obesity in 32%; 64% of these patients were treated with hypoglycaemic drugs and 36% with diet only; nearly 55% of them had micro-vascular or macro-vascular complications. Elevated levels of AST, ALT and GGT were present only in 3%, 7% and 11% of patients, respectively. The overall prevalence of hepatic steatosis was 89% (severe in 15%), confirmed in 80% of cases by CAP (available in 196 cases). LSM mean values were not significantly different in patients with and without steatosis (5.6 ± 2.7 vs 4.8 ± 1.2 kPa). In patients with steatosis, presence of severe fibrosis (LSM ≥ 8.7/7.2 kPa) was detected in 29 (11%) and correlated in multivariate analysis with elevated serum GGT (OR 1.02; CI 95% 1-1.04; p = 0.04), hyperuricemia (OR 9.8; CI 95% 1.9-50; p = 0.006), BMI (OR 1.2; CI 95% 1-1.05; p = 0.04), severe steatosis (OR 14; CI 95% 2.2-88.7; p = 0.005), and HbA1c > 7% (OR 1.1; CI 95% 1.1-22.2; p = 0.04). LSM, even when considered as continuous variable, did not show any significant association with diabetic complication status, hypoglycaemic treatment and diabetes duration.
Conclusion: NAFLD is highly prevalent in T2DM patients (89%), advanced liver fibrosis is detectable in 11% of them, especially if severe steatosis, obesity and hyperuricemia also coexist. We suggest a non-invasive screening for liver fibrosis in patients with T2DM and NAFLD, irrespective of serum transaminase levels and diabetic complications.

SAT-315

Clinical utility and application of non-invasive tests of fibrosis in the selection of patients with advanced fibrosis due to NASH in the Phase 2 ATLAS trial

Rohit Loomba[1], Naim Alkhouri[2], Simone Strasser[3], Vincent Wai-Sun Wong[4], Raul Aguilar Schall[5], Bryan Mccolgan[5], Mani Subramanian[5], Stephen Djedjos[5], Robert Myers[5], Zachary Goodman[6], Aasim Sheikh[7], Guy Neff[8], Bal Bhandari[9], Nadege Gunn[10], Kris V. Kowdley[11]. *[1]University of California at San Diego, La Jolla, United States; [2]Texas Liver Institute, University of Texas Health San Antonio, San Antonio, United States; [3]University of Sydney, Sydney, Australia; [4]Department of Medicine and Therapeutics, The Chinese Hospital of Hong Kong, Hong Kong, Hong Kong; [5]Gilead Sciences, Inc., Foster City, United States; [6]Inova Fairfax Hospital, Falls Church, United States; [7]GI Specialists of Georgia, Marietta, United States; [8]Florida Research Institute, Lakewood Ranch, United States; [9]Delta Research Partners, Bastrop, United States; [10]Pinnacle Clinical Research, Austin, United States; [11]Swedish Medical Center, Seattle, United States*
Email: bryan.mccolgan@gilead.com

Background and aims: Liver biopsy is a barrier to clinical trial enrollment in NASH. We describe the utility of non-invasive tests (NITs) to enroll patients with advanced fibrosis (F3-F4) due to NASH.
Method: The ATLAS study (NCT03449446) enrolled patients based on: 1) a biopsy showing F3-F4 fibrosis per the NASH CRN classification (the biopsy cohort); or 2) in the absence of a prior biopsy, an ELF test ≥ 9.8 and liver stiffness (LS) by transient elastography (TE; FibroScan) ≥ 14.0 kPa using the XL probe (the NIT cohort). Patients in the NIT cohort had baseline biopsies and were randomized regardless of results. Analyses are based on an interim data cut.
Results: Of the 645 screened patients with evaluable fibrosis stage (median age 59 years, 62% women, 61% with diabetes, median BMI 33.7 kg/m^2), 395 were enrolled. Fifty-five (14%) qualified based on NIT criteria; F3-F4 fibrosis was confirmed in 87% (48/55) (4% F0, 4% F1, 5% F2, 22% F3, 65% F4). Patients in the biopsy cohort with F3-F4 fibrosis had demographics, liver biochemistry, and serum fibrosis markers similar to those in the NIT cohort, but with higher LS by TE (Table). The proportions of patients with NAS ≥ 4 (87% vs 86%) and cirrhosis (65% vs 53%; p = 0.09) did not differ between the NIT and biopsy cohorts. Within the NIT cohort, biopsy length was shorter in patients with F0-F2 vs F3-F4 (1.3 vs 2.2 cm; p = 0.18). Patients with F0-F2 fibrosis also had lower BMI (31.0 vs 34.4 kg/m^2; p = 0.11), less diabetes (43% vs 75%), and less lobular inflammation and ballooning.

Table: Baseline Laboratory and Histological Features

Parameter	Screen Failures F0-F2 (n = 148)	Biopsy Cohort F3-F4 (n = 442)	NIT Cohort* F0-F2 (n = 7)	NIT Cohort* F3-F4 (n = 48)
ALT, U/L	32	42	21	47
FIB-4	1.2	2.0	0.9	2.3
ELF	8.9	10.0	10.1	10.6
LS by TE†, kPa	9.0	14.8	14.4	21.2
Lobular inflammation grade 3	22 (15)	257 (58)	1 (14)	29 (60)
Ballooning grade 2	50 (34)	348 (79)	4 (57)	39 (81)

Data are median or n (%).
* Patients in the NIT cohort are not included in the screen failures or biopsy cohort.
† LS using FibroScan XL probe. Data in n = 123 screen failures, n = 363 with F3-F4 in the biopsy cohort, and all in the NIT cohort.

Conclusion: In this Phase 2 trial of patients with NASH, a combination of ELF and LS by TE identified the target population in 87% of patients. Enrollment based on NITs should be considered for future NASH studies to reduce reliance on biopsy.

SAT-316

Non-invasive assesment of arterial stiffness and carotid intima-media thickness in children with non-alcoholic fatty liver disease

Yuriy Stepanov[1], Nataliya Zavhorodnia[1], Olha Lukianenko[1], Victoriya Yagmur[1], Irina Konenko[1], oksana petishko[1]. *[1]"Institute of gastroenterology of the National academy of medical sciences of Ukraine", Dnipro, Ukraine*
Email: sirenkolga@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is associated with an increased risk of cardiovascular disease developing. The increase of local arterial stiffness and carotid intima-media thickness are the earliest structural and functional changes that can be used for instrumental evaluation.
Aim: To study the elastic features of the carotid arteries wall in NAFLD patients and its association with steatohepatitis.
Method: 113 patients aged 8-17 years were examined. Diagnosis of hepatic steatosis was conducted using FibroScan®502touch

(Echosens, Paris, France). Ultrasonic examination of vessels was carried out by Soneus P7 (Kharkiv, Ukraine). The carotid intima media thickness (cIMT) was examined at the standard point at maximum zooming. Patients group distribution was performed according to the presence of obesity/overweight, liver steatosis/steatohepatitis (according to controlled attenuation parameter and ALT level): group 1 consisted of 34 children with simple steatosis and overweight/obesity, group 2-22 children with steatohepatitis and overweight/obesity, group 3-43 children with overweight/obesity without steatosis, (control) group 4-14 children with normal weight.
Results: There was an increase in the pulse wave velocity (PWV), as well as the elastic modulus (EM) in children with NAFLD, with the significant differences of these parameters in patients with simple steatosis. Children with simple steatosis and steatohepatitis differed from the control group by a significant increase in the carotid wall stiffness index (SI) (p < 0, 05). Patients with non-alcoholic steatohepatitis had the highest values of cIMT (0, 051 ± 0, 001) mm, which significantly differentiated these patients from the control group and children with overweight without steatosis (p < 0, 05).
Conclusion: The course of NAFLD in children is accompanied by vascular changes in the form of increased local arterial stiffness and carotid intima media thickness in the case of steatohepatitis.

SAT-317

Fibroscan as a tool to improve cardiovascular disease stratification: Truth or myth?

Rui Magalhães[1,2,3], Joana Teixeira Magalhães[1,2,3], Carla Maria Moura Marinho[1,2,3], José Cotter[1,2,3]. *[1]Hospital Senhora da Oliveira, Gastrenterology, Guimarães, Portugal; [2]Life and Health Sciences Research Institute (ICVS), School of Medicine, University of Minho, Braga, Portugal; [3]ICVS/3B's, PT Government Associate Laboratory, Guimarães/ Braga, Portugal*
Email: rui.magalhaes.med@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease worldwide. Transient elastography (TE, Fibroscan) with controlled attenuation parameter (CAP) has already been proven as an accurate measure for hepatic fibrosis and steatosis. However, its role in stratifying cardiovascular (CV) risk is unknown.
Method: Cohort, retrospective, single center study, including consecutive NAFLD patients that underwent Fibroscan. Patients were followed at least a year. Co-variables were chosen bearing in mind clinical relevance and literature evidence. The correlation towards the outcome variable (Cardiovascular event) was assessed with univariate and multivariate analysis, using SPSS-p value < 0.05 was considered statistically significant
Results: We assessed 96 patients with NAFLD, of whom 64 (66, 7%) were female, with a mean age of 51, 6 years old, all Caucasian. From our cohort, 55.2% of the patients met criteria for metabolic syndrome. Several variables had statistical significance towards cardiovascular events incidence on the univariate analysis. (Cardiac failure; Hypertension; dyslipidemia, diabetes mellitus, metabolic syndrome, body mass index, CAP higher 290 db/m, Framigham score and some therapeutics, hypocoagulation agents, antiplatelet agents, statins, antihypertension agents.) We report 14 (14, 4%) cardiovascular events during follow-up, the CAP mean in this subgroup was 318, 4 db/m. For CAP values superior to 290 db/m (decibels per meter), the odd of incidence of cardiovascular events were 4, 2 times higher, for each unit of cap increase (Odds ratio crude 4, 250; p value 0.05). Adjusting the regression multivariate model with previous significant variables, the association trend to statistically non-significance. Framingham score was not correlated statistically with CAP values.
Conclusion: We were able to stablish a correlation between CAP and incidence of cardiovascular disease events. Meaning that, a CAP increase is associated with increase of incidence on CV events, mainly in high cap values, over 290 db/m. However, this correlation is diluted adjusting to another CV risk predictor covariables. Fibroscan is easy to apply, safe and a cost-effective Method to evaluate NAFLD. CAP values are related to CV events, nevertheless, further studies are needed to identify properly the subpopulation that would most benefit from this feature.

SAT-318

Comparative accuracy of NAFLD fibrosis score, apri score, and FIB-4 score in predicting significant fibrosis in African Americans and Caucasians with non-alcoholic fatty liver disease

Hemnishil Marella[1], Surosree Ganguli[2], Yala Kirthi Reddy[1], Peter Snell[1], Brian Murphy[1], Pradeep Podila[3], Anna Jones[3], Yu Jiang[4], Satish Kedia[5], Uchenna Agbim[3], Benedict Maliakkal[3,6], Satheesh Nair[7], Sanjaya Satapathy[8]. *[1]University of Tennessee Health Science Center, Internal Medicine, Memphis, United States; [2]University of Louisville, Internal Medicine, Louisville, United States; [3]Methodist University Hospital, Hepatology, Memphis, United States; [4]University of Memphis, Division of Epidemiology, Biostatistics, and Environmental Health, Memphis, United States; [5]School of Public Health, University of Memphis, Division of Social and Behavioral Sciences, Memphis, United States; [6]Methodist University Hospital, University of Tennessee Health Sciences Center, Transplant Surgery, Division of Surgery, Memphis, United States; [7]Methodist University Hospital, University of Tennessee Helath Sciences Center, Transplant Surgery, Division of Surgery, Memphis, United States; [8]Methodist University Hospital, University of Tennessee Helath Sciences Center, Transplant Surgery, Division of Surgery, Memphis, United States*
Email: sanjaya.satapathy@yahoo.com

Background and aims: NAFLD Fibrosis score (NFS), FIB-4 score and APRI scores are non-invasive scoring systems for the staging of liver fibrosis in patients with chronic liver diseases. There is no systematic study that has compared the accuracy of these scores with liver histology in NAFLD among African American and Caucasians. In a large cohort of NAFLD patients we aimed to compare NFS, FIB-4 and APRI score in predicting histologically confirmed significant fibrosis (defined as fibrosis stage ≥ 2) in African American and Caucasian patients using liver biopsy as the gold standard.
Method: A retrospective review of the electronic medical records (EMR) from January 2006 thru December 2016 was performed at a large transplant center using ICD-9/ICD-10 codes to identify NAFLD patients (N = 3, 749). Patients with significant alcohol abuse, HIV, hepatitis B, hepatitis C and ≤ 18 years were excluded. Further manual review of the histological/surgical pathology reports was conducted to confirm NAFLD in these patients to form the final cohort of 904 NAFLD patients: 230 of these were African American and 674 were Caucasian (after exclusion of 25 with other ethnicities).
Results: Of the 904 patients (230 African American and 674 Caucasian) included in the analysis, 480 (53.0%) had liver biopsy prior to or at the time of bariatric surgery, and the remainder (n = 424) had liver biopsy for elevated liver biochemistries, or at the time of non-bariatric abdominal surgeries. Distribution of fibrosis stage in African American vs Caucasian were as follows: stage 0: 92 (40.0%) vs. 205 (30.4%), stage 1: 99 (43.0%) vs. 233 (34.6%), stage 2: 33 (14.3%) vs. 127 (18.9%), stage 3: 6 (2.6%) vs. 56 (8.3%), and stage 4: 0 (0%) vs. 53 (7.9%). In African American, AU-ROC (Area under the Receiver Operating Curve) for NFS in predicting significant fibrosis was 0.60 (95% CI: 0.48-0.71), for APRI score was 0.70 (95% CI: 0.61-0.79), for FIB-4 score was 0.60 (95% CI: 0.50-0.70). In Caucasian, AU-ROC for NFS in predicting significant fibrosis was 0.71 (95% CI: 0.67-0.76), for APRI score was 0.78 (95% CI: 0.74-0.82), for FIB-4 score was 0.79 (95% CI: 0.75-0.83).
Conclusion: In this large cohort of Adult patients with biopsy proven NAFLD, the majority of which were morbidly obese undergoing bariatric surgery, NFS, FIB-4, and APRI scores were all highly predictive of significant fibrosis in the Caucasian population. However, only APRI score can reliably predict significant fibrosis in African American patients with NAFLD. This suggests that ethnicity

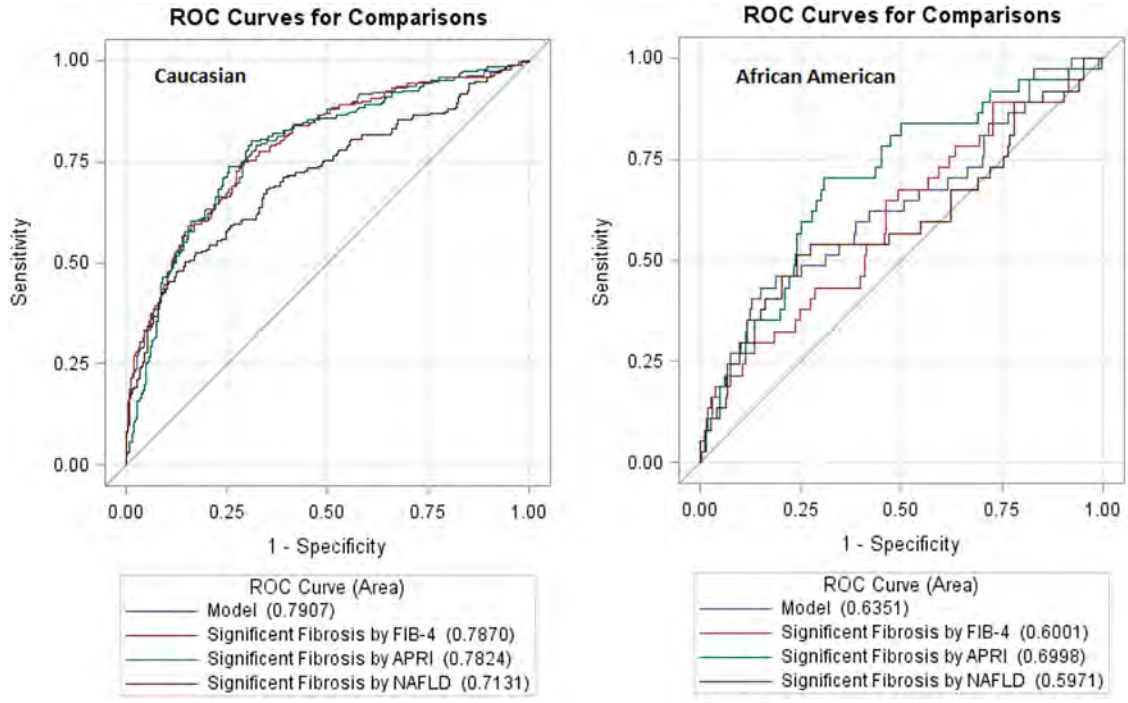

Figure: (abstract: SAT-318)

influences non-invasive fibrosis scoring systems and additional adjustments will be needed so that they can be universally applicable.

SAT-319

Fibroblast growth factor 21 is independently associated with severe hepatic steatosis in non-obese HIV-infected patients

Michael Praktiknjo[1], Djayadi Natalie[1], Bischoff Jenny[1], Mohr Raphael[1], Robert Schierwagen[1], Alessandra Pohlmann[1], Carolynne Schwarze-Zander[1], Jan-Christian Wasmuth[1], Christoph Boesecke[1], Jürgen Rockstroh[1], Jonel Trebicka[2,3,4].
[1]University of Bonn, Department of Internal Medicine I, Bonn, Germany; [2]University of Frankfurt, Department of Internal Medicine I, Frankfurt, Germany; [3]University of Southern Denmark, Department of Gastroenterology, Odense, Denmark; [4]European Foundation for the Study of Chronic Liver Failure-EF Clif, Barcelona, Spain
Email: michael.praktiknjo@ukbonn.de

Background and aims: Severe hepatic steatosis shows a high prevalence and contributes to morbidity and mortality in human immunodeficiency virus (HIV) infected patients. Known risk factors include obesity, dyslipidemia and features of metabolic syndrome. Fibroblast growth factor 21 (FGF-21) is associated with hepatic glucose and lipid metabolism. This study aimed to evaluate FGF-21 as a biomarker for severe hepatic steatosis in non-obese HIV-infected patients.
Method: This is a prospective, cross-sectional, monocentric study including HIV-infected out-patients. Hepatic steatosis was measured via controlled attenuation parameter (CAP) using FibroScan 502 touch (ECHOSENS, France). Peripheral blood samples were collected and analysed for FGF-21. Demographic and clinical characteristics were collected from patient's health records.
Results: In total, 75 non-obese HIV-monoinfected patients were included in this study. Prevalence of severe hepatic steatosis was 37%. Patients with severe hepatic steatosis showed significantly higher levels of FGF-21. Univariate analysis revealed FGF-21, BMI, hyperlipidemia and arterial hypertension as significant, while multivariate analysis showed only BMI and FGF-21 as significant independent risk factors for severe hepatic steatosis.
Conclusion: This study presents FGF-21 as an independent and stronger predictor of severe hepatic steatosis than blood lipids in HIV-infected patients. Moreover, BMI predicts severe steatosis even in non-obese HIV-monoinfected patients. Furthermore, this study supports existing metabolic risk factors and expands them to non-obese HIV-infected patients.

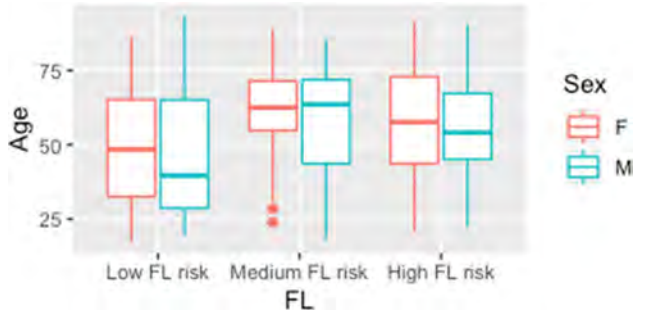
SAT-320

The use of the fatty liver index and fibroscan to determine the prevalence of non-alcoholic fatty liver disease in an Irish population

Louise Rabbitt[1], Dr Mairéad Mcnally[2], Ms Mary Bohan-Keane[3], Ms Margaret Scarry[3], Dr Laura Reynolds[1], Dr Kate Hinchion[1], Dr Carol Goulding[1,4]. *[1]Galway University Hospital, Acute Medical Unit, Galway, Ireland; [2]Mater Misericordiae University Hospital, Gastroenterology, Dublin, Ireland; [3]Galway University Hospital, Hepatology, Galway, Ireland; [4]Galway University Hospital, Gastroenterology, Galway, Ireland*
Email: louise.rabbitt@nuigalway.ie

Background and aims: Rates of non-alcoholic fatty liver disease are increasing worldwide. Non-alcoholic fatty liver disease is now the second most common indication for liver transplant in the USA. The Fatty Liver Index has been developed as a non-invasive predictor of fatty liver. This prospective cohort study used the fatty liver index to indicate the prevalence of non-alcoholic fatty liver disease in a population of patients presenting to an Acute Medical Unit in the West of Ireland, and to subsequently perform a fibroscan on those with high FLI scores to assess for the degree of hepatic steatosis and fibrosis in this group.
Method: All patients attending the Acute Medical Unit in a six-month period were invited to participate. Patients with excess alcohol consumption or pre-existing liver disease were excluded. Using established fatty liver index cut-offs; 414 participants were grouped into low (FLI ≤ 30), medium (30 < FLI ≤ 60) and high (FLI >) risk of non-alcoholic fatty liver disease. Patients with fatty liver index scores > 60 were invited to attend a follow-up clinic at which more detailed

examination took place, including fibroscan and controlled attenuation parameter score.
Results: 138 participants were in the low risk group, 92 in the medium risk group and 184 (45%) were in the high risk group. Male sex ($p < 0.0001$) and increasing age ($p < 0.0001$) were associated with higher risk. Patients in the high risk group (N = 184) were invited back for follow-up; of these, 120 attended. Of these 120, 13 participants had an elevated fibroscan score > 7kPa. Higher fatty liver index scores were associated with higher controlled attenuation parameter scores ($p < 0.0001$) but there was no association between fibroscan score and fatty liver index score ($p = 0.53$). Fasting glucose and HbA1c were both found to be associated with higher fibroscan scores, with a 1 mmol/L change in glucose having a 0.604 average increase in fibroscan (95% CI 0.097 to 1.111; $p = 0.021$), while an increase of 1% in HbA1C lead to a mean change of 0.054 in fibroscan (95% CI 0.015 to 0.092; $p = 0.007$).

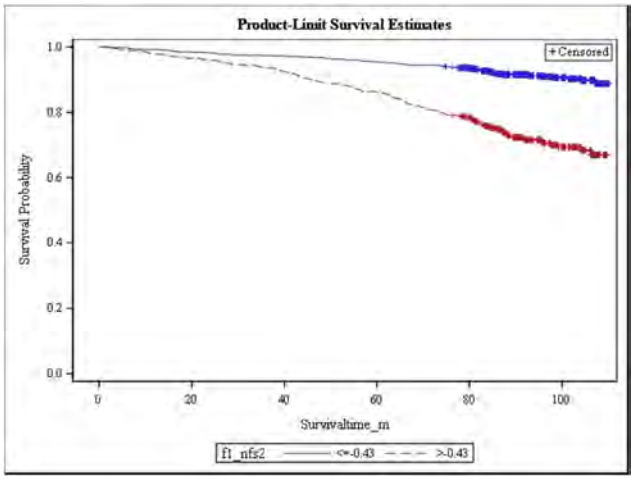


Conclusion: 44.4% of patients presenting to an Acute Medical Unit were at high risk of non-alcoholic fatty liver disease. Reassuringly despite a large number of people at risk of fatty liver, only 10.8% of the high risk group and 3% of all those recruited were found to have a fibroscan score > 7kPa, i.e. had significant fibrosis or cirrhosis.

SAT-321
Liver fibrosis scores predict mortality in the general population
Alexander Kluttig[1], Alexander Zipprich[2], Cristina Ripoll[2]. [1]*Martin Luther University-Halle Wittenberg, Epidemiology, Halle (Saale), Germany;* [2]*Martin Luther University-Halle Wittenberg, Internal Medicine 1, Halle (Saale), Germany*
Email: cristina_ripoll@yahoo.es

Background and aims: Most studies evaluating non-invasive fibrosis measurement are limited to the hepatological setting. Studies focusing on the general population have been centered on Methods such as transient elastography, which are not available to primary care givers. The aim was to evaluate the association of easily available non-invasive markers of fibrosis in the general population with mortality.
Method: This study is an analysis of the population-based CARLA study evaluating cardiovascular disease risk factors in a population of middle-elderly adults (45-83 yrs) in Germany (Greiser BMC Cardiovascular Disorder 2005) between 2002 and 2006. Two follow-up examinations were performed 2007-2010 and 2013, respectively. Vital status of participants was regulary registered, last time in 2016. The cause of death was defined as specified in the official death certificate. Easily available non-invasive fibrosis scores were calculated (NFS, FIB4, APRI, Lok, GUCI, Forns and BARD) and compared regarding overall mortality, CVD mortality and liver associated mortality with ROC curves. Their independent prognostic value for overall mortality, cardiovascular and liver mortality adjusted by age, CVD risk factors (BMI, diabetes, smoking, arterial hypertension, physical activity), and baseline comorbidities (liver disease and cancer) was evaluated with Cox regression analysis.
Results: 1436 subjects were included in the analyses (mean age 67 (SD 9)years, male 55%, mean BMI 28.4 (SD 4.7)). During follow-up 220 people died, (100 CVD or liver associated). NFS and Forns had the greatest AUC for overall mortality (see table) and cardiovascular/liver related mortality [AUC = 0.78 (95%CI 0.73-0.82) and 0.75 (95%CI 0.70-0.80), respectively]. On multivariate Cox analysis, both were identified as independent predictors of overall mortality [NFS HR 1.60 (95% CI 1.41-1.82), Forns HR.1.17 (95%CI 1.10-1.25)] and cardiovascular and liver disease mortality [NFS HR = 1.99 (95%CI 1.62-2.44); Forns HR = 1.21 (95%CI 1.12-1.32)]. The NFS cut-off –0.43 was the best to predict mortality (Se 72%, Sp 72%). KM curves are shown on figure (log-rank 93.9, $p < 0.001$).

Variable	AUC (95% CI)
NFS	0.732 (0.696-0.768)
FIB4	0.594 (0.554-0.635)
APRI	0.569 (0.526-0.612)
Lok	0.633 (0.591-0.657)
GUCI	0.510 (0.465-0.555)
Forns	0.709 (0.672-0.745)



Conclusion: The non-invasive fibrosis score, NFS, is an independent predictor of overall, cardiovascular and liver mortality in the general population. This easily available score (age, BMI, impaired fasting glucose or diabetes, AST, ALT, platelets and albumin) can be calculated in the primary care setting and select patients that should be referred for specialist care.

SAT-322
Comparison of point shear wave elastography (ElastPQ-pSWE) and FibroScan Transient Elastography (F-TE) for liver fibrosis staging in patients with NAFLD

Background and aims: ElastPQ is a recently-introduced point shear wave elastography technique used to non-invasively assess liver fibrosis. We compared liver stiffness measured by both ElastPQ and Transient Elastography with Fibroscan (F-TE) in a cohort of

Table: (abstract: SAT-322)

	ElastPQ				FIBROSCAN				
	Cut-off (kPa)	Sensitivity (%)	Specificity (%)	AUC	Cut-off (kPa)	Sensitivity (%)	Specificity (%)	AUC	P value
F ≥ 2	6.9	80	73	0.837	7.9	82	71	0.847	0.5866
F ≥ 3	8.4	87	83	0.881	10.2	77	80	0.847	0.2186
F4	12.4	94	91	0.981	13.5	88	86	0.934	0.04

consecutive patients with NAFLD. We further evaluated the performance of ElastPQ in a subgroup of patients with available histology.
Method: Anthropometric parameters [weight, height, BMI and waist circumference (WC)] were measured on the same day of routine bloods tests. Elastography measurements were carried out using F-TE (Fibroscan, Echosens, Paris) and ElastPQ (Affiniti 70G, Philips) in all recruited patients.
Results: We enrolled 414 consecutive patients with NAFLD, mean age 55 ± 13y, BMI 31.5 ± 5.7 kg/m^2, waist circumference (WC) 107 ± 15 cm, 59% male, 44% with diabetes, 55% hypertension, 77% hyperlipidaemia.
ElastPQ had a good correlation with F-TE (Spearman's = 0.786, p < 0.001), which was better for mild and moderate stages of fibrosis. A difference ≥ 2 kPa between the two techniques was found in 105 patients. On univariate analysis predictors of such difference were diabetes (p < 0.001), BMI (p = 0.015), WC (p = 0.040), AST (p < 0.001), Hb1Ac (p = 0.003), ALP (p = 0.005), GGT (0.041), Platelets (p = 0.004), INR (p = 0.010) and a liver stiffness ≥ 10 kPa measured by F-TE (p < 0.001). On multivariate analysis the only independent predictor was F-TE ≥ 10 kPa (OR: 6.152, 95% CI 3.247-11.655, p < 0.001).
In the subgroup of 125 patients with available histology, the distribution of fibrosis was as follow: F0 = 15 (12%), F1 = 44 (35%), F2 = 27 (22%), F3 = 22 (18%), F4 = 17 (14%).
The optimal cut-off values of ElastPQ for individual stages of fibrosis were lower than those of F-TE. ElastPQ showed the same good diagnostic performance for F ≥ 2 and F ≥ 3 but a better diagnostic performance for F4 compared to F-TE (Table 1).
Conclusion: ElastPQ and F-TE showed a good correlation in patients with NAFLD, which is better for low values of liver stiffness. The optimal cut-off values of ElastPQ are lower than those of F-TE for individual stages of fibrosis. ElastPQ seems to have a better diagnostic accuracy than F-TE in diagnosing liver cirrhosis but this finding needs to be confirmed in larger cohorts.

SAT-323
Selenoprotein P levels discriminate the degree of hepatic steatosis and are related to the NAS score in patients with non-alcoholic fatty liver disease

Chiara Rosso[1,1], Ramy Younes[1], Elisabetta Morello[2], Melania Gaggini[3], Gian Paolo Caviglia[1], Chiara Marinoni[1], Maria Jose Garcia Blanco[4], Antonella Olivero[1], Giorgio Maria Saracco[1], Amalia Gastaldelli[3], Antonina Smedile[1], Elisabetta Bugianesi[1]. [1]*University of Turin, Department of Medical Sciences, Turin, Italy;* [2]*University of Turin, Department of Clinical and Biological Sciences, Turin, Italy;* [3]*Institute of Clinical Physiology, CNR, Cardiometabolic Risk Unit, Pisa, Italy;* [4]*University Hospital of La Princesa, Department of Internal Medicine, Madrid, Spain*
Email: chiara.rosso@unito.it

Background and aims: Alterations in glucose and lipid metabolism in the setting of insulin resistance (IR) play an important role in the progression from Non-alcoholic Fatty Liver (NAFL) to Non-alcoholic Steatohepatitis (NASH) via oxidative stress. Selenoprotein P (SeP) is a selenium carrier protein with antioxidant properties that is higher in obese and diabetic subjects but its potential role as biomarker of NASH is not fully elucidated yet. The aim of this study was to assess the usefulness of SeP in discriminating NASH from simple steatosis in a well characterized cohort of biopsy proven NAFLD patients.
Method: We studied 208 subjects with histological diagnosis of NAFLD (145 male). Plasma SeP levels concentrations were measured with a quantitative sandwich enzyme-linked immunosorbent assay (ELISA). Histology was scored according to Kleiner. NASH was diagnosed by the local pathologist according to the joint presence of steatosis, inflammation and ballooning (with or without fibrosis).
Results: Overall, 153 (73.6%) subjects had NASH. Plasma SeP levels were significantly higher in patients with NASH compared to those with simple steatosis (5.3 ± 1.5 *vs* 6.2 ± 2.1, p = 0.0037). Circulating SeP mainly correlated with BMI (r = 0.4, p < 0.0001), visceral obesity by waist circumference (r = 0.2, p = 0.0089), AST (r = 0.3, p = 0.0001) and fasting plasma glucose (r = 0.3, p < 0.0001). Among histological features, plasma SeP showed a stepwise increase according to hepatic steatosis grade (p = 0.0007) and was able to discriminate mild (5-33%) from significant (≥ 33%) steatosis. Furthermore, circulating SeP increased according to the NAS score (p = 0.0131). At univariate logistic regression analysis, the higher SeP tertile (SeP values ≥ 6.3 ug/ml) was associated to NASH and to significant steatosis (≥ 33%) with an OR of 2.3 (95% CI = 1.1-5.0, p = 0.035) and 2.2 (95% CI = 1.2-4.1, p = 0.0095), respectively.
Conclusion: Circulating SeP levels increased in patients with NASH and were associated to both hepatic steatosis and NAS score suggesting its potential role as biomarker in the setting of NAFLD.

SAT-324
Sonic hedgehog immunohistochemistry is a tissue biomarker of ballooned hepatocytes

Michael Schild[1], Manal Abdelmalek[2], Anna Mae Diehl[2], Cynthia Guy[1]. [1]*Duke University, Pathology, Durham, United States;* [2]*Duke University, Gastroenterology, Durham, United States*
Email: michael.schild@duke.edu

Background and aims: Accurate identification of ballooned hepatocytes (HCs) is important for liver disease categorization (eg, ballooning helps distinguish steatosis from steatohepatitis). Ballooning recognition can be challenging on routine stains. Experimental evidence has confirmed that expression of Hedgehog (Hh) ligand is upregulated by HCs during cellular stress (eg, endoplasmic reticulum stress and lipotoxicity). Sonic Hh (SHh) immunohistochemistry (IHC) can be used to mark ballooned HCs in non-alcoholic fatty liver disease (NAFLD); however, the patterns of SHh IHC have not been fully characterized across a spectrum of liver diseases with ballooning/enlargement and/or cytoplasmic clearing.
Method: Formalin-fixed paraffin-embedded sections from the following liver diseases were retrospectively analysed: adult NAFLD, paediatric NAFLD, NAFLD with glycogenosis, alcohol-related liver disease (ALD), Wilson disease (WD), alpha-1 antitrypsin deficiency (A1AT), acute large duct obstruction (ALDO), chronic hepatitis B (HBV) and neonatal giant cell hepatitis (NGCH). Haematoxylin and eosin, trichrome, and SHh IHC were evaluated.
Results: SHh IHC expression results are detailed in Table 1. Ballooned HCs of adult NAFLD, paediatric NAFLD, ALD, WD, and A1AT show strong cytoplasmic positivity. The following are negative for diffuse

strong SHh IHC: non-ballooned hepatocytes of adult and paediatric NAFLD, ALD, WD, and A1AT. Furthermore, glycogenosis, cholate stasis and the enlarged HCs of NGCH are also negative.

Table 1: Sonic hedgehog IHC marks ballooned hepatocytes

Disease	# of cases	HandE: Cases with ballooned/ enlarged hepatocytes, n (%)	SHh IHC: Ballooned/ cleared hepatocytes	SHh IHC: Non-ballooned/ non-enlarged hepatocytes
Adult NAFLD	15	13 (87%)-ballooned	Positive	Negative
Paediatric NAFLD	9	3 (33%)-ballooned	Positive	Negative
NAFLD with glycogenosis	4	3 (75%)-ballooned	Positive	Negative
		4 (100%)-glycogenosis	Negative	
ALD	9	6 (67%)-ballooned	Positive	Negative
WD	6	1 (17%)-ballooned	Positive	Negative
		2 (33%)-cholate	Negative	
A1AT	6	6 (100%)-ballooned	Positive	Negative
ALDO	5	5 (100%)-cholate	Negative	Negative
HBV	5	3 (60%)-cholate	Negative	Negative
NGCH	6	6 (100%)-giant cells	Negative	Negative

Conclusion: Ballooned HCs, present in a spectrum of liver diseases, show strong cytoplasmic positivity for SHh IHC. Other types of HCs with cytoplasmic clearing and/or enlargement are negative for strong SHh over-expression. SHh IHC is a specific and reliable tissue biomarker of hepatocellular ballooning.

SAT-325

Implementation of a primary care shear-wave elastography-based pathway to identify non-alcoholic fatty liver disease patients with advanced fibrosis in a large North American urban population

Abdel-Aziz Shaheen[1], Kiarash Riazi[1], Alexandra Medellin[2], Deepak bhayana[2], Roy Park[2], Linda Slocombe[3], Monica Sargious[3], Mark G Swain[1]. *[1]University of Calgary, Cumming School of Medicine, Division of Gastroenterology and Hepatology, Department of Medicine, Calgary, Canada; [2]EFW Radiology Group, Calgary, Canada; [3]Primary Care Networks, Alberta Health Services, Calgary, Canada*
Email: azshaheen@me.com

Background and aims: Approximately 24% of adults have NAFLD. Identification of NAFLD patients with advanced fibrosis within the general population is challenging. Therefore, we developed and implemented a 2-D SWE case-identification pathway, driven by primary care physicians, to facilitate referrals of NAFLD patients in primary care with high risk for advanced fibrosis.
Method: Our hepatology and primary care (PCN; primary care networks, covering ~95% of the 1.4 million Calgary population) team co-developed the NAFLD clinical care pathway with a community-based radiology group proficient with SWE. Primary care physicians access the NAFLD pathway for patients with any of the following conditions: overweight, obesity, diabetes mellitus, elevated liver enzymes or fatty liver detected by imaging. Patients with suspected NAFLD (i.e. routine serology excluded other causes of chronic liver disease) were then assessed by SWE. NAFLD patients with liver stiffness by SWE ≥ 8kPa (or an inconclusive result) were referred to hepatology, and those with SWE < 8.0 kPa were managed in primary care using a standardized management pathway. To ensure high quality implementation of the pathway, we completed a training period from Oct 2016-Feb 2018.
Results: Between March-October 2018 we evaluated 1868 patients with suspected NAFLD. NAFLD prevalence by ultrasound was 91.8% (n = 1715). NAFLD patients were more likely women (53.4%) with median age of 54 (IQR: 45-63). Elevated liver enzymes, impaired glucose tolerance or diabetes, and obesity were prevalent (52.1%, 40.5% and 59.7%, respectively). Median SWE was 4.4kPa (3.7-5.5kPa). In our cohort, 1586 NAFLD patients (92.6%) had SWE < 8kPa, not requiring referral to a hepatologist, while 7.4% (n = 127) had either SWE ≥ 8kPa (3.0%) or an inconclusive result (4.4%) and had hepatology referral. Among patients with inconclusive SWE results, liver stiffness by transient elastography ≥ 8kPa was subsequently documented in 79% (59/75) of patients. Compared with non-referred patients, referred patients were older (median age 57 vs 54, P = 0.04), had higher BMI (median 38 vs 32, P < 0.01), and were more likely to have impaired glucose tolerance/diabetes (66.7% vs 45.0%, P = 0.03). In our cohort, FIB-4 and NFS classified 36.5% and 61.4% of NAFLD patients above cut-off of 1.30 and −1.45 respectively. Both FIB-4 and NFS were not correlated with SWE (r = 0.16 and 0.30 respectively). Among referred patients, liver biopsy was obtained (to date) in 27 patients (F0 in 1, F1 in 7, F2 in 7, F3 in 8 and F4 in 4).
Conclusion: The implementation of a primary care-accessible SWE program for NAFLD patients in a large urban population facilitated successful fibrosis risk stratification. The prevalence of advanced fibrosis was 6.4% among patients with risk factors for NAFLD. Serum-based fibrosis scores (i.e. FIB-4, NFS) were not correlated with SWE and would lead to higher referral rates to hepatology.

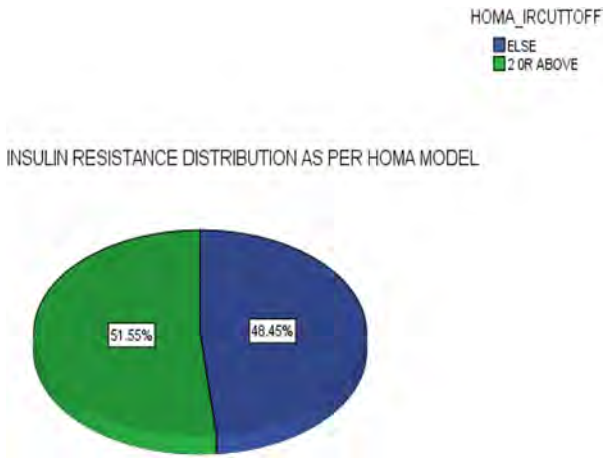
SAT-326

Influence of NAFLD diagnosed by controlled attenuation parameterin patients of chronic hepatitis B with mildly elevated alt

Asim sharif[1], Zaigham Abbas[2], shoukat samejo[2]. *[1]ziauddin university hospital karachi, gastroentrology, karachi, Pakistan; [2]Karachi, gastroentrology, Karachi, Pakistan*
Email: asimsharif22@gmail.com

Background and aims: International guidelines vary regarding treating patients with mildly elevated ALT up to 2 times upper limit of normal. Patients with chronic hepatitis B infection may have elevated ALT due to infection itself, NAFLD or both.So it becomes difficult to decide whether to treat or postpone the treatment of hepatitis B.The aim of this ongoing study is to find out the role of NAFLD as a cause of elevated ALT in hepatitis B patients.
Method: The HBsAg positive patients visiting the GI clinic with mildly elevated ALT between up to 2 times upper limit of normal were further evaluated by body mass index (BMI), waist circumference, exclusion of concomitant hepatitis D or C, LFTs, quantitative HBV DNA, HBeAg, and fibroscan. The presence of steatosis was assessed by controlled attenuation parameter (CAP) in decibels/meter (dB/m) and was scaled from 0-3 (0 = 1-4%, 1 = 5-33%, 2 = 34-66%, 3 = 66-100%). The elasticity as an indicator of fibrosis was measured in kilopascals (kPa) and was scored from F0-F4.Significant fibrosis (F2 or more) was considered at ≥ 8 kPa and steatosis at ≥ 225 dB/m. Those patients who had HBV DNA of more than 2000 IU/ml and significant fibrosis were considered for hepatitis B treatment.
Results: Total number of patients evaluated so far in this ongoing study were 150. M:F ratio was 1:2. Mean age 36.4 ± 11.5 years (range 13-69). Mean BMI 28.1 (range 14.2-38.5). Mean waist circumference 95.8 ± 14.8 cm. 20/150 (13%) had diabetes while 6% were hypertensive. There was absence of steatosis in 34 (22.6%) patients according to CAP score, 24 (16%) had grade 1 steatosis, 35 (23.3%) grade II steatosis and 57 (38%) grade III steatosis. 50/150 had significant fibrosis of F2 or more.34/150 (22.6%)had DNA levels of above 2000. Insulin resistance as assessed by HOMA-IR model correlated significantly with the BMI (p = 0.00), waist circumference (p = 0.004), G-gt (p = 0.05) and CAP score (p = 0.00)but not with the HBV DNA levels (p = 0.009) and ALT levels (p = 0.336). Among those with elevated ALT and significant fibrosis, HBV DNA of more than

2000 was seen in 20 patients. Out of these 3 had no fat as per CAP score so increase ALT levels were purely due to HBV. Among those with elevated ALT and HBV DNA of less than 2000, 24 had significant fibrosis of F2 or more suggesting a contribution of NAFLD.



Conclusion: A significant number of HBsAg positive patients with mildly elevated ALT are overweight, have significant steatosis and fibrosis but low HBV DNA levels. This aspect is important while making decision about the treatmentof hepatitis B in the newly diagnosed patients with mildly elevated ALT.

SAT-327

The change of skeletal muscle mass is associated with hepatic steatosis in non-alcoholic fatty liver disease

Do Seon Song[1], U Im Chang[1], Jeong Won Jang[1], Si Hyun Bae[1], Seung Kew YOON[1], Jin Mo Yang[1]. [1]*The Catholic University of Korea, Department of Internal Medicine, Suwon, Korea, Rep. of South*
Email: jmyangdr@catholic.ac.kr

Background and aims: We aimed to investigate the association between the change of muscle mass and change of fibrosis and steatosis in NAFLD patients.
Method: We analyzed 2, 893 NAFLD subjects who had health check-up more than twice in St. Vincent′s Hospital between November 2009 and December 2017. NAFLD was diagnosed by ultrasound, and appendicular muscle mass (ASM) was assessed by Inbody 720. Sarcopenia index was calculated as ASM divided by weight (SI%) and ASM divided by body mass index (SI-BMI). Non-invasive markers were used to evaluate the severity of hepatic fibrosis and steatosis; NAFLD fibrosis score (NFS), Fibrosis-4 (Fib-4) score, and Forn′s index for fibrosis, and hepatic steatosis index (HSI) and fatty liver index (FLI) for steatosis.
Results: The mean age was 47.3 ± 10.4 years, and 1956 subjects (67.6%) were male. Diabetes, hypertension, metabolic syndrome were more prevalent in sarcopenic subjects ($p < 0.01$), and non-invasive fibrosis and steatosis markers were higher in sarcopenic subjects ($p < 0.01$). The mean interval between two health check-up was 39.8 ± 21.9 months. There was no significant association between the change of NFS, Fib-4, and Forn's index and the change of SI% and SI-BMI (all $p > 0.1$). However, the changes of HIS and FLI were significantly associated with the change of SI% and SI-BMI (all $P < 0.01$). Multivariate logistic analysis demonstrated the independent association between the change of skeletal muscle mass and the changes of non-invasive steatosis markers after adjusting for other confounding factors (all $p < 0.001$). However, the changes of non-invasive fibrosis markers did not show an independent association with the change of appendicular muscle mass after adjusting for other confounders (all $p > 0.1$)
Conclusion: The change of muscle mass is strongly associated with the change of hepatic steatosis, but not the change of fibrosis.

SAT-328

Controlled attenuation parameter for evaluating liver steatosis in type 2 diabetes patients

Ioan Sporea[1], Ruxandra Mare[1], Raluca Lupusoru[1], Nistorescu Silviu[1], Alina Popescu[1], Roxana Sirli[1], Mirela Danila[1]. [1]*Victor Babes University of Medicine and Pharmacy, Gastroenterology and Hepatology, Timișoara, Romania*
Email: isporea@umft.ro

Background and aims: The **aim** of the present study was to assess factors that associate with the severity liver steatosis, in a cohort of type II diabetic patients, using a non-invasive Method: Transient Elastography (TE) with Controlled Attenuation Parameter (CAP).
Method: The study included 284 type II diabetic patients, who were prospectively randomized (every first 6 patients who were referred to the Metabolic Disease Outpatient Clinic on a consultation day), evaluated in the same session by means of CAP (FibroScan EchoSens) to assess liver steatosis. Each patient was evaluated for the presence of viral hepatitis (B, C, D) and an AUDIT-C score was performed to exclude alcohol abuse. Also subjects characteristics, epidemiological data and biochemical tests were recorded. For differentiation between stages of steatosis we used the following cut-off values [1]: S1 (mild)-232.5 db/m, S2 (moderate)-255 db/m, S3 (severe)-290 db/m. Variables tested for the association with steatosis were: body mass index (BMI), abdominal circumference, years after diagnosis, cholesterol, triglycerides, gender, glycemia, glycosylate hemoglobin, oral antidiabetics treatment and insulin treatment. Spearman rank coefficient was used to test correlation between two study variables. Logistic regression was used for multivariate model to assess the association between CAP and other variables.
Results: 284 subjects (112 males and 172 females) were prospectively studied. 29/284 (10.2%) were S0, 17/284 (6%) were S1, 51/285 (17.9%) were S2 and 187/284 (65.9%) were S3 (than 83.8% of diabetic patients had moderate and severe steatosis by CAP). The mean values of CAP were 203 ± 73.5 for S0; 244 ± 14 for S1; 272 ± 24 dB/m for S2, 345 ± 77.7 dB/m for S3. In univariate analysis CAP showed a significant correlation with body mass index (BMI), abdominal circumference, triglycerides and with oral antidiabetics treatment. Multivariate regression analysis confirmed the correlation with oral antidiabetics treatment [OR = 4.4, 95% CI (2.06; 9.52), $p < 0.0001$] and BMI [OR = 1.2, 95% CI (1.09; 1.32); $p = 0.002$], but not with all other variables.
Conclusion: In our group, 83.8% of diabetic patients had moderate and severe steatosis by CAP. Body mass index (BMI), abdominal circumference, triglycerides and with oral antidiabetics treatment were associated with the severity of liver steatosis.

Email: katharina.staufer@meduniwien.ac.at

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is regarded the most common chronic liver disease worldwide. Yet, distinctive objective features allowing firm exclusion of alcohol-

related liver disease (ALD) are lacking. This study investigated the detection rate of alcohol consumption in patients with NAFLD based on ethyl glucuronide in hair (hEtG).
Method: In this multicentric prospective study, patients with NAFLD and ALD were consecutively included based upon history of alcohol intake assessed by standardized questionnaires (SIAC, AUDIT-C) using a cut-off of 20 g ethanol (EtOH)/d in females, and 30 g/d in males, while ruling out other liver diseases according to standard criteria. EtG (hEtG) as well as the confirmatory fatty acid ethyl ester ethyl-palmitate were measured in hair by gas chromatography-mass spectometry in segments of 0-3 cm and 3-6 cm, allowing a reliable, quantitative proof of alcohol consumption within up to 6 months. Additionally, EtG in urine (uEtG), as well as carbohydrate deficient transferrin (CDT), mean corpuscular volume (MCV) and gamma glutamyl transpeptidase (GGT) were assessed. Results were additionally stratified by BMI.
Results: Of 172 patients, 66.9% (n = 115/172) were primarily classified as NAFLD, and 33.1% as ALD (n = 57/115). In total, 31.4% of hEtG tests, and 51.5% of ethyl-palmitate tests were positive for alcohol consumption. hEtG and ethyl-palmitate indicated excessive alcohol consumption (> 60 g/d) in 14.5%, and 20.9% of patients, respectively. In NAFLD patients, in 20.0% (n = 23/115) excessive alcohol consumption, and in 37.4% (n = 43/115) moderate repeated alcohol consumption (10 to < 60 g EtOH/d) was indicated. In contrast, CDT, MCV, GGT, and uEtG were elevated in only 2.9%, 0.0%, 40.9%, and 10.5% of NAFLD patients. BMI negatively correlated with hEtG levels (r:-0.450, $p < 0.001$), and mean hEtG content was significantly lower in patients with BMI ≥ 30 than BMI < 30 (7.0pg/mg vs. 43.6pg/mg, $p < 0.001$). Within the group of normal to overweight NAFLD patients (BMI < 30) even up to 55% (n = 22/40) showed moderate repeated alcohol consumption, and 25% (n = 10/40) excessive alcohol consumption, whereas in patients with obesity (BMI ≥ 30) moderate repeated alcohol consumption, and excessive alcohol consumption was detected in 18.7% (n = 14/75), and 4.0% (n = 3/75).
Conclusion: hEtG and/or ethyl-palmitate in hair indicated moderate repeated alcohol consumption of 10 to < 60 g EtOH/d in 37.4%, and excessive alcohol consumption ≥ 60 g EtOH/d in 20.0% of NAFLD patients, which could not be detected by commonly used alcohol markers such as CDT, MCV, or GGT. The rate of harmful alcohol consumption was especially high in patients with BMI < 30. Analysis of long-term ethanol metabolites in hair, such as hEtG and ethyl-plamitate may therefore represent an important tool for the differential diagnosis of ALD and NAFLD.

SAT-330

Whole metabolome profiling identifies the combination of an eicosanoid, a bile acid and an androgen as a highly accurate marker of liver fibrosis in patients with non-alcoholic fatty liver disease

Email: Felix.Stickel@hirslanden.ch

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is among the most frequent causes of liver disease and estimates based on imaging and biopsy studies suggest that about 20-30% of adults in the United States and Europe have excess hepatic fat accumulation, and are at risk of developing progressive fibrosis, end-stage liver disease or hepatocellular carcinoma. Liver biopsy is considered the gold standard in the diagnostic evaluation of patients with suspected NAFLD, and fibrosis at index biopsy identifies those at risk of progression. However, liver biopsy is uncomfortable, more expensive than most non-invasive tools and carries a procedure-related risk which together renders it unsuitable for regular screening. This study aims to identify novel non-invasive markers by metabolite profiling that correlate with histological key lesions of progressive NAFLD.
Method: In this multicenter cohort study, 74 patients with biopsy-proven NAFLD (NAFL, n = 42; NASH, n = 32) and 62 healthy blood donors were enrolled. Among the NAFLD patients, 13 had advanced fibrosis (≥ F2) while the remaining 61 showed absent or mild fibrosis (F0-F1). Obtained EDTA plasma samples were subjected to metabolite analysis by the GC-MS- and LC-MS/MS-based MxP® Broad Profiling approach, and by the targeted platforms MxP® Steroids, MxP® Lipids and MxP® Eicosanoids. The metabolic data were statistically analyzed by applying univariate (analysis of variance) as well as multivariate (random forest, elastic net, and linear discriminant analysis) algorithms, and peak signals were compared to key histology lesions of NAFLD, i.e. fibrosis, activity, and steatosis.
Results: A multi-marker panel, consisting of an eicosanoid, a bile acid and an androgen, successfully differentiated the EDTA plasma samples into two main clusters: fibrosis stage ≥ 2 and fibrosis stage < 2 (AUC = 0.95, Sens = 0.92, Spec = 0.90, PPV = 0.225, NPV = 0.997). Thus, our biomarker outperforms the FIB4 index (AUC = 0.80), the ELF score (AUC = 0.82), and plasma levels of caspase-cleaved keratin 18 fragments (AUC = 0.68).
Conclusion: The identified metabolite panel was significantly associated with liver fibrosis stage in NAFLD patients and reveals an excellent test performance to detect early prognostic histological liver lesions. In sum, this biomarker holds high promise to accurately detect fibrosis in NAFLD patients non-invasively in plasma, and thus may serve as a novel non-invasive screening tool in NAFLD patients.

Background and aims: The use of real world evidence to characterize the long-term consequences of non-alcoholic steatohepatitis (NASH) has been hampered by the absence of a unique code distinguishing it from non-alcoholic fatty liver disease (NAFLD) prior to the adoption of version 10 of the International Classification of Disease (ICD-10) in October 2015. Our study uses machine learning to identify NAFLD patients likely to have a claim for ICD-10 NASH based on claims observed in the ICD-9 era.
Method: In data from the first year of the ICD-10 era (October 2015-September 2016), we identified 10, 717 patients with a NASH diagnosis. A random ~30% sample of patients with no evidence of NASH (N = 90, 214) was selected for comparison. All included patients were enrolled during the final 2 years of the ICD-9 era (October 2013-September 2015) and had a claim for NAFLD during this period. We used the ensemble method Super Learner with 10-fold cross-validation to build a predictive algorithm for ICD-10 NASH based on 12 pre-defined variables (age, sex, and 10 comorbidities known to be associated with NASH/NAFLD including diabetes, obesity and others),

and ICD-9 and medication claim codes agnostically selected by a Bayesian odds ratio (BOR) procedure from a pool of 3, 153 that met defined data sparsity thresholds. The final predictor was validated on a reserved 10% sample of the data. Performance metrics included area under the receiver operating curve (AUC), as well as sensitivity and specificity at a threshold chosen to maximize the Youden index.
Results: The final predictive algorithm, a weighted meta-learner based on 19 discrete base learners, the 12 pre-defined variables, and 60 BOR-selected claim codes, had a validated AUC of 0.76, with a sensitivity and specificity of 0.62 and 0.75, respectively. Using claims data from October 2010 to August 2015, we identified ICD-9-era NAFLD patients with a minimum of 2 years of data to predict claims of ICD-10 NASH. Using the Youden index threshold, we identified 216, 180 additional patients with predicted NASH, bringing the total number of observed NASH patients to 284, 143.
Conclusion: Super Learner combined with BOR variable selection produced a model with a high AUC for identifying patients with predicted ICD-10 NASH during the ICD-9 era. This application of machine learning enables the construction of cohorts spanning ICD-9 and ICD-10 to more fully understand the epidemiology and disease burden of NASH.

SAT-333

Non-alcoholic steatohepatitis significantly decreases microsomal liver function in the absence of fibrosis, which allows the use of the 13C-aminopyrine breath test for its non-invasive detection

Wim Verlinden[1,2], Eugénie Van Mieghem[1], Laura Depauw[1], Thomas Vanwolleghem[1,2], Peter Michielsen[1,2], Luisa Vonghia[1,2], An Verrijken[2,3], Eveline Dirinck[2,3], Luc Van Gaal[2,3], Sven Francque[1,2]. *[1]Antwerp University Hospital, Hepatology, Edegem, Belgium; [2]University of Antwerp, Laboratory of experimental medicine and pediatrics, Antwerp, Belgium; [3]Antwerp University Hospital, Endocrinology, diabetology and metabolism, Edegem, Belgium*
Email: wimfmverlinden@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has become the most frequent cause of chronic liver disease in Western countries, with an increasing prevalence. The presence of non-alcoholic steatohepatitis (NASH) can lead to a more aggressive clinical course with fibrosis progression and hepatocellular carcinoma, which necessitates early NASH detection. Currently, the diagnosis of NASH is based on histology, though with the high prevalence of NAFLD, a non-invasive method is needed. The 13C-aminopyrine breath test (ABT) evaluates the function of the cytochrome P450 enzymes of the liver (microsomal liver function) and could be a potential candidate. We aimed to firstly, evaluate a potential change in liver microsomal function in NASH patients; secondly, evaluate the diagnostic power of ABT to detect non-fibrotic NASH (NASH-F0-1); and thirdly evaluate the diagnostic power of ABT to detect fibrotic NASH (NASH-F2-4)
Method: A retrospective analysis was performed on consecutive patients suspected of NAFLD who underwent a liver biopsy and ABT between 2002 and 2018 at the Antwerp University Hospital. Subgroups were created for patients without NASH (noNASH), patients with NASH but without significant fibrosis (NASH-noF) and patients with NASH and significant fibrosis (NASH-F).
Results: 454 patients were included (33% noNASH, 40% NASH-noF, 27% NASH-F). A significant difference ($p < 0.0001$) in ABT was found between noNASH, NASH-noF and NASH-F with a cumulative excretion of 14.6 ± 6.6, 12.8 ± 5.4 and 10.4 ± 5.5%dose, respectively. The cumulative excretion (cABT) proved a better predictor of NASH and fibrosis than peak excretion. The predictive power of cABT as a single test was low for NASH-noF and NASH-F with AUROCs of 0.620 and 0.650, respectively. A predictive model was created adding ALT, C-peptide and age to cABT, which increased the AUROC to 0.775 to detect NASH-noF. A model adding AST to cABT increased the AUROC to 0.796 to detect NASH-F. Cut-off values were determined for optimal accuracy, 90% sensitivity and 90% specificity to predict both NASH-noF and NASH-F.
Conclusion: The microsomal liver function of patients with NASH is significantly decreased even in the absence of fibrosis highlighting the sole impact of steatohepatitis on patients' health. The ABT is a valuable tool in assessing the presence of non-fibrotic and fibrotic NASH; and could therefore be used as a supplementary diagnostic tool in clinical practice.

SAT-334

Liver steatosis in HIV-positive patients with and without HBV coinfection accessing care in a programmatic setting in Africa

Giovanni Villa[1], Richard Phillips[2,3], Colette Smith[4], Dorcas Owusu[2], Adam Abdullahi[1], Harrison Austin[1], Laila Sayeed[5], David Chadwick[5], Sanjay Bhagani[6], Anna Maria Geretti[1]. *[1]University of Liverpool, Institute of Infection and Global Health, Liverpool, United Kingdom; [2]Kwame Nkrumah University of Science and Technology, Kumasi, Ghana; [3]Komfo Anokye Teaching Hospital, Medicine, Kumasi, Ghana; [4]University College London, Infection and Population Health, London, United Kingdom; [5]James Cook University Hospital, Centre for Clinical Infection, Middlesbrough, United Kingdom; [6]Royal Free Hospital NHS Foundation Trust, London, United Kingdom*
Email: geretti@liverpool.ac.uk

Background and aims: Owing to the success of antiretroviral therapy (ART), non-communicable diseases, including non-alcoholic fatty liver disease (NAFLD), are an emerging concern in HIV care. There is a paucity of data on NAFLD in sub-Saharan Africa, where HIV and HBV infection co-exists. Using controlled attenuation parameter (CAP) readings, this study investigated liver steatosis in a programmatic HIV care setting in Ghana.
Method: Consecutive patients accessing outpatient care over a 2-week period underwent CAP and liver stiffness measurement by FibroScan®. Liver steatosis was graded (S0-S3) using recommended cut-offs (248, 268, 280 dB/m). Patients also underwent clinical examination, laboratory testing, and collection of ART history and demographic, anthropometric, and lifestyle data including alcohol consumption. Metabolic syndrome (MS) was defined using the criteria of the International Diabetes Federation.
Results: Among 330 adults (72% females; median age 48 years), 90/330 (27%) were HBsAg positive. Patients had received ART for a median of 8.9 years and had a median CD4 count of 620 cells/mm^3; 163/330 (49%) had detectable HIV RNA. Overall, 92/330 (28%) were overweight and 41/330 (12%) were obese. Mild, moderate, or severe hypertension was diagnosed in 80/330 (24%), 34/330 (10%), and 27/330 (8%), respectively. Total cholesterol, LDL, and triglycerides were raised in 111/330 (34%), 82/330 (25%), and 68/330 (21%) patients, respectively; 17/330 (5%) had diabetes; 78/330 (24%) had MS. Regular alcohol consumption was reported by 16/330 (5%). CAP readings were S0 in 261/330 (79%) patients, S1 in 26/330 (8%), S2 in 20/330 (6%), and S3 in 23/330 (7%). Liver stiffness was F0-F1 in 280/330 (85%) patients, F2 in 34/330 (10%), F3 in 11/330 (3%), and F4 in 5/330 (2%). In the univariable model, body mass index, central obesity, hypertension, plasmatic lipids, glycated haemoglobin, MS and CD4 count showed a significant association with ≥ S1 steatosis. After adjustment for gender, CD4 count and exposure to stavudine, tenofovir and nevirapine, subjects with MS retained eight-fold higher odds of ≥ S1 steatosis (aOR 8.37, 95% CI 4.43-15.8, $p < 0.01$). There was no effect of HBsAg status.
Conclusion: In this mature HIV cohort, a significant subset had MS (24%) and ≥ S1 steatosis (21%). Whereas a minority (5%) had significant liver fibrosis, the high prevalence of hepatitis B and liver steatosis identify a clear need for diagnosis and management strategies in the region.

SAT-335

A simple biomarker panel predictive of advanced fibrosis in patients with non-alcoholic steatohepatitis

Email: zobair.younossi@inova.org

Background and aims: NASH is an important cause of chronic liver disease. In patients with NASH, histologic stage of fibrosis is an independent predictor of mortality. Given the limitations of liver biopsy, non-invasive biomarkers that can accurately predict significant and advanced fibrosis are highly desirable.
Aim: To use serum from patients with biopsy-proven NASH to develop a biomarker panel to accurately predict advanced fibrosis in NASH.
Method: Serum samples were obtained from our prospective serum bank from patients with histologic NAFLD. All patients had consented before liver biopsy and serum was collected at the time of biopsy and snap-frozen. All liver biopsies were read by the study pathologist with the diagnosis of NASH and the stage of fibrosis being made according to an established protocol. Extensive clinical data were collected at the time of liver biopsy. Serum levels of 58 proteins were evaluated using Luminex Bead-based Multiplex Assays. Univariate Mann-Whitney tests and multivariate logistic regressions were used to determine predictors of significant and advanced fibrosis.
Results: Of 150 NAFLD patients, 100 patients had histologic NASH with 75 having NASH and significant fibrosis (F2-F4 by NASH Clinical Research Network classification). Those with NASH and significant fibrosis were more likely to be diabetic, had higher ALT and AST and lower platelet counts (all p values < 0.05). NASH patients with significant fibrosis also had higher level of serum Cathepsin D, Chitinase 3-Like 1 (CHI3L1)/YKL40, Collagen IV, FAP, ICAM-1/CD54, IGFBP-7, IL-1 beta, MIP-3 beta/CCL19, MMP-7, TIMP-1, and Thrombospondin-2, and lower levels of IGFBP-3, IL-8/CXCL8, and MMP-9 ($p < 0.05$). Using multivariate regression analysis, after stepwise selection of potential predictors among clinico-demographic and biomarker parameters, lower IGFBP-3 (odds ratio (OR): 0.98, 95% CI: 0.97-0.99, p = 0.0003) and higher Thrombospondin-2 (OR: 1.47, 95% CI: 1.28-1.69, p <.0001) were independently predictive of significant fibrosis; the area under the curve (AUC) was 0.86 (0.80-0.92). The same parameters, IGFBP-3 (OR: 0.98, 95% CI: 0.97-0.99, p = 0.0004) and Thrombospondin-2 (OR: 1.35, 95% CI: 1.21-1.51, p <.0001), were also predictive of advanced fibrosis (F3-4); AUC = 0.85 (0.78-0.91).
Conclusions: We have developed a simple biomarker panel able to predict advanced fibrosis in NASH. After external validation, this panel could potentially be used in clinical practice to identify NASH patients with significant and advanced fibrosis.

lLver stiffness measurement: An alternative practical predictor for early kidney dysfunction in patients with non-alcoholic fatty liver disease

DQ Sun[1], Fang-Zhou Ye[2,3], HALUK TARIK Kani[4], Chen-Fei Zheng[5], Pei-Wu Zhu[6], Hong-Lei Ma[2], Wen-Yue Liu[7], Hao-Yang Zhang[8], Xiao-Dong Wang[2,9], Wei-Jie Yuan[10], Yong-Ping Chen[2,9], Yusuf Yılmaz[4], Ming-Hua Zheng[2,9,11]. *[1]Affiliated Wuxi Second Hospital, Nanjing Medical University, Department of Nephrology, Wuxi, China; [2]the First Affiliated Hospital of Wenzhou Medical University, NAFLD Research Center, Department of Hepatology, Wenzhou, China; [3]Wenzhou Medical University, School of the First Clinical Medical Sciences, Wenzhou, China; [4]Marmara University School of Medicine, Department of Gastroenterology, Istanbul, Turkey; [5]the First Affiliated Hospital of Wenzhou Medical University, Department of Nephrology, Wenzhou, China; [6]the First Affiliated Hospital of Wenzhou Medical University, Department of Clinical Laboratory, Wenzhou, China; [7]the First Affiliated Hospital of Wenzhou Medical University, Department of Endocrinology, Wenzhou, China; [8]Sun Yat-sen University, School of Public Health, Guangzhou, China; [9]Wenzhou Medical University, Institute of Hepatology, Wenzhou, China; [10]Shanghai General Hospital of Nanjing Medical University, Department of Nephrology, Shanghai, China; [11]Key Laboratory of Diagnosis and Treatment of Severe Hepato-Pancreatic Diseases of Zhejiang Province, Wenzhou, China*
Email: blueman1320@163.com

Background and aims: Increasing evidences suggest that non-alcoholic fatty liver disease (NAFLD) is strongly associated with chronic kidney disease. Earlier prediction of early kidney dysfunction (EKD) in NAFLD is pivotal, while the screen method is limited. In this study, we aimed to explore the potential value of liver stiffness measurement (LSM) in EKD.
Method: Biopsy-proved NAFLD patients were included from the First Affiliated Hospital of Wenzhou Medical University and Marmara University School of Medicine, Istanbu. Fibrosis stage was ranged from 0-4, according to the NASH CRN criteria. By transient elastography, LSM with M probe ≥ 8.0 kPa was defined as liver fibrosis. EKD was defined as microalbuminuria and eGFR ≥ 60 ml/min/1.73m^2. OR and 95% confidence intervals for microalbuminuria were calculated using multivariate logistic regression analysis.
Results: A total of 214 biopsy-proved patients were included, of whom 61.2% had liver fibrosis. The prevalence of microalbuminuria significantly increased in liver fibrosis, when compared with no liver fibrosis (22.14% vs. 4.82%). NAFLD patients with microalbuminuria had higher fibrosis stage, mean arterial pressure levels, HOMA-IR values and BMI. After adjustment of traditional confounders including BMI, waist circumference, hypertension, type 2 diabetes and HOMA-IR, liver fibrosis was independently associated with increased risk of microalbuminuria (OR = 5.12, $p < 0.05$). In subgroup analysis with LSM, the trend between liver fibrosis with microalbuminuria was similar. Furthermore, compared with LSM score < 8.0 kPa, LSM ≥ 8.0 kPa had higher prevalence of microalbuminuria.
Conclusion: Liver fibrosis is independently associated with microalbuminuria in NAFLD patients. Higher LSM score may identify NAFLD patients with EKD, which can remind hepatologist to give more intensive surveillance and even treatment to reduce the risk of development of EKD over time.

NAFLD: Therapy

SAT-337

Evaluation of anti-fibrotic properties of OCA and INT-767 in an in vitro system of NAFLD

Beatrice Anfuso[1], Natalia Rosso[1], Luciano Adorini[2], Claudio Tiribelli[1]. *[1]Fondazione Italiana Fegato -ONLUS, Trieste, Italy; [2]Intercept Pharmaceuticals, New York, United States*
Email: b.anfuso@fegato.it

Background and aims: An effective treatment for Non-Alcoholic Steatohepatitis (NASH) is still missing. Fibrosis is the most significant predictor of mortality in NASH. FXR agonists have been proposed as anti-fibrotic treatment. In this study, we assessed the anti-fibrotic effect of the FXR agonist obeticholic acid (OCA, INT-747) and the dual FXR/TGR5 agonist INT-767 in a well-established *in vitro* co-culture model reproducing NASH development.

Method: Human hepatoma (Huh7) and hepatic stellate (HSCs, LX2) cells were simultaneously co-cultured (SCC) at a 5:1 ratio and exposed to 1200 µM of free fatty acids (FFAs) without or with OCA or INT-767. Exposure in absence of FFAs was tested for side effects. Working concentrations were selected based on cell viability curves. Expression of ACTA2, Col1a1, FXR and SHP was evaluated at 24, 96, and 144h. Extracellular collagen deposition and metalloproteinase 2 and 9 (MMP2-9) activity were evaluated at 96 and 144h (alphaLISA and Innozyme assay kit, respectively) and compared to the FXR agonists tropifexor and GS-9674.
Results: Based on cell viability, 0.1, 1 and 10 µM were selected for both OCA and INT-767. Exposure to FFAs induced HSCs activation (ACTA2 and Col1a1 ($p < 0.05$)) and extracellular collagen deposition ($p < 0.01$ at 144h) vs. CTRL. Compounds co-treatment did not affect ACTA2 and Col1a1 gene expression, while OCA, and to a lesser extent INT-767, significantly reduced FXR and induced SHP expression.
Interestingly, OCA induced a dose-dependent reduction of collagen at both 96h ($p < 0.05$ and 0.01 vs. FFAs, with 1 and 10 µM, respectively) and 144h ($p < 0.01$ with 10 µM). Similarly, INT-767 induced collagen reduction (1 µM at 96h, $p < 0.05$). Tropifexor was more effective at 0.5 and 0.1µM at 144h ($p < 0.05$), while GS-9674 at 96h ($p < 0.01$) but this effect did not persist over time. Neither OCA nor INT-767 altered collagen deposition in the absence of FFAs.
MMP2-9 activity was reduced at 96h in FFA-treaded cells ($p < 0.05$ vs. DMSO), while OCA counteracted this effect ($p < 0.05$). INT-767 also induced a slight increase in MMP2-9 activity. No significant modulation of MMP2-9 activity was induced by tropifexor or GS-9674.
Conclusion: All FXR agonists tested reduce collagen deposition. OCA exerts a more potent and long-lasting effect (−50% vs. FFAs) compared to INT-767 (−30%), tropifexor (−20%) and GS-9674 (−35%). These effects appear to be related to modulation of the FXR pathway, and to increased extracellular matrix degradation as indicated by enhanced MMP2-9 activity.
This work was supported by Intercept Pharmaceuticals.

SAT-338

Oral arginine supplementation attenuates the progression of steatosis to non-alcoholic steatohepatitis through preventing translocation of bacterial endotoxin

Anja Baumann[1], Dragana Rajcic[1], Annette Brandt[1], Finn Jung[1], Anika Nier[1], Cheng Jun Jin[2], Ina Bergheim[1]. *[1]University of Vienna, Department of Nutritional Sciences, Vienna, Austria; [2]Friedrich-Schiller University Jena, Institute of Nutritional Sciences, Jena, Germany*
Email: ina.bergheim@univie.ac.at

Background and aims: While being one of the most prevalent liver diseases world-wide, therapeutic strategies of non-alcoholic fatty liver disease still primarily focus on lifestyle interventions frequently associated with low adherence and high relapse rates. Several studies suggest that an oral supplementation of L-arginine (Arg) may prevent the development of liver diseases of various etiologies with protective effects also being associated with a protection of intestinal barrier function. Starting from this background, the aim of the present study was to assess the effects of an oral supplementation of Arg on the progression of a pre-existing diet-induced steatosis and molecular mechanisms involved.
Method: Female C57BL/6J mice (n = 8/group) were pair-fed either a liquid control diet (C) or a fat-, fructose- and cholesterol-rich diet (FFC) for 8 weeks to induce steatosis. For 5 additional weeks mice were fed either C or FFC with or without 2.49 g Arg/kg body weight. In addition, C57BL/6J mice fed FFC or C ± Arg were treated with the arginase inhibitor nor-NOHA (0.01 g/kg body weight). Indices of liver damage and inflammation as well as intestinal barrier function and arginase activity in proximal small intestinal tissue were determined.
Results: Despite similar caloric intake and weight gain after 13 weeks of feeding, liver damage in FFC-fed mice progressed to non-alcoholic steatohepatitis with marked signs of inflammation, e.g. significant higher number of neutrophils and F4/80-positive cells, and macrovesicular fat accumulation while FFC-fed mice receiving Arg for 5 weeks only showed hepatic steatosis. Furthermore, glucose tolerance was significantly disturbed and elevated bacterial endotoxin levels in portal plasma were only found in FFC-fed mice but not in FFC+Arg-fed animals. Moreover, the loss of arginase activity found in proximal small intestine of FFC-fed mice was markedly attenuated in FFC+Arg-fed mice being also associated with lower nitric oxide levels. Furthermore, the treatment with the arginase inhibitor nor-NOHA attenuated the beneficial effects of Arg on bacterial endotoxin levels found in FFC-fed mice.
Conclusion: In summary, our data suggest that an oral supplementation of Arg attenuates the progression of non-alcoholic fatty liver disease in mice through preventing the loss of intestinal barrier function. (DFG FKZ: BE2376/6-3)

SAT-339

Socioeconomic deprivation is associated with non-response to lifestyle interventions in non-alcoholic fatty liver disease

Kris Bennett[1,2], David Sheridan[1,2]. *[1]University Hospitals Plymouth NHS Trust, South West Liver Unit, Plymouth, United Kingdom; [2]University of Plymouth, Institute of Translational and Stratified Medicine, Plymouth, United Kingdom*
Email: kbennett6@nhs.net

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most prevalent liver disease globally and affects over 20 million people in the UK. Whilst socioeconomic deprivation has been associated with several risk factors for NAFLD, such as diabetes mellitus and obesity, the association with NAFLD is not well described. The goal of NAFLD treatment is regression of liver fibrosis to reduce all-cause mortality. Therefore, the aim of this study was to assess the likelihood of achieving fibrosis regression by lifestyle modification and the relationship between socioeconomic deprivation, disease severity and outcomes.
Method: All patients attending for Transient Elastography (Fibroscan) with a suspected or confirmed diagnosis of NAFLD at Derriford Hospital (Plymouth) between January 2015 and May 2018 were retrospectively included. Participants were all given lifestyle advice for diet and physical activity modification. Those with missing data or invalid scans (median/IQR ratio > 0.3) were excluded. Follow-up Fibroscan data was recorded where available. Clinically significant regression was defined as a reduction of liver stiffness measurement (LSM) by > 2 kPa. Demographic data was collected and postcode was cross referenced with the English Indices of Deprivation 2015 which ranks levels of deprivation in 32, 844 neighborhoods across England, based on key indicators in seven different domains of deprivation. An overall rank of relative deprivation, the Index of Multiple Deprivation (IMD), is calculated from these domains. A lower rank indicates a greater relative degree of deprivation.
Results: 158 patients with NAFLD underwent Fibroscan during the inclusion period. The median initial LSM was 9 kPa (SD = 9.7). There was no association between IMD and initial LSM severity. 123 patients had a follow-up Fibroscan (median interval 469 days). 40/123 (32%) demonstrated LSM regression > 2kPa. There was a significant difference in IMD between those who had LSM regression (M = 15533, SD = 8826) and no regression (M = 12165, SD = 8367), p = 0.04. The greatest contribution to the difference in IMD was in the domain of barriers to housing. Furthermore, there was a correlation between IMD and LSM regression; r = -.19, p = 0.04, implying social deprivation was associated with non-response to lifestyle intervention, and was more marked in females than males.
Conclusion: This study suggests that socioeconomic deprivation in NAFLD is associated with decreased likelihood of liver fibrosis regression with lifestyle intervention. Given that first-line treatment for NAFLD is lifestyle modification (weight loss, diet and increased activity), deprivation may negatively impact a person's ability to achieve these changes. This has implications for behavioral

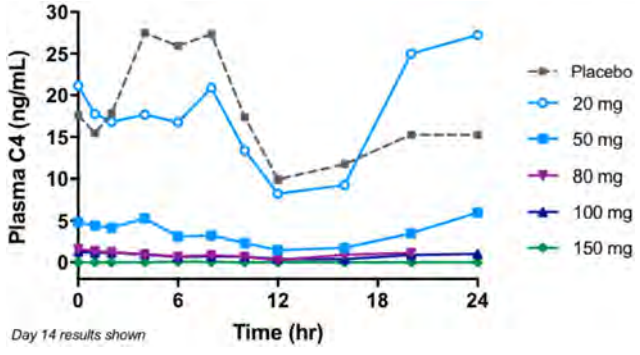
interventions and services, which should target populations with socioeconomic deprivation to improve clinical outcomes.

SAT-341

MET409, an optimized sustained FXR agonist, was safe and well-tolerated in a 14-day phase 1 study in healthy subjects

Hubert Chen[1], Karl Cremer[1], Eric Bischoff[1], Kyoung-Jin Lee[1], Rozalyn Littler[1], Jeroen van de Wetering[2], Gerhard Arold[2], Minh-Nguyet Duong[2], Ken Song[1]. [1]*Metacrine, Inc., San Diego, United States;* [2]*PRA Health Sciences, Groningen, Netherlands*
Email: hchen@metacrine.com

Background and aims: FXR (farnesoid X receptor) agonists for the treatment of non-alcoholic steatohepatitis (NASH) have evolved, although each iteration has had drawbacks. FXR agonists derived from either bile acid/steroidal or non-bile acid core structures have shown increased low-density lipoprotein (LDL) cholesterol levels, as well as moderate to severe pruritus within 14 days of dosing. Non-bile acid FXR agonists that have progressed into clinical development are hampered by transient FXR engagement with once-daily dosing, likely limiting efficacy. Sustained FXR engagement appears key to efficacy based on pre-clinical and clinical studies. MET409 is an optimized next-generation FXR agonist with features of a novel non-bile acid structure, enhanced potency and sustained FXR engagement. We conducted a double-blind, placebo-controlled, single-ascending dose (SAD) and a 14-day multiple-ascending dose (MAD) phase 1 study in healthy subjects to determine the safety, tolerability, pharmacokinetics (PK) and pharmacodynamics (PD) of MET409.
Method: Healthy men aged 18 to 65 years-old were randomized to either MET409 or placebo (6:2 allocation in SAD portion; 8:2 allocation in MAD portion). The primary objective was to assess the safety and tolerability of MET409. The secondary objectives were to establish the PK and PD profiles of MET409, with PD assessed by plasma levels of 7α-hydroxy-4-cholesten-3-one (C4) and fibroblast growth factor 19 (FGF19).
Results: Both single (20-400 mg) and multiple doses (20-150 mg) of MET409 were safe and well-tolerated. There were no serious adverse events, and the severity and frequency of adverse events were comparable between MET409 and placebo. MET409 exhibited sustained PK and PD profiles with once-daily dosing. There were dose-dependent increases in maximum concentration (C_{max}) and exposure ($AUC_{0\text{-}24}$), with elimination half-life ($T_{1/2}$) of ~15 hrs on Day 1 and ~50 hrs on Day 14 at an expected therapeutic level (50 mg). MET409, at ≥ 50 mg, suppressed plasma C4 levels (↓~80-95%) relative to placebo, with suppression observed throughout 24 hours (Figure). Increased FGF19 levels were also observed. MET409 did not increase serum LDL cholesterol, a differentiating attribute relative to other FXR agonists and FGF19 analogs. There were mild, dose-dependent decreases in high-density lipoprotein cholesterol and triglycerides. Mild pruritus, observed only at > 3x exposure above expected therapeutic level, did not require medical intervention or dosing interruption.



Conclusion: MET409, an optimized FXR agonist, demonstrated sustained FXR engagement and an encouraging safety and tolerability profile-including a lack of adverse impact on LDL cholesterol levels – in healthy male subjects.

Morphometric collagen analysis discerns anti-fibrotic effects of INT-767 and OCA in NASH mouse models using second harmonic generation imaging

Li Chen[1], Mathieu Petitjean[1], Luciano Adorini[2], Jonathan Roth[2]. [1]*Genesis Imaging Services, Princeton, United States;* [2]*Intercept Pharmaceutical, San Diego, United States*
Email: li.chen@pharmanest.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a highly prevalent liver disorder that can gradually progress to liver inflammation and fibrosis, including non-alcoholic steatohepatitis (NASH). The farnesoid X receptor (FXR) and transmembrane G protein-coupled receptor 5 (TGR5) regulate bile acid metabolism, inflammation, fibrosis, and inhibit NASH. Here, we assess the anti-fibrotic efficacy of INT-767 (a dual FXR/TGR5 agonist) and obeticholic acid (OCA) (an FXR agonist) in a diet-induced NASH mouse model with a focus on the morphometric quantification of the fibrosis phenotype imaged by Second Harmonic Generation (SHG).
Method: Leptin- deficient ($lep^{ob/ob}$) mice were fed with normal chow or with high-fat diet to induce NASH. Mice were biopsied and confirmed to have steatosis (score 3) and fibrosis (stage 2-3) before treatment (n = 10/group) with vehicle, INT-767 (10 mg/kg), or OCA (30 mg/kg) for 8 wks. Unstained liver histological sections were imaged with Genesis 200® system which uses SHG to produce images specific to collagens I and III. Image analysis of the SHG images quantified morphometric traits of the collagen fibers, including fiber length, width, area, perimeter, tortuosity, and texture. The distribution of each morphometric traits was described by normalized quantitative fibrosis parameters (qFPs). Liver collagen area, density, and reticulation index were also measured. The qFPs were combined to generate a Composite Fibrosis Score (CFS, 0 to 10), a continuous phenotypic quantifier of fibrosis.
Results: INT-767 reduced liver collagen fiber area and fiber density, while OCA decreased it to a lesser degree. This can be expected due to the 3-fold higher potency of INT-767 compared to OCA in FXR activation. Neither drug affected the collagen reticulation structure. The qFPs, reported on heat charts, show highest values for Vehicle, mid values for OCA, and lowest values for INT-767. INT-767 is more effective than OCA in improving fibrosis area, fiber density, qFPs, and Composite Fibrosis Scores (mean CFS ± SEM; Vehicle 6.5 ± 0.5, OCA 6.1 ± 0.3, INT-767 4.5 ± 0.2). Thus, INT-767 has higher anti-fibrotic effects compared to OCA in ob/ob NASH mice.
Conclusion: These data confirm that morphometric analysis of SHG images is an effective label-free method to describe and quantify the severity and progression of liver fibrosis and may differentiate pharmacological agents. These data enrich previous findings obtained using conventional methods.

SAT-343

Alagebrium ameliorates NAFLD progression in mice fed a high advanced glycation end products diet via direct inhibition of Kupffer cells and indirect inhibition of hepatic stellate cell activation

Hettya Kandage Dinali Helan Fernando[1], Christopher Leung[2], Peter Angus[2], Chandana Herath[1]. [1]*The University of Melbourne, Department of Medicine, Heidelberg, Australia;* [2]*Austin Hospital, Heidelberg, Australia*
Email: hettiyaf@student.unimelb.edu.au

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common liver disease in the world, affecting up to 30% of the adult population. Although it is a major cause of liver disease related premature illness and deaths, there is no established drug therapy for

this condition. Advanced glycation end products (AGEs), formed when reducing-sugars react with proteins during food processing, have been implicated as a second hit that drives NAFLD progression to liver fibrosis. Therefore, in the present study, we investigated the therapeutic potential of AGE cross-link breaker, alagebrium (Ala), on dietary AGE-induced NAFLD progression.
Method: C57Bl/6 mice were fed a high AGE diet for 40 weeks. They were orally gavaged with Ala for the last 10 weeks. Liver samples were collected to determine gene expressions, oxidative stress and fibrosis. In addition, the effect of Ala on AGE clearance was determined by gavaging labelled AGEs in mice fed the high AGE diet for 4 weeks. Prophylactic and therapeutic effects of Ala (1μM and 100μM) on the expression of proinflammatory cytokines by murine Kupffer cells (KUP5) exposed to AGEs (200μg/ml) were determined. Reactive oxygen species (ROS) generation by these cells was measured using a fluorescent dye. The effect of AGEs on activation of human hepatic stellate cells (LX2) directly or indirectly via Kupffer cells was investigated in the absence or presence of Ala.
Results: Ten weeks of Ala treatment significantly ($p < 0.001$) reduced liver fibrosis which was accompanied by reduced ($p < 0.01$) expression of proinflammatory and profibrotic cytokines compared to high AGE fed mice. Two weeks of Ala treatment improved liver AGE clearance in high AGE fed mice. Oxidative stress, as assessed by 4-HNE immunostaining, which was significantly ($p < 0.0001$) increased by high dietary AGEs was attenuated ($p < 0.001$) by Ala treatment. In support of this, Ala treatment significantly ($p < 0.01$) reduced ROS generation as well as proinflammatory cytokine expression by AGE-treated KUP5 cells. Whilst AGEs applied directly failed to activate LX2 cells, application of AGE-treated KUP5 conditioned media activated LX2 cells, as reflected by increased α-SMA expression. The activation of LX2 cells was however prevented when the cells were incubated with AGEs and Ala treated KUP5 conditioned media, suggesting that Ala likely inhibited AGE-induced cytokine release by KUP5 cells.
Conclusion: AGEs exacerbate NAFLD progression to liver fibrosis by mechanisms involving Kupffer cells which secrete large amounts of ROS and proinflammatory cytokines, leading to activation of hepatic stellate cells. We also conclude that alagebrium increases AGE clearance and has potential to inhibit NAFLD progression to liver fibrosis.

SAT-344
MSDC-0602K targets the mitochondrial pyruvate carrier to treat non-alcoholic steatohepatitis

Brian Finck[1], Kyle Mccommis[1], Jerry Colca[2]. [1]*Washington University School of Medicine, Medicine, St. Louis, United States;* [2]*Cirius Therapeutics, Kalamazoo, United States*
Email: bfinck@wustl.edu

Background and aims: MSDC-0602K is an insulin sensitizing thiazolidinedione that binds and inhibits the mitochondrial pyruvate carrier 2 (MPC2). Genetic deletion of Mpc2 in hepatocytes (liver-specific (LS)-Mpc2-/- mice) inhibits stellate cell activation and fibrosis in mice fed a diet that induces NASH (HTF-C diet). MSDC-0602K is now in a clinical trial for NASH. Herein, we evaluated intercellular crosstalk between hepatocytes and stellate cells in response to Mpc2 pharmacologic or genetic inhibition.
Method: Wild-type and LS-Mpc2-/- mice were fed either the HTF-C to induce NASH or low fat (LF) diet. After 4 weeks on plain HTF-C diet, a subset of mice were switched to HTF-C diet including MSDC-0602K. Histologic and gene expression analyses of liver were conducted and plasma miRNA profiled by RNA sequencing.
Results: As expected, treatment with MSDC-0602K reduced histologic and gene expression markers of NASH in liver. In plasma, we found 112 miRNAs that were upregulated and 60 miRNAs that were downregulated by HTF-C diet compared to LF. Compared to plasma from untreated HTF-C diet-fed mice, MSDC-0602K treatment increased 44 miRNAs and decreased 39 miRNAs. Many miRNAs that were increased in HTF-C diet fed mice, were reduced by MSDC-0602K treatment and vice versa. Several miRNAs known to have roles in liver injury or fibrogenesis were affected by MSDC-0602K treatment. We also profiled miRNAs in plasma from WT and LS-Mpc2-/- mice that were fed HTF-C diet in the presence or absence of MSDC-0602K. Only 29 miRNAs were affected by loss of Mpc2 in hepatocytes (compared to wild-type controls). Moreover, the effect of MSDC-0602K was not markedly affected by loss of Mpc2 in hepatocytes, though some miRNA changes were Mpc2-dependent.
Conclusion: MSDC-0602K has potent effects on reducing stellate cell activation, other markers of NASH, and levels of circulating miRNAs. However, the effects of MSDC-0602K on plasma miRNAs were not affected by loss of Mpc2 in hepatocytes. This suggests that MSDC-0602K has hepatocyte-independent effects on miRNA release. The small number of hepatocyte MPC2-dependent miRNAs will be further investigated for effects on stellate cell activation.

SAT-345
Novel mitochondrial pyruvate carrier modulators to treat non-alcoholic steatohepatitis and insulin resistance

Wesley Hodges[1], Kyle Mccommis[1], Brian Finck[1]. [1]*Washington University School of Medicine, St. Louis, United States*
Email: bfinck@wustl.edu

Background and aims: The mitochondrial pyruvate carrier (MPC) has emerged as a novel target for treating non-alcoholic steatohepatitis (NASH). Indeed, a thiazolidinedione derived MPC inhibitor, MSDC-0602, is completing phase 2 clinical trials for NASH in 2019 (EMMINENCE; NCT02784444). MSDC-0602 is a potent insulin sensitizer and it is believed that its beneficial effects on hepatic fibrosis and steatosis are mediated, at least part, by its insulin-sensitizing and other beneficial metabolic effects of modulating hepatic pyruvate metabolism. We sought to identify other small molecules that interact with the MPC that could be new therapeutic leads.
Method: A BRET-based MPC reporter assay system that responds to molecules that interact with the MPC was used to test for direct interaction of candidate compounds with the MPC complex. We also used mice with tissue-specific deletion of the MPC for in vivo drug treatment and for generating isolated mitochondria for ex vivo analyses. Mice were made to be obese and insulin resistant by feeding a high fat diet for 12 weeks prior to acute treatment of MPC inhibitor by oral gavage.
Results: Use of the BRET reporter system confirmed previous reports of MPC interacting drugs, including other thiazolidinediones (pioglitazone and rosiglitazone), zaprinast, an inhibitor of phosphodiesterase 5 (PDE5), and 7ACC2, which was originally purported to be a lactate transport inhibitor. An Asp residue in the MPC complex was shown to be critical for the interaction between the protein complex and thiazolidinediones or zaprinast, but not 7ACC2. Zaprinast and 7ACC2 were investigated further and shown to interact with the MPC with EC_{50}s of nM concentrations. Zaprinast and 7ACC2 also potently inhibited pyruvate-mediated respiration in isolated WT, but not MPC-deficient mitochondria, demonstrating a direct mitochondrial effect and MPC-dependence for this inhibition of pyruvate metabolism. Consistent with a suppression of gluconeogenesis, MPC inhibitors also suppressed glucose production by isolated hepatocytes in an MPC-dependent manner. Lastly, administration of zaprinast or 7ACC2 improved glucose tolerance, insulin sensitivity, and reduced the expression of NASH markers in liver of diet-induced obese mice.
Conclusion: In conclusion, these data provide proof of concept evidence in a mouse model for the efficacy of novel MPC modulators as insulin sensitizing agents and NASH therapeutics. Moreover, despite differing mechanisms for interacting with the MPC complex, both 7ACC2 and zaprinast had similar effects on insulin sensitivity and NASH end points demonstrating a generalization of the MPC inhibitor mechanism of action.

SAT-346

Icosabutate induces a potent reduction in hepatic oxidative stress in rodent models of metabolic stress and fibrosing NASH

David A. Fraser[1], Detlef Schuppan[2], Xiao-Yu Wang[2], Michael Feigh[3], Ditte Denker Thorbek[4], Cristina Alonso[5], Marta Iruarrizaga-Lejarreta[5], Nataša Nikolić[6], Arild Rustan[6], Tore Skjaeret[1]. [1]*Northsea Therapeutics, Naarden, Netherlands;* [2]*Unversity of Mainz, Mainz, Germany;* [3]*Gubra, Hørsholm, Denmark;* [4]*Gubra, Hørsholm, Denmark;* [5]*OWL Metabolomics, Derio, Spain;* [6]*University of Oslo, Oslo, Norway*
Email: david.fraser@northseatherapeutics.com

Background and aims: Polyunsaturated fatty acids and their metabolites target multiple signaling pathways regulating hepatic inflammation and metabolism. However, their accumulation into cellular membranes and proneness to peroxidation could potentially reduce their efficacy in conditions associated with increased oxidative stress, such as NASH. Icosabutate is a structurally-engineered eicosapentaenoic acid (EPA) derivative designed to resist both β-oxidation and incorporation into complex cellular lipids, including plasma and mitochondrial membranes. Potent anti-fibrotic effects were observed after icosabutate treatment in diverse rodent models of NASH, whereas no effects were seen with either EPA or the FXR agonist, obeticholic acid (OCA). The potential role of hepatic oxidative stress in mediating these differences was investigated.

Method: Uptake and partitioning of [^{14}C]icosabutate and [^{14}C]EPA into cellular lipids in Huh7 cells was investigated over 24h. Oxidised (GSSG) and reduced (GSH) glutathione were measured in liver samples collected from 3 mouse NASH models: (1) high-fat (31%) diet (HFD) fed mice treated with 0.3mmol/kg icosabutate or EPA; (2) choline-deficient amino acid defined (CDAA) diet fed mice treated with 0.3mmol/kg icosabutate or EPA; (3) *ob/ob* mice with biopsy confirmed NASH fed a diet rich in fat/trans-fat, fructose and cholesterol (AMLN diet) treated with icosabutate (135mg/kg) or OCA (30mg/kg).

Results: In Huh7 cells [^{14}C]icosabutate and its metabolites were almost entirely (< 5% total radioactivity) absent from complex cellular lipids, whereas > 90% of EPA was cell-associated at 24h (45-fold higher conc. of EPA vs. icosabutate in phospholipid fraction). *In vivo*, icosabutate reduced mean hepatic GSSG by 34, 20 and 33% (all $p < 0.001$) which contributed to 29%, 37% (both $p < 0.01$) and 84% ($p < 0.001$) increases in the hepatic GSH/GSSG ratio vs. control in the HFD, CDAA and AMLN mice respectively. In contrast OCA increased GSSG ($p < 0.05$) whilst a significant fall in GSH (−37%) and the GSH/GSSG ratio (−38%) was observed after EPA treatment (both $p < 0.01$). In AMLN mice, hepatic transcript levels of catalase and SOD1/SOD2 and were increased by icosabutate (all $p < 0.001$) whereas glutathione reductase was unchanged. Hepatic GSSG correlated with hepatic Col1A1 transcripts ($p = 0.001$) and collagen (HYP) content ($p < 0.005$) in the CDAA model and with myofibroblast activation (α-SMA), collagen (HYP) content and Col1a1 (%) protein content (all $p < 0.005$) in the AMLN model.

Conclusion: Icosabutate is highly resistant to cellular accumulation and acts as a potent hepatic antioxidant. In both AMLN *ob/ob* and CDAA NASH models, hepatic GSSG concentrations are highly correlated with fibrosis levels. Improvements in hepatic oxidative stress differentiates icosabutate from both EPA and OCA and likely contributes to its anti-fibrotic efficacy in NASH.

SAT-347

MRI-PDFF response in MGL-3196 and placebo treated patients predicts reduction in ballooning and inflammation components of NAS and NASH resolution in a 36-week serial liver biopsy study

Stephen Harrison[1], Cynthia Guy[2], Rebecca Taub[3], Mustafa Bashir[2]. [1]*Oxford University, Oxford, United Kingdom;* [2]*Duke University, Raleigh, United States;* [3]*Madrigal Pharmaceuticals, Conshohocken, United States*
Email: stephenharrison87@gmail.com

Background and aims: MGL-3196 is a liver-directed, orally active, highly selective THR-β agonist which may reduce NASH by increasing hepatic fat metabolism and normalizing liver function. In a 12-week interim and 36 week final analysis, MGL- 3196 treated patients had reduced liver fat on MRI-PDFF compared with Placebo (pbo) patients and more MGL-3196 (60%) treated than pbo (18%) patients showed at least 30% reduction in hepatic fat (PDFF response) ($p < 0.0001$). NASH resolution was 39% in MGL-3196 patients who were MRI-PDFF responders at Week 12 ($p < 0.001$). We assessed whether response

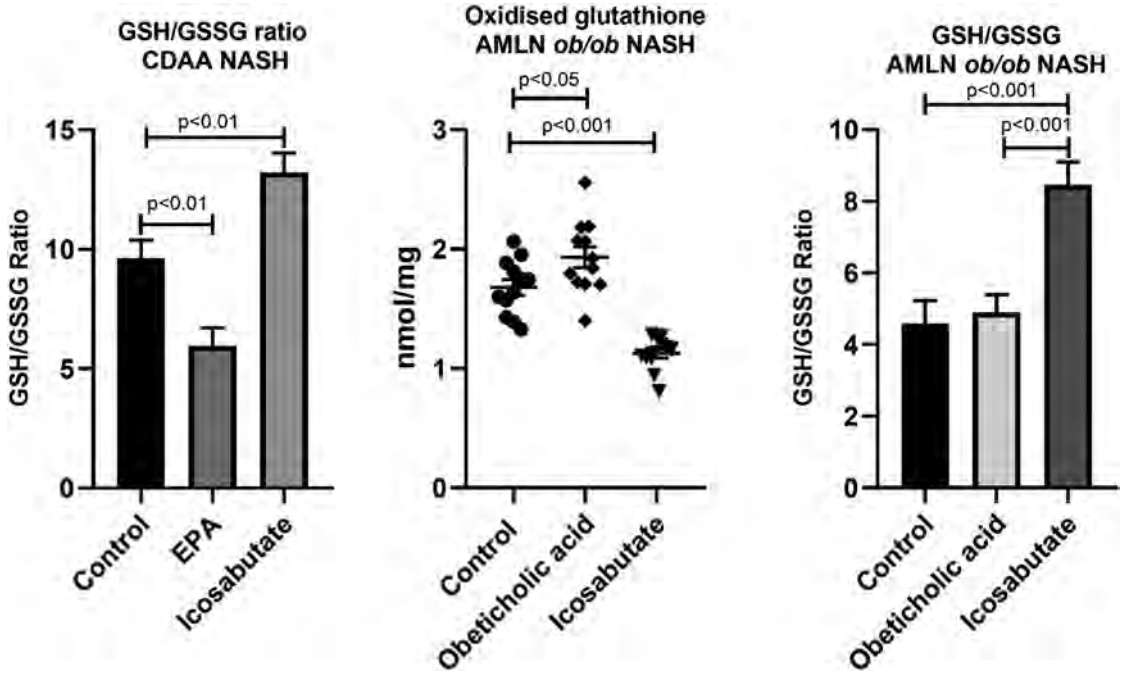

Figure: (abstract: SAT-346)

and magnitude of response on MRI-PDFF at week 12 in pbo or MGL-3196 patients predicted ALT improvement and histologic response on liver biopsy at Week 36.

Method: MGL-3196-05 (NCT02912260) was a 36-week multicenter, randomized, double-blind, pbo-controlled serial MRI-PDFF, paired liver biopsy study in adults with biopsy-confirmed NASH (NAS ≥ 4, F1-F3) and hepatic fat fraction ≥ 10%, assessed by MRI- PDFF. At 36 weeks 107 paired liver biopsies, 73 drug-treated, 34 pbo were assessed. NAS component, correlation and responder analyses were conducted to examine the predictive power of MRI-PDFF response on histologic response of NAS components and ALT reduction in pbo and MGL-3196 patients.

Results: In MGL-3196 patients, week 12 MRI-PDFF response versus non-response predicted NASH resolution at Week 36 (p = 0.001). MGL-3196 PDFF or steatosis responders compared with MGL-3196 non-responders were more likely to show a reduction in other components of NAS (ballooning, inflammation) (OR 8.86, p = 0.0036). In MGL-3196 patients, Week 12 PDFF response correlated with improvement in steatosis (direct relationship), improvement in inflammation and ballooning components of NAS (0.42) and reduction in ALT (0.34). Pbo patients with ≥ 5% weight loss were likely PDFF responders (71%, p = 0.007). In pbo patients PDFF response correlated with weight loss (0.58), which predicted inflammation and ballooning responses (0.58). In pbo patients with < 3% weight loss, ballooning reduction was not correlated with any improvement in steatosis, inflammation, fibrosis or ALT. In MGL-3196 patients, a ballooning reduction without a reduction in steatosis and/or MRI-PDFF response was not associated with improvement in inflammation, fibrosis or ALT.

Conclusion: In both MGL-3196 and placebo treated patients, MRI-PDFF response correlated with reduction in ballooning and inflammation scores on liver biopsy and was associated with NASH resolution. In pbo, but not MGL-3196, patients most of the response was driven by weight loss. These data suggest that reduction of hepatic fat is a critical component of NASH improvement and resolution.

SAT-348

Low frequencies of lifestyle interventions and liver-specific medications in a multicentric prospective real world NAFLD cohort: The fatty liver assessment in Germany (FLAG) study

Wolf Peter Hofmann[1], PD Dr. Schattenberg Jörn[2], Nektarios Dikopoulos[3], Frank Lammert[4], Renate Heyne[5], Jeannette Schwenzer[6], Michael P. Manns[7], Marion Muche[8], Lisa Schubert[1], Patrick Ingiliz[9], Anna Schmidt[10], Kerstin Stein[11], Stefan Zeuzem[12], Peter Buggisch[13]. *[1]Gastroenterologie am Bayerischen Platz, Berlin, Germany; [2]Mainz University Hospital, Mainz, Germany; [3]Gastroenterologie und Innere Medizin, Dornstadt, Germany; [4]Saarland University Hospital, Homburg/Saar, Germany; [5]Leberzentrum am Checkpoint Berlin, Berlin, Germany; [6]Bauchzentrum Biesdorf, Berlin, Germany; [7]Medizinische Hochschule Hannover, Hannover, Germany; [8]Charité University Hospital, Berlin, Germany; [9]Zentrum für Infektiologie Berlin Prenzlauer Berg (ZIBP), Berlin, Germany; [10]Magen-Darm-Zentrum Köln, Köln, Germany; [11]Hepatologie in Magdeburg, Magdeburg, Germany; [12]Goethe University Frankfurt, Frankfurt, Germany; [13]IFI Institute, Hamburg, Germany*
Email: wolfpeter.hofmann@icloud.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) affects approximately 25% of the German population. However, there is only limited knowledge about the prevalence of NAFLD with advanced fibrosis, the frequencies of lifestyle interventions (e.g. nutritional counselling and physical activity) and the use of available medications that may have a beneficial effects on comorbidities and NAFLD. Cohort studies in a "real life" setting represent a suitable tool to study clinical outcomes in patients with NAFLD and assess standards of health care.

Method: The fatty liver assessment in Germany (FLAG) study is a prospective, multicentric cohort study initiated by the association of gastroenterologists in private practice (BNG) in cooperation with University Hospitals and the German Liver Foundation covering secondary and tertiary health care levels. Data collection is performed using an electronic case report form and data quality is verified by plausibility checks and off-site monitoring. Patients characteristics as well as laboratory parameters that allow calculation of non-commercial, non-invasive liver fibrosis scores and genetic profiling are collected. Liver stiffness measurement (LSM) data are included when available. Lifestyle interventions, medications, as well as clinical events are assessed at baseline and followed-up prospectively.

Results: Baseline data from the first 400 Patients with NAFLD were analyzed including 52% men with a mean age of 52 years. By calculating the non-invasive serum score FIB-4 index, 9.4% of patients had advanced fibrosis (F3-F4 fibrosis). Accordingly, those with F3-F4 fibrosis had higher mean LSM (14.1 kPa vs. 8.1 kPa) values as compared to patients with no advanced fibrosis. Type 2 diabetes mellitus (T2DM), arterial hypertension, and a history of cardiovascular events were more frequent in those with F3-F4 fibrosis as compared to patients without advanced fibrosis (47%, 89%, and 19% vs. 19%, 44%, and 14%, respectively; $p < 0.02$ for T2DM and arterial hypertension, respectively). In 17% of the patients, any NAFLD medical intervention was recorded including vitamin E, vitamin D, UDCA, and silymarin, respectively. Nutritional counselling took place in 28% of the patients and 15% of the patients reported physical activity at least 2 time per week.

Conclusion: In this multicentric prospective cohort study, baseline data of patients with NAFLD give insights in the real world patient care in Germany. The prevalence of patients with advanced fibrosis confirms previous estimates. There is a low frequency and heterogeneity in use of available medications that may affect NAFLD outcome. Lifestyle interventions should be strenghtend and their effectiveness will be assessed during prospective data collection

SAT-349

Improvement of hepatic inflammation and fibrosis independently of weight loss from a short, individualized, web-based exercise program in patients with NAFLD

Yvonne Huber[1], Daniel Pfirrmann[2], Christian Labenz[1], Eva Kalliga[1], Nadine Gehrke[1], Beate Straub[3], Diana Leeming[4], Heike Bantel[5], Peter Galle[1], Perikles Simon[2], PD Dr. Schattenberg Jörn[1]. *[1]University Medical Centre of the Johannes Gutenberg-University Mainz, Department of Internal Medicine I, Mainz, Germany; [2]Johannes Gutenberg-University Mainz, Department of Sports Medicine, Rehabilitation and Prevention, Mainz, Germany; [3]University Medical Centre of the Johannes Gutenberg-University, Institute of Pathology, Mainz, Germany; [4]Nordic Bioscience Clinical Studies, Herlev, Denmark; [5]Hannover Medical School, Department of Gastroenterology, Hepatology and Endocrinology, Hannover, Germany*
Email: yvonne.huber@unimedizin-mainz.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease. Pharmacologic therapies for NAFLD are not available and lifestyle modification remains the cornerstone of therapy. The aim of this trial was to evaluate the effects of a short, web-based individualized exercise program on surrogate markers of hepatic steatosis, inflammation and fibrosis.

Method: 44 patients with histological confirmed NAFLD were enrolled into this prospective, interventional single arm study (NCT02526732). The exercise program consisted of combined aerobic and resistance exercise training over 8 weeks, integrated into the patients' daily routine through a web-based platform with weekly bidirectional feedback. A follow-up exam was performed in week 20, 12 weeks after cessation of the individualized program. Changes in liver function tests as well as surrogate markers of hepatic steatosis, inflammation and fibrosis were evaluated.

Results: A total of 41 patients completed the assigned training goal (93.2%). Eight weeks of individualized exercise lead to a small weight loss by 0.9% ($p < 0.01$), nonetheless improvement of ALT (−14.3%, $p < 0.01$) and AST (−18.2%, $p < 0.001$) occurred. Surrogate scores of disease severity including the fatty liver index (FLI) and fibrosis scores (FiB-4 and APRI) were significantly reduced after the intervention. Median liver stiffness determined by transient elastography declined from 7.4 to 6.4 kPa ($p < 0.05$). Inflammatory markers including hsCRP and Ferritin decreased, as well the cytokeratin 18 fragment M30, (baseline: 383.1 U/l to week 8: 318.8 U/l, $p < 0.01$). Pro-coallagen-3 (Pro-C3) decreased significantly at end of follow-up (baseline: 145 ng/ml to week 20: 119 ng/ml, $p < 0.01$), while C4M2, reflecting type IV collagen degradation, increased ($p < 0.05$), suggesting increased collagen turn-over compatible with fibrosis regression.
Conclusion: A short, individualized course of exercise is sufficient to improve surrogate markers of hepatic steatosis, inflammation and fibrosis independently of weight loss.

SAT-350

YH25724, a novel long-acting GLP-1/FGF21 dual agonist, exhibits marked anti-fibrotic effects in different experimental models of liver fibrosis

Dohoon Kim[1], Junhwan Kim[1], Tae Wang Kim[1], Han Hong[1], Hyun Choi[1], Ji-Eun Yang[1], Da-Na Jeong[1], Mi Kyeong Ju[1], Minji Seo[1], Su Kyung Kim[1], Ju-Young Park[1], Byung Hyun Choi[1], Han-Joo Kim[1], Kyoung Kyu Ahn[1], Jong-Gyun Kim[1], Pierre Bedossa[2,3], Vlad Ratziu[4], Se-Woong Oh[1], Soongyu Choi[1]. *[1]Yuhan Corporation, Seoul, Korea, Rep. of South; [2]Liverpath, Paris, France; [3]University of Newcastle, Newcastle, United Kingdom; [4]Hôpital Pitié-Salpêtrière and Sorbonne Université, Paris, France*
Email: junhwankim@yuhan.co.kr

Background and aims: YH25724 is a novel long-acting dual agonist consisting of a GLP-1 variant and an FGF21 variant fused to an immunoglobulin Fc region. Due to complementary mechanisms of action, GLP-1 and FGF21 dual agonism may represent an effective therapeutic strategy for the treatment of non-alcoholic steatohepatitis (NASH). In a diet-induced obese mouse model of NASH, YH25724 significantly improved metabolic profiles with anti-steatotic, anti-inflammatory and anti-fibrotic effects. In the current study, we investigated whether YH25724 exerts anti-fibrotic effects in two different rat models.

Method: A choline-deficient, L-amino acid-defined, cholesterol-supplemented (CDAA/chol) diet-induced model and a thioacetamide (TAA)-induced liver fibrosis model were established in Wistar rats. In the CDAA/chol model, rats were fed a CDAA/chol diet over 12 weeks to induce fibrosis and treated with YH25724 subcutaneously during the last 8 weeks. In the TAA model, rats were given 0.03% (w/v) TAA in drinking water for 22 weeks to induce liver fibrosis and treated with YH25724 subcutaneously during the last 8 weeks. In both models, vehicle-treated rats were used as controls. The extent of liver fibrosis was assessed using picrosirius red staining (PSR) or hydroxyproline (HP) content, and liver fibrosis staging was evaluated with semi-quantitative scores. Hepatic alpha-smooth muscle actin (α-SMA) expression was evaluated by immunohistochemistry. Serum fibrosis markers were measured by ELISA.
Results: In the CDAA/chol model, all vehicle-treated rats developed fibrosis after the CDAA/chol diet regimen. PSR staining revealed that the area of fibrosis was significantly reduced in the YH25724-treated group. In the TAA model, all vehicle-treated rats progressed to liver cirrhosis, while fibrosis stage was significantly reduced in the YH25724-treated group. PSR staining, HP content and α-SMA expression were significantly reduced in the YH25724-treated group. Furthermore, serum levels of cytokeratin-18, TGF-β1, Pro-C1, Pro-C3 and hyaluronic acid were significantly decreased in the YH25724-treated group.
Conclusion: YH25724 markedly attenuated the progression of fibrosis in rat models. These data support the general anti-fibrotic potential of this hybrid molecule, which occurs independent of body weight reduction. YH25724 may therefore provide not only metabolic but also strong anti-fibrotic benefits in patients with NASH.

SAT-351

Biomarkers and clinical characteristics associated with non-alcoholic steatohepatitis fibrosis progression in the CENTAUR study

Email: nicolas.lanthier@uclouvain.be

Background and aims: Cenicriviroc (CVC) is an oral C-C chemokine receptor type 2/5 antagonist currently being evaluated for the treatment of liver fibrosis in adults with non-alcoholic steatohepatitis (NASH). In the Phase 2b CENTAUR study, CVC treatment resulted in a significant, durable antifibrotic benefit compared with placebo (PBO). The aims of this CENTAUR analysis were to characterise the subpopulation of fibrosis progressors (FPs) initially treated with PBO during Year 1 (Y1) compared to fibrosis non-progressors (FNs), and to evaluate the effect of CVC in FPs on histology and biomarkers of fibrosis during Year 2 (Y2).
Method: Adults with histologically confirmed NASH, non-alcoholic fatty liver disease activity score (NAS) ≥ 4 and liver fibrosis Stages 1-3 (NASH Clinical Research Network) received CVC 150 mg once daily (Arm A) or PBO (Arm C), respectively, for 2 years; Arm B received PBO in Y1 and crossed over to CVC in Y2. FPs were defined as subjects who experienced worsening in fibrosis by ≥ 1 stage from baseline (BL) to Y1 and were identified from the PBO-treated modified intent-to-treat population (N = 126) in Y1 (Arms B and C). Clinical characteristics and serum biomarkers were analysed at BL and over time. Histology was assessed by a central pathologist blinded to treatment assignment. The effect of CVC (Arm B) vs PBO (Arm C) on FPs was assessed during Y2.
Results: Of Y1 PBO-treated subjects in Arms B and C (N = 126), 29% (n = 37) were identified as FPs (mean age: 52.1 years; mean body mass index: 34.1 kg/m^2; NAS ≥ 5: 89%; type 2 diabetes mellitus: 46%). A greater proportion of FPs compared to FNs at BL were female (62% vs 49%), Hispanic/Latino (89% vs 78%) and had higher disease activity (NAS ≥ 5: 89% vs 71%; hepatocellular ballooning grade 2: 65% vs 51%). Considerably more FPs vs FNs had fibrosis Stage 1 (65% vs 20%) and aspartate aminotransferase > 30 U/L (89% vs 74%) at BL. During Y1, increases in serum transforming growth factor (TGF)-beta and tissue inhibitor of metalloproteinase-1 (TIMP-1), and liver biopsy alpha-smooth muscle actin (SMA) staining and collagen proportionate area were observed for FPs vs FNs. During Y2, CVC treatment was associated with a lesser decrease in collagen area, increased TIMP-1, and reduced alpha-SMA staining and attenuated serum TGF-beta concentrations compared to PBO (Figure).
Conclusion: The unique study design of CENTAUR enabled characterisation of NASH FPs during Y1 and evaluation of the antifibrotic effect of CVC in Y2. Female sex, ethnicity and inflammatory disease activity are key characteristics of FPs. In those FPs, CVC treatment was associated with a reduction of some biomarkers of fibrosis (TGF-beta and alpha-SMA) vs PBO in Y2. These findings warrant further investigation.

A combination of the ACC inhibitor GS-0976 and the nonsteroidal FXR agonist GS-9674 improves hepatic steatosis, biochemistry, and stiffness in patients with non-alcoholic steatohepatitis

Eric Lawitz[1], Edward Gane[2], Peter Ruane[3], Jr. Robert Herring[4], Ziad H. Younes[5], Paul Kwo[6], Jie Zhang[7], Catherine Jia[7], Jay Chuang[7], Bryan Mccolgan[7], Chuhan Chung[7], Mani Subramanian[7], Robert Myers[7], Michael Middleton[8], Kelvin Li[9], Marc Hellerstein[9], Mazen Noureddin[10], Stephen Harrison[11], Rohit Loomba[8]. *[1]Texas Liver Institute, University of Texas Health San Antonio, San Antonio, United States; [2]Liver Unit, Auckland City Hospital, Auckland, New Zealand; [3]Ruane Clinical Research, Los Angeles, United States; [4]Quality Medical Research, Nashville, United States; [5]GastroOne, Germantown, United States; [6]Stanford University School of Medicine, Palo Alto, United States; [7]Gilead Sciences, Inc., Foster City, United States; [8]University of California at San Diego, San Diego, United States; [9]University of California Berkeley, Berkeley, United States; [10]Cedars-Sinai Medical Center, Los Angeles, United States; [11]Pinnacle Clinical Research, San Antonio, United States*
Email: bryan.mccolgan@gilead.com

Background and aims: Preclinical data suggest that the combination of an ACC inhibitor and FXR agonist is more effective than monotherapy in the treatment of NASH. Here, we describe the combination of the ACC inhibitor, GS-0976, with the nonsteroidal FXR agonist, GS-9674, in patients with NASH.
Method: Twenty patients with NASH diagnosed by a magnetic resonance proton density fat fraction (MRI-PDFF) ≥ 10% and liver stiffness ≥ 2.88 kPa by magnetic resonance elastography (MRE), or historical biopsy consistent with NASH and F2-F3 fibrosis were enrolled. Patients received GS-0976 20 mg and GS-9674 30 mg orally once daily for 12 weeks. Data from two cohorts treated with either GS-0976 20 mg or GS-9674 30 mg daily for 12 weeks are provided for comparison. MRI-PDFF and MRE and serum fibrosis markers were centrally read at baseline (BL) and week 12 (W12). Deuterated water was administered to measure hepatic de novo lipogenesis (DNL).
Results: In the combination cohort, 55% had diabetes and the median BMI was 38.7 kg/m^2. Compared with BL, significant reductions at W12 in combination-treated patients were observed for PDFF (median: 16.4% vs 9.8%; p < 0.001), MRE-stiffness (3.76 vs 3.43 kPa; p = 0.018), serum TIMP-1 (263.4 vs 240.7 ng/ml; p = 0.012), PIII-NP (10.6 vs 8.4 ng/ml; p = 0.003), ALT, and GGT. At W12, a ≥ 30% relative decline in PDFF was observed in 14/19 patients (74%). Compared with monotherapies, combination therapy resulted in greater reductions in hepatic PDFF, ALT, GGT, and hepatic DNL (Table). Combination treatment was safe and well-tolerated with AE rates similar to monotherapies; no patient reported ≥ grade 2 pruritus or discontinued study medications due to AEs.

Table: Median Relative (%) Changes in Imaging, Biochemistry, and Fibrosis Markers at W12

	GS-0976 20 mg (n = 10)	GS-9674 30 mg (n = 10)	GS-0976 20 mg + GS-9674 30 mg (n = 20)
MRI-PDFF	-42.7*	-15.6*	-45.3*
≥ 30% reduction in MRI-PDFF, % (n)	70% (7/10)	0	74% (14/19)
MRE	-8.9	-8.3	-9.0*
ALT	-33.5	-29.7	-37.2*
GGT	-1.6	-19.3*	-32.4*
TIMP-1	-11.6*	6.6*	-7.1*
PIII-NP	-11.9	8.8	-12.1*
DNL	-22.0*	7.5	-30.1*

*p < 0.05 at BL vs W12 using Wilcoxon signed-rank test

Conclusion: The combination of GS-0976 and GS-9674 for 12 weeks was safe and led to improvements in hepatic steatosis, liver stiffness, liver biochemistry, and markers of fibrosis in NASH.

SAT-353

The effect of metformin on hepatic fatty acid partitioning; an investigation using human in vivo and in vitro models

Charlotte Green[1], Thomas Marjot[1,2], Catriona Mcneil[1], Jonathan Hazlehurst[1,3], Ahmad Moolla[1], Jane Francis[4], Stefan Neubauer[4], Jeremy Tomlinson[1], Leanne Hodson[1]. *[1]University of Oxford, Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, United Kingdom; [2]University of Oxford, Translational Gastroenterology Unit, NIHR Oxford Biomedical Research Centre, Oxford, United Kingdom; [3]University of Birmingham, Institute of Metabolism and Systems Research, Birmingham, United Kingdom; [4]University of Oxford, Oxford Centre for Clinical Magnetic Resonance Research, Oxford,*

United Kingdom
Email: leanne.hodson@ocdem.ox.ac.uk

Background and aims: Many individuals with non-alcoholic fatty liver (NAFLD) disease will be taking metformin, the first-line therapeutic drug for type 2 diabetes (T2D). Whereas rodent models have shown that metformin decreases high-fat diet-induced steatosis, human studies have shown no reduction in liver fat despite increases in hepatic insulin sensitivity and reductions in body weight. The reason for the discrepancy remains unclear. We aimed to determine the effect of metformin on hepatic de novo lipogenesis (DNL) and fatty acid oxidation pathways in humans subjects and in cellular hepatocyte models.
Methods: Ten insulin-resistant, metformin-naïve human subjects underwent 12-weeks metformin treatment (2g/day). Pre- and post-treatment, subjects had magnetic resonance spectroscopy (MRS) to determine liver fat content and underwent metabolic phenotyping including 2-step euglycemic hyperinsulinemic clamp and stable isotope infusions. In vitro, Huh7 cells were cultured in human serum and fatty acids to induce steatosis and subsequently treated with metformin for 48 hrs. Cells were collected and intracellular triglyceride content and markers of fatty acid oxidation were measured.
Results: In human subjects, basal plasma glucose and triglyceride were significantly lower post-metformin treatment. There was no change in plasma non-esterified fatty acid or 3-hydroxybutyrate levels. Hepatic insulin sensitivity and whole body fatty acid oxidation did not change. Liver fat content on MRS was maintained following metformin treatment (15.9 ± 11.6 v 17.1 ± 12.8%) despite 2kg weight loss ($p < 0.05$). DNL tended to increase after metformin treatment and was significantly higher post treatment during the low-dose insulin clamp (AUC $p < 0.05$). In line with the human data, Huh7 cells treated with metformin maintained intracellular triglyceride, and there was no effect on triglyceride secretion or production of 3-hydroxybutyrate.
Conclusion: Our data demonstrate that metformin does not decrease hepatic steatosis in insulin resistant human subjects. De novo lipogenesis was increased following metformin treatment which may have offset any reductions in liver fat conferred by weight loss. Markers of hepatic fatty acid oxidation remained unchanged. This data demonstrates a change in fatty acid partitioning post-metformin and suggests that upregulated DNL may contribute to its glucose lowering effect. Whilst metformin has a role in T2D, we suggest that it does not represent a viable treatment strategy specifically for NAFLD.

SAT-354

Aramchol, SCD1 inhibitor, improves liver glucose homeostasis in NASH

José M. Mato[1], Laura delaCruz-Villar[1], David Fernández-Ramos[1], Fernando Lopitz[1], Mikel Azkargorta[1], Félix Elortza[1], Marta Iruarrizaga-Lejarreta[2], Cristina Alonso[2], Lucía Barbier-Torres[3], Shelly C Lu[3], Liat Hayardeny[4], Tali Gorfine[4], Arun J. Sanyal[5]. *[1]CIC bioGUNE-Centro de Inv. Cooperativa en Biociencias, Derio, Spain; [2]OWL (One Way Liver S. L.), Derio, Spain; [3]Cedars-Sinai Medical Center, Los Angeles, United States; [4]Galmed pharmaceuticals, Tel Aviv, Israel; [5]Virginia Commonwealth University, Richmond, United States*
Email: director@cicbiogune.es

Background and aims: We have previously shown that Aramchol, an arachidyl cholic acid adduct that targets SCD1 (stearoyl CoA desaturase 1, a key enzyme that catalyzes the first reaction committing fatty acids into triglyceride synthesis), has a unique mechanism of action that targets both the metabolic alterations that characterize NASH (accumulation of lipids, lipotoxicity and oxidative stress) and fibrosis. In a one year study in 247 NASH patients, Aramchol significantly reduced liver fat, improved histology and hepatic biochemistry. At week 52 placebo patients exhibited an increase in HbA1C, while those treated with Aramchol (400 and 600 mg/day) showed a reduction with a dose response pattern. The differences from placebo were statistically significant suggesting Aramchol also targets glucose metabolism. The aim of this study was to elucidate the mechanism by which Aramchol regulates hepatic glucose metabolism using the methionine and choline deficient (MCD) diet mouse model of NASH.
Methods: We collected liver samples from mice fed the MCD diet containing 0.1% methionine (0.1MCD) for four weeks, which developed steatohepatitis and fibrosis, as well as mice receiving a control diet; and the liver metabolomes and proteomes were determined. A group of 0.1MCD fed mice were given Aramchol (5mg/kg/day or 1 mg/kg/day, for the last 2 weeks).
Results: 0.1MCD fed mice developed steatohepatitis and showed a statistically significant reduction 1.5 to 4 fold of liver glucose, glucose 6 phosphate, fructose 6 phosphate and fructose 1, 6 bisphosphate (FBP) as well as altered protein content of a variety of glycolytic/gluconeogenic enzymes, including glucokinase, glucose 6 phosphate isomerase, fructose 1, 6 bisphosphate phosphatase, enolase, pyruvate kinase and phosphoenolpyruvate carboxykinase, as compared to mice fed the control diet. As shown previously, Aramchol treatment improved NASH features reducing lipid accumulation, inflammation and fibrosis. We also found a significant improvement of glycolysis/gluconeogenesis in 0.1MCD fed mice treatd with Aramchol in a dose dependent manner. It is important to note that FBP, the product of the first irreversible step in glycolysis, is a gauge of the cells nutrient status that regulates AMPK, via its interaction with aldolase B, and pyruvate kinase activity. Of note, we found a statistically significant increase in aldolase activity in livers from 0.1MCD fed mice that decreased in Aramchol treated mice.
Conclusions: These results show that Aramchol targets not only the alterations in lipid metabolism that characterize NASH but additionally improves liver glucose homeostasis.

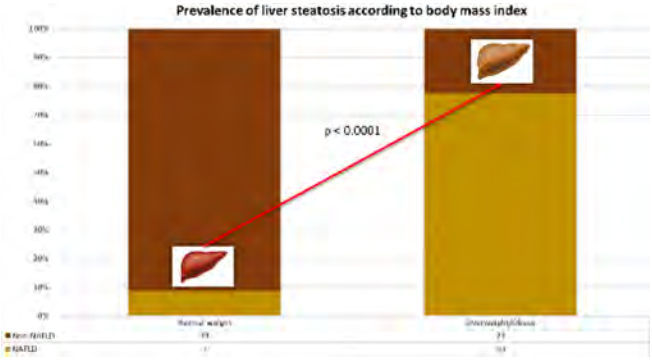
SAT-355

Fatty liver trends in Southern Italy: Mediterranean or Americanized lifestyle habits?

Emilio Molina Molina[1], Harshitha Shanmugam[1], Domenica Maria Di Palo[1], Marilena D'Ambrosio[1], Getachew Debas Belew[2], Piero Portincasa[1]. *[1]University of Bari Aldo Moro, Clinica Medica "A. Murri", Department of Biomedical Sciences and Human Oncology, Bari, Italy; [2]University of Coimbra, Center for Neuroscience and Cell Biology, UC-Biotech, Cantanhede, Portugal*
Email: piero.portincasa@uniba.it

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease worldwide, and its current prevalence is estimated to be ≈ 25. Weight loss, with diet and physical activity as main components of healthy lifestyles, is to date the primary therapy for the management of NAFLD. We aimed to assess unhealthy food intake (as "Junk Score") and physical activity frequency with regards to age and liver steatosis, as part of lifestyle habits, in a cohort from Southern Italy.
Method: 1, 124 subjects were enrolled (437 males, mean age 39 ± 0.9 years; 687 females, mean age 39 ± 0.7 years) as young (≤ 30 years, n = 554) and adult (> 30 years, n = 570) individuals, either healthy or as outpatients for gastrointestinal disorders. "Junk Score" was calculated based on the intake of high-fat, high-sugar food (range 0-50). Physical activity frequency was classified in sedentary, low, medium and high (0, 1-2, 3-4 and > 4 times/week, respectively). Liver steatosis was assessed by ultrasound (0 = absent; 1 = present; Noblus Hitachi, Italy).
Results: Mean body mass index was 23 kg/m^2 and 33 kg/m^2 ($p < 0.0001$; without and with NAFLD, respectively). Prevalence of liver steatosis and overweight/obesity (≥ 25 kg/m^2) increased with age (from 6% to 38% and from 17% to 65%; $p < 0.0001$ for both; in subjects ≤ and > 30 years, respectively). "Junk Score" significantly increased with age (from 24.9 ± 0.6 to 34.2 ± 1.3 and from 24.7 ± 0.6 to 35.4 ± 0.7; $p < 0.0001$ for both; in subjects ≤ and > 30 years, without and

with NAFLD, respectively). The prevalence of subjects at each physical activity frequency was 61% vs. 84%, 18% vs. 7%, 16% vs. 5% and 5% vs 4% for sedentary, low, medium and high (without vs. with NAFLD; p < 0.0001 for sedentary vs. low in both groups) respectively. The prevalence of sedentary adults (> 30 years) without NAFLD was lower than those with NAFLD (47% vs. 88%; p < 0.0001).



Conclusion: In the Italian region of Apulia, prevalence of fatty liver is high and rising with age in subjects with no apparent liver disease (23%). Poor quality of diet, reflected by "Junk Score," and number of sedentary subjects are significantly associated with NAFLD, as part of unhealthy lifestyle habits. The "Horizon 2020 Foie Gras" project in Southern Italy is currently investigating educational, feasible and low-cost therapeutic approaches in order to promote healthy lifestyle habits urgently.

SAT-356

Anti-metabolic, anti-inflammatory and anti-fibrotic properties of ART-648, a novel phosphodiesterase 4 inhibitor as a potential clinical candidate for non-alcoholic steatohepatitis

Yuichiro Amano[1], Shuntarou Tsuchiya[1], Mitsuharu Matsumoto[1], Hikaru Ueno[1], Nobuhiro Nishigaki[1], Osamu Isono[1], Guido Hanauer[2], Kazumasa Miyawaki[1], Kimio Tohyama[1], Hirohisa Miyashita[1], Mayumi Imai[1], Fumi Shimizu[1], Akira Tanaka[3], Hiroshi Nagabukuro[3]. *[1]Takeda Pharmaceutical Company Limited, Fujisawa, Japan; [2]Takeda Pharmaceutical Company Limited, Zurich, Switzerland; [3]ARTham Therapeutics Inc., Yokohama, Japan*
Email: hiroshi.nagabukuro@arthamther.com

Background and aims: Phosphodiesterase 4 (PDE4) is ubiquitously expressed in the entire body and plays multiple physiological and pathophysiological roles via increase of intracellular cyclic AMP modulation. Inhibition of PDE4 is a known pharmacological target for inflammatory disorders such as chronic obstructive pulmonary disease and psoriasis. Since PDE4 inhibition is also suggested to improve metabolic and fibrotic disorders, a novel selective PDE4 inhibitor, ART-648, was validated for the treatment of non-alcoholic steatohepatitis (NASH) using in vitro and in vivo models relevant for multiple pathophysiologies underlying the disease.
Method: ART-648 was orally administered to dyslipidemic low-density lipoprotein receptor null (LDLr-/-) mice fed modified choline-deficient diet, in either prophylactic (1, 3, and 10 mg/kg for 7 weeks) or therapeutic modes (4 and 8 mg/kg for 10 weeks). ART-648 (1, 3 mg/kg) was also dosed in diet-induced obese (DIO) mice. Anti-inflammatory and anti-fibrotic effects of ART-648 were evaluated in human and murine whole blood, THP-1 derived macrophages and human primary stellate cells.
Results: ART-648 dose-dependently decreased hepatic fibrosis area ($p < 0.05$), triglyceride content ($p < 0.05$) and gene expression of collagen-I ($p < 0.05$), TNF-α ($p < 0.05$), and TIMP-1 ($p < 0.05$). At the doses with robust anti-fibrotic efficacy, > 50% target engagement with ART-648 over 16 hours per day was simulated. ART-648 significantly decreased body weight ($p < 0.025$), food intake ($p < 0.025$) and fat mass ($p < 0.025$) in DIO mice. A single administration of ART-648 increased oxygen ($p < 0.025$) and energy ($p < 0.025$) expenditure in DIO mice. ART-648 decreased gene expression of TNF-α and αSMA, which were accompanied with intracellular cAMP elevation in THP-1 cells or hepatic stellate cells, respectively. In human whole blood, ART-648 inhibited TNF-α release-induced by LPS in a concentration-dependent manner.

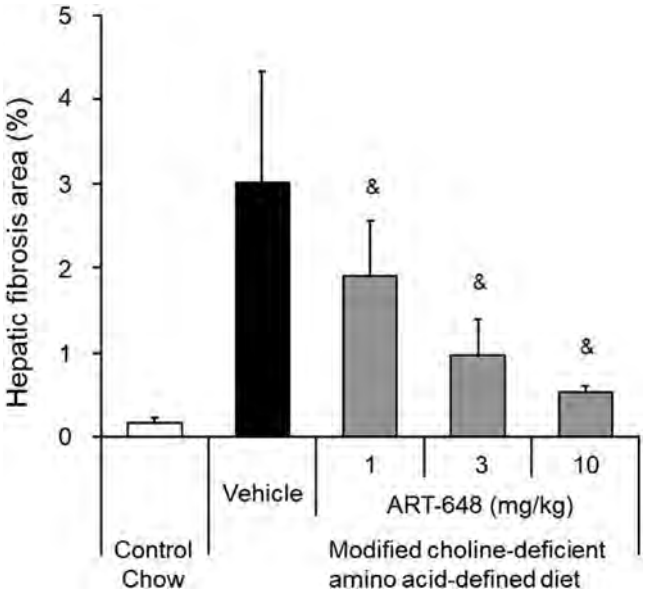


Figure: Prophylactic effects of TAK-648 on hepatic fibrosis area in LDLr -/- mice with modified choline-deficient amino acid-defined diet

Conclusion: Anti-fibrotic, anti-inflammatory and anti-metabolic effects of ART-648 were evident, suggesting potential to be an efficacious pharmacotherapy for NASH pending clinical demonstration of its benefits in NASH treatment.

SAT-357

Tropifexor, a farnesoid X receptor agonist for the treatment of non-alcoholic steatohepatitis: Interim results based on baseline body mass index from first two parts of Phase 2b study FLIGHT-FXR

Arun Sanyal[1], Patricia Lopez[2], Eric Lawitz[3], Won Kim[4], Jee-Fu Huang[5], Pietro Andreone[6], George Boon Bee Goh[7], Yi-Cheng Chen[8], Vlad Ratziu[9], Yoon Jun Kim[10], Marno Ryan[11], Martin Weltman[12], Andreas Geier[13], Juergen Loeffler[2], Felicity Schaefer[14], Sujata Vaidyanathan[14], Miljen Martic[2], Clifford Brass[14]. *[1]Virginia Commonwealth University, Virginia, United States; [2]Novartis Pharma AG, Basel, Switzerland; [3]Texas Liver Institute, University of Texas Health, San Antonio Texas, United States; [4]Boramae Medical Center, Seoul National University Hospital, Seoul, Korea, Rep. of South; [5]Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; [6]Center for Research Study on Hepatitis, University of Bologna, Bologna, Italy; [7]Singapore General Hospital, Outram road, Singapore; [8]Chang Gung Memorial Hospital, Taoyuan, Taiwan; [9]Hôpital Pitié Salpêtrière, Paris, France; [10]Seoul National University Hospital, Seoul, Korea, Rep. of South; [11]St Vincent's Hospital, Victoria, Australia; [12]Nepean Hospital, New South Wales, Australia; [13]University of Würzburg, Würzburg, Germany; [14]Novartis Pharmaceutical Corporation, East Hanover, United States*
Email: arun.sanyal@vcuhealth.org

Background and aims: Tropifexor (TXR) is a highly potent non-bile acid farnesoid X receptor (FXR) agonist. In single dose Phase 1 trials, the pharmacodynamic response was linear in healthy subjects up to 1, 000 μg/d. In FLIGHT-FXR Parts A and B tropifexor was dosed at 90 μg/d while in the currently ongoing Part C doses up to 200 μg/d are tested.

Method: FLIGHT-FXR (NCT02855164) is a Phase 2 randomized, double-blind, placebo-controlled trial with an adaptive design of 3 sequential parts to assess safety, tolerability and efficacy in NASH patients. Treatment duration in Parts A and B was 12 weeks. Population included 198 patients (47% male) with liver fat, elevated alanine transaminase (ALT) and NASH on either a historical biopsy or phenotype. Pooled results from treatment arms common to Parts A and B (placebo: 46; TXR 60 μg: 37; TXR 90 μg: 85) were assessed in both pre-specified baseline BMI subgroups for target engagement (fibroblast growth factor-19 [FGF19] and 7-hydroxy-4-cholesten-3-one [C4]), changes from baseline in ALT, gamma-glutamyl transaminase (GGT), liver fat (magnetic resonance imaging-proton density fat fraction [MRI-PDFF]) and safety. Statin initiation was not allowed during the trial.

Results: Results in the BMI subgroups are shown in table as geometric mean of percentage changes from baseline to Week 12, except for FGF19 (change 4 hours post dose from pre-dose at Week 6). p values are not shown as hypothesis testing was not done. Effect of TXR on ALT, GGT and PDFF was more pronounced in subgroup of lower BMI. TXR was well tolerated without safety signals of clinical relevance (including pruritus and lipids).

	BMI (kg/m^2) < 35 (Non-Asian) or < 30 (Asian)			BMI (kg/m^2) ≥ 35 (Non-Asian) or ≥ 30 (Asian)		
Stratum	Placebo n = 28	TXR 60 μg n = 21	TXR 90 μg n = 52	Placebo n = 18	TXR 60 μg n = 16	TXR 90 μg n = 33
FGF19	22	360	586	68	277	447
C4	2.8	−33.2	−40.4	37.3	−48.9	−61.8
GGT	−10.8	−47.0	−61.3	−6.8	−38.4	−48.7
ALT	−18.6	−26.0	−26.8	−10.6	−14.8	−19.5
MRI-PDFF	−13.1	−19.9	−18.8	−5.5	−12.9	−11.4
LDL-C	−9.7	10.0	12.7	0.7	8.9	6.9
HDL-C	−4.8	−1.9	−7.7	−3.9	−6.1	−11.9
TG	1.2	1.0	5.7	0.9	−6.7	−2.3
Weight	−0.1	−1.0	−1.1	0.0	−1.2	−1.6

Conclusion: In both BMI subgroups, TXR results provide evidence of target engagement, anti-inflammatory and anti-steatotic effects with favorable safety and tolerability. Consistent trends of lower responses in sub-group receiving lower dosing by body weight support testing higher TXR doses (140 and 200 μg/d) in the biopsy-based Part C, which may provide improved efficacy without jeopardizing safety.

SAT-358

Sodium glucose cotransporter 2 inhibitor, canagliflozin ameliorate liver function in Japanese patients with type 2 diabetes mellitus: Subgroup analyses of clinical trials

Yuya Seko[1], Yoshio Sumida[2], Kazuyo Sasaki[3], Yoshito Itoh[4], Hiroaki Iijima[5], Toshio Hashimoto[6], Shinichi Ishii[6], Nobuya Inagaki[7].
[1]Kyoto Prefectural University of Medicine, Kyoto, Japan; [2]Aichi Medical University, Nagakute, Japan; [3]Mitsubishi Tanabe Pharma Corporation, Osaka, Japan; [4]Kyoto Prefectural University of Medicine, Department of Gastroenterology and Hepatology, Kyoto, Japan; [5]Mitsubishi Tanabe Pharma Corporation, Tokyo, Japan; [6]Mitsubishi Tanabe Pharma Corporation, Tokyo, Japan; [7]Kyoto University Graduate School of Medicine, Department of Diabetes, Endocrinology and Nutrition, Kyoto, Japan
Email: yuyaseko@koto.kpu-m.ac.jp

Background and aims: Sodium glucose cotransporter 2 inhibitor (SGLT2I) was developed for the treatment of patients with type 2 diabetes mellitus (T2DM). The aim of this pooled and subgroup analyses was to investigate the efficacy of canagliflozin on liver function and its safety in high alanine aminotransferase (ALT) patients (ALT > 30 U/L).

Method: This post hoc analysis of canagliflozin in T2DM patients was divided into Study 1 (pooled analysis of 12- and 24-week a multicenter, randomized, placebo-controlled, double-blind, parallel-group study in Japanese T2DM patients) and Study 2 (52-week monotherapy/combination therapy study). The canagliflozin 100 mg group data were compared with placebo or baseline ALT subgroup (baseline ALT > 30 or ≤ 30 U/L) data. The primary end point was change in ALT level from baseline. Secondary end points were changes in efficacy-related parameters and adverse events (AEs).

Results: In the high ALT subgroup, the mean ALT change at 12 weeks in canagliflozin group (−10.3 ± 11.7) was significantly greater than placebo group (−3.2 ± 17.6 U/L) (p = 0.0206); while no significant difference was shown in the low ALT subgroup (Study 1). Glycosylated hemoglobin (HbA1c) and body weight were significantly reduced in both ALT subgroups (all P < 0.0001, Studies 1 and 2). In the high ALT subgroup, the mean change in ALT significantly also decreased at 52 weeks (−16.0 ± 18.8 U/L) (p < 0.0001, Study 2). The results of the correlation analysis in the high ALT subgroup showed a negative correlation between the change in ALT and baseline ALT at both 12 weeks (r = -0.605, P < 0.0001) and 52 weeks (r = -0.638, P < 0.0001). The incidence of AEs or serious AEs in the canagliflozin group was the same as those in the placebo group and there was no difference according to ALT level (Studies 1 and 2).

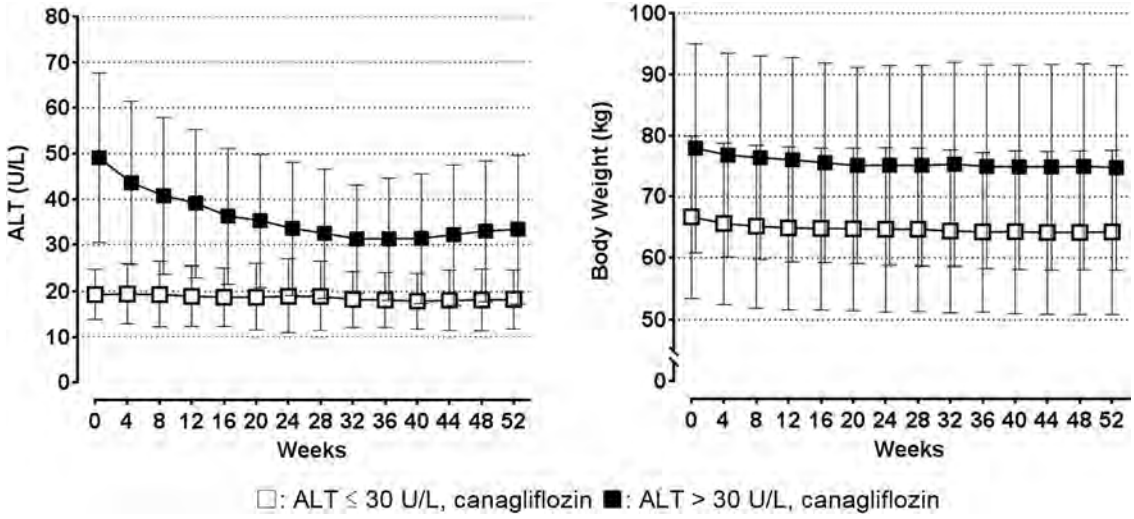

Figure: (abstract: SAT-358): Change in ALT and body weight over 52 weeks (Study 2).

Conclusion: In T2DM patients with impaired liver function, canagliflozin may improve liver function, reduce HbA1c and body weight, and be well tolerated. The treatment with SGLT2I may provide a clinical benefit to type 2 diabetes mellitus patients with NAFLD.

SAT-359

Pharmacokinetics and safety of pegbelfermin (BMS-986036) administered in the abdomen and upper arm to normal, overweight, and obese healthy participants

Giridhar Tirucherai[1], Johanna Mora[1], Ratna Revankar[1], Edgar Charles[1].
[1]*Bristol-Myers Squibb, Princeton, United States*
Email: giridhar.tirucherai@bms.com

Background and aims: Pegbelfermin (BMS-986036), a PEGylated human fibroblast growth factor 21 (FGF21) analogue, improved steatosis, liver injury, and fibrosis biomarkers in a phase 2 study of overweight (OW) and obese (OB) patients with non-alcoholic steatohepatitis (NASH). This phase 1 study evaluated pharmacokinetics (PK) and safety of a single subcutaneous (SC) pegbelfermin dose administered in the abdomen and upper arm to normal, OW, and OB healthy participants (ppts).
Method: MB130-070 was an open-label, fixed-sequence, crossover study in ppts grouped by body mass index (BMI [kg/m^2]; normal, 18.0 ≤ 25.0; OW, > 25.0 ≤ 30.0; OB, > 30.0 ≤ 40.0). Ppts received 20 mg pegbelfermin on Day 1 of successive treatment periods via injection to the abdomen (period 1) and upper arm (period 2). On Days 8, 15, 22, and 29 of each period, serum was collected for PK analysis and safety was assessed.
Results: Thirty ppts received an abdominal injection of pegbelfermin (n = 10/cohort); 29 ppts received pegbelfermin via upper arm injection (normal and OW, n = 10 each; OB, n = 9). Most ppts were male (90%), median age was 31 y. Serum pegbelfermin exposure was up to 30% higher after upper arm vs abdominal administration in normal and OW ppts, but similar between sites in OB ppts (table). Within administration sites, serum pegbelfermin exposure was up to 21% and 67% higher in normal vs OW and OB ppts, respectively. Five ppts reported 6 adverse events (AEs; n = 3 each in OW and OB ppts) after abdominal injection; 12 ppts reported 18 AEs (n = 6, normal; n = 4, OW; n = 8, OB) after upper arm injection. All AEs were of mild to moderate intensity; no serious AEs or deaths occurred. One ppt discontinued due to a non-treatment-related AE; 1 OW ppt was positive for anti-FGF21 antibodies at Days 15 and 29 of period 2.

	Abdomen			Upper Arm		
	Normal n = 10	Overweight n = 10	Obese n = 10	Normal n = 10	Overweight n = 10	Obese n = 9
C_{max}, ng/ml (%CV)[a]	757 (40)	694 (58) 23[b]	566 (49) —	889 (39)	906 (54) 68[b]	540 (55) —
% increase[b]	34[b]			65[b]		
AUC_{0-T}, h*ng/ml (%CV)[a]	52533 (34)	43507 (47) 25[b]	34767 (58) —	63519 (27)	57260 (39) 51[b]	37963 (56) —
% increase[b]	51[b]			67[b]		

[a]Geometric mean; [b] Relative to geometric mean values for obese ppts.

Conclusion: Pegbelfermin was generally well tolerated when administered SC to the abdomen or upper arm in healthy normal weight, OW, and OB ppts. There was a trend towards increased exposure with decreased BMI. Exposure after abdominal or upper arm administration was generally similar in OB ppts, but up to 30% higher in normal and OW ppts when administered to upper arm relative to the abdomen. A dose-ranging study is underway to evaluate histological and biomarker responses to 10, 20, and 40 mg QW pegbelfermin in patients with NASH.

SAT-360

A phospholipid-based therapeutic perspective for the regression of liver fibrosis: a study on human immortalized hepatic stellate cells

Paola Luciani[1], Lorine Brülisauer[1], Cristina Zivko[1], Florian Weber[1].
[1]*Institute of Pharmacy, Department of Pharmaceutical Technology, Jena, Germany*
Email: paola.luciani@uni-jena.de

Background and aims: During liver fibrogenesis, the myofibroblastic transdifferentiation (or activation) of hepatic stellate cells (HSCs) is a reversible key event. Essential phospholipids have shown to exert antifibrotic effects with their polyenylphosphatidylcholine (PPC) fraction and specifically with their phospholipid 1, 2 dilinoleoylphosphatidylcholine (DLPC) playing a major role. However, the mechanism behind it, as well as the exact role of the PPC components, remain still unclear. In this study, novel PPC-based formulations were developed and evaluated for their antifibrotic properties by means of an *in vitro* model based on human immortalized HSCs, LX-2.
Method: LX-2, in their standard activated state, were treated with liposomes either directly or after additional activation for 24 h with TGF-β_1. Liposomes were prepared using 1, 2-dilinoleoyl-*sn*-glycero-3-phosphocholine (DLPC), soy phospholipid with 75% phosphatidylcholine (S80), soy phospholipid 80% with $MgCl_2$ or with $CaCl_2$ (S80 M and S90, respectively), 2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) and DOPC/DLPC (53/47 mol%). Lipid droplets were examined by Oil Red O staining, the scar production was followed with Sirius Red and Fast Green, and the α-SMA by immunocytochemistry. Membrane fluidity variations of adherent LX-2 were studied by means of fluorescence anisotropy of 1, 6-diphenyl-1, 3, 5-hexatriene (DPH) and 1- (4-trimethylammoniumphenyl)-6-phenyl-1, 3, 5-hexatriene *p*-toluenesulfonate (TMA-DPH).
Results: The incubation of LX-2 with DLPC, S80, S80 M, S90, DOPC/DLPC liposomes revealed increased lipid droplets, low content of collagen compared to non-collagenous proteins, and low α-SMA. In contrast as expected, the negative control, DOPC treatment showed opposite features. The anisotropy values of DPH, relative to the inner core of the cell membranes, revealed a low motional order upon treatment with TGF-β_1. On the contrary, all the lipids used, but specifically S80, induced a major increase of the membrane fluidity. The motional order at the interface regions, as measured with TMA-DPH, resulted mostly affected by DLPC, DOPC and DOPC/DLPC direct treatments.
Conclusion: Liposomes of S80, S80 M and S90 showed more promising characteristics as antifibrotic treatments compared to the DLPC ones, used as a positive control for the reported ability to inactivate HSCs. The three PPCs will be further formulated as oral dosage forms and investigated as possible chronic therapy for fibrosis regression.

Immunology except viral hepatitis

SAT-371

Alleviation in NK cells cytotoxicity following inhibitions of Neuroligin-4 (NLG4) receptor by recombinant beta-neurexin involving IL-4 pathway

Johnny Amer[1], Ahmad Salhab[1], Rifaat Safadi[1]. [1]*Hadasah Hebrew University Hospital, Jerusalem, Israel*
Email: johnnyamer@hotmail.com

Background and aims: Neuroligin-4 receptors (NLG4) are post-synaptic adhesion proteins that control the maturation and function of synapses in the central nervous system (CNS). NK cells from Non-

alcoholic Fatty liver Disease (NAFLD) patients exert high expressions of NLG4 and are thought to interfere with NK cell activity. NLG4 receptor interacts through immune synapse with its ligand β-neurexin (cell-adhesion molecules) and is thought to play an important step in fibrogenesis. We investigated a potential role of recombinant β-neurexin to inhibit NLG4 elevations of NK cells in an *in vitro* co-culture condition.

Method: NK cells isolated form peripheral blood of NAFLD patients lacking metabolic syndrome were pre-incubated with 4 and 10 nM recombinant β-neurexin for 3 hours prior to incubations with hepatic stellate cells (HSCs; LX2- cell line). Following 24 hours, cells were trypsinized and analyzed by flow-cytometry for NK activity by CD107a (Degranulation marker- a marker for NK activation) and LX2 activities (α-smooth-muscle intensities). Interlukine-4 (IL4) expressions were also assessed in NK cells.

Results: LX2 cell line express 75% of β-neurexin. In co-cultures, recombinant β-neurexin significantly decreased the receptor expressions of NLG4 on NK cells and was well correlated with the increase in the recombinant concentrations. In additions, NK cells showed significantly increased lysosomal-associated membrane protein-1 (CD107a, NK activation marker) from 13% to 50% and 53% with the 4 and 10 nM recombinant, respectively ($p < 0.03$). Compared to LX2 mono-cultures, elevations of NK cells CD107a activity was associated with increased LX2 killing; as αSMA mean fluorescence intensities of HSCs decreased from 2948 in cultures without the recombinant to 2552 and 2066 in cultures with the 4 and 10 nM recombinant, respectively, ($p < 0.01$). NK cells pre-treated with the recombinant β-neurexin showed decreased in IL-4 secretion in both the concentrations (2-folds, $P = 0.04$).

Conclusion: β-neurexin-NLG4 recognition mediates HSCs-NK immune synapse to control release of NK vesicles. Recombinant β-neurexin activates NK cells to promote anti-fibrotic effects through increased HSCs killing. These effects were associated with decreased expression in the NLG4 receptor as well as with inhibition of the pro-fibrogenic marker IL4 in the NAFLD NK cells. NLG4 modulation of CD107a activity of NK cells extends the understandment and therapeutic strategies in fatty liver disease.

SAT-372

High prevalence of anti HLA Class II de novo donor-specific antibodies during rejection after liver transplantation

Jordi Colmenero[1], Pablo Ruiz[1], Nayelli Flores[1], Monica Vasquez[2], Garcia Raquel[1], Gonzalo Crespo[1], Jaume Martorell[3], Miquel Navasa[1]. *[1]Liver Transplant Unit, Hospital Clinic, IDIBAPS, CIBERehd, University of Barcelona, Barcelona, Spain; [2]Liver Transplant Unit, Hospital Clinic, University of Barcelona, barcelona, Spain; [3]Immunology Service, Hospital Clínic, IDIBAPS, University of Barcelona, Barcelona, Spain*
Email: jcolme@clinic.ub.es

Background and aims: Anti-HLA donor specific antibodies (dnDSA) after liver transplantation (LT) are currently under investigation. Recent studies show an incidence of dnDSA after LT ranging from 10-25%. However, the prevalence of dnDSA in LT recipients with alloimmune injury (ALO) and non-aloimmune liver injury (non-ALO) is unknown.

Method: Ccase-control cross-sectional study to investigate the prevalence of dnDSA in LT recipients with ALO and non-ALO compared to LT recipients without liver injury (control group, CONT). CONTROL: LT recipients with normal liver tests, normal elastography and no rejection within 6 months. ALO: biopsy-proven T-cell mediated rejection or antibody-mediated rejection lesions, including nodular regenerative hyperplasia (NRH). Non-ALO: liver injury other than ALO. Screening Luminex was performed in all patients and Single Antigen Luminex Assay was performed in those with positive screening. Results are expressed as median (IQR).

Results: The cohort consisted of 83 LR recipients: 20 ALO, 15 non-ALO and 37 CONT. The overall cohort was screened for dnDSA at a median of 30 (300) months after LT (32% < 12 m, 43% 1-5 years, 25% > 5 years). The median age was 57 (47), 29% were female with previous pregnancy in 46%. The pretransplant liver disease was alcohol-related (33%), viral (29%), cholestasic/autoimmune (21%) or other. The immunosupression at DSA assessment was calcineurin inhibitor ± MMF/steroids in 95% of patients and 37% patients had experienced previous episodes of rejection. There were no significant differences regarding age, gender and time since LT between groups. ALO patients had previous rejection more frequently than non-ALO and CONT (61% vs 45% vs 20%, $p = 0.11$, respectively), higher values of ALT (168 (426) vs 138 (471) vs 23 (20) UI/ml), $p = 0.025$) and higher liver stiffness [and 8.2 (12) vs 4.9 (8) vs 5.5 (8) kPa; $p = .010$). The prevalence of positive dnDSA class II was 55% vs 20% vs 8% in ALO vs non-ALO vs CONT ($p = 0.6$ and $p = 0.015$, respectively). All dnDSA in ALO targeted the DQ locus. The median MFI tended to be higher in ALO patient [9445 (23026)] compared to non-ALO and CONT [6026 (19978) vs 1500 (16840, $p = 0.067$)]. Of note, three patients had NRH and focal C4d deposition and high titers of dnDSA class II anti-DQ (median MFI 23500). The prevalence of and dnDSA class I was 0% vs 5 vs 6.3% % in ALO vs non-ALO vs CONT.

Conclusion: Class II dnDSA are common in patients with active alloinmune injury. Further studies are needed to investigate the clinical and histological implications of dnDSA in LT recipients with T-cell mediated rejection.

SAT-373

Peritoneal mucosal-associated invariant T cells functionally differ from their exhausted circulating counterparts in decompensated cirrhosis

Oluwatomi Ibidapo-obe[1], Sven Stengel[1], Nilay Köse[1], Andreas Stallmach[1], Michael Bauer[2,3], Tony Bruns[1,3]. *[1]Jena University Hospital, Department of Internal Medicine IV, Jena, Germany; [2]Jena University Hospital, Department of Anesthesiology and Intensive Care, Jena, Germany; [3]Jena University Hospital, Center for Sepsis Control and Care, Jena, Germany*
Email: akinhanmioluwatomi@gmail.com

Background and aims: Mucosal associated invariant T (MAIT) cells are innate-like T cells that are fast-acting using their invariant T cell receptor to recognize microbial riboflavin antigens presented by MR1. Previously, we reported a depletion of MAIT cells in the peripheral blood of patients with cirrhosis alongside a peritoneal accumulation during spontaneous bacterial peritonitis. We now aimed to further compare antibacterial responses and migration properties of circulating and peritoneal MAIT cells.

Method: Mononuclear cells were isolated from peripheral blood and ascitic fluid (AF) from patients with decompensated cirrhosis in the absence or presence of spontaneous bacterial peritonitis (SBP), and mononuclear cells from healthy donors served as a control. Cells were incubated with filtered bacterial culture supernatants. Migration of healthy MAIT cells was investigated using static trans well migration assays. Cells were quantified and phenotyped using flow cytometry.

Results: Filtered AF from patients with SBP was sufficient to activate MAIT cells from healthy individuals in presence of antigen-presenting cells. In contrast to circulating MAIT cells from patients with cirrhosis, which showed impaired TNF and IFN-g production in response to bacterial supernatants or PMA, peritoneal MAIT cells from patients with decompensated cirrhosis released significant amounts of IFN-g after stimulation with *E. coli*. Although peritoneal macrophages expressed higher levels of surface MR1 compared to circulating monocytes, peritoneal MAIT cell activation, was not restricted to MR1 as shown by blocking experiments.

Using migration assays, we observed a preferential migration of activated MAIT cells towards filtered AF from patients with SBP in comparison to patients without SBP. Consistent with their cytokine receptor expression, MAIT cells migrated against gradients of CCL5, CXCL10, and CCL20 as compared to conventional T cells. Interestingly,

the state of peritoneal MAIT cell activation, as indicated by CD69 expression, correlated with the severity of liver disease in the absence of SBP and with markers of inflammation in the presence of SBP.
Conclusion: Our results suggest that MAIT cells are preferentially recruited over conventional T cells to the peritoneal cavity in the context of SBP. In contrast to circulating MAIT cells, peritoneal MAIT cells remain potent producers of inflammatory cytokines, and their activation status indicates more advanced liver disease.

SAT-374

Interleukin 35 exerts its suppressive function in chronic liver failure through the induction of an immunosuppressive HLA-G+CD4+ regulatory T -cell population

Wafa Khamri[1], Cathrin Gudd[1], Marigona Krasniqi[1], Rooshi Nathwani[1], Arjuna Singanayagam[1], Sofia Azam[1], Tong Liu[1], Fanny Lebosse[1], Naveenta Kumar[1], Rocio Castro Seoane[1], Thomas Barbera[1], Trevor Askwith[2], Christopher Weston[3], Mark Thursz[1], Charalambos Antoniades[1]. *[1]Imperial College London, Division of Integrative Systems Medicine and Digestive Disease, London, United Kingdom; [2]University College London, Translational Research Office, School of Pharmacy, London, United Kingdom; [3]University of Birmingham., Centre for Liver Research and National Institute for Health Research, Biomedical Research Unit, Birmingham, United Kingdom*
Email: w.khamri@imperial.ac.uk

Background and aims: Infections account for over 50% of hospital admissions of patients with chronic liver disease (CLD) and are the main precipitant for rapid decompensation to Acute-on-chronic-liver failure (ACLF) carrying a mortality rate > 50%. Our data strongly indicate a predominant defect in T cell responses in chronic liver failure. IL-35 is a key mediator of immune suppression and a potent inhibitor of T cell functions. We aim to establish the role of IL-35 in the failure to mount a proper adaptive-immune-mediated response in chronic liver failure
Method: Circulating levels of IL-35 in patients with CLD, ACLF and healthy controls (HCs) were measured using ELISA. Hepatic sinusoidal endothelial cells (HSECs) conditioned in sera from chronic liver failure patients or HCs were assessed for IL-35 secretion and synthesis in supernatants and in cell lysates using ELISA and the Wes^{TM} system, respectively. Multicolour flow cytometry was used to screen for IL-35-secreting T cells from peripheral mononuclear cells using surface and intracellular staining. The suppressive capacity of $CD4^+IL\text{-}35^+$ T cells was tested using flow-based CFSE suppression assays and multiplex cytokine detection platform. We tested the role of circulating IL-35 as well as recombinant cytokines (IL-35, IL-22 and IL-12) in the induction of this suppressive phenotype
Results: IL-35 levels were significantly increased in CLD and ACLF compared to HC (p = 0.01 and P = 0.001, respectively). In liver-failure-conditioned media, HSECs were competent producers of high levels of IL-35. In the peripheral blood, we identified an expanded $CD4^+IL\text{-}35^+$T cell population expressing high levels of the tolerogenic marker HLA-G. We further defined this population to be $CTLA\text{-}4^{high}CD62L^{low}IL\text{-}10^{low}$. Suppression assays demonstrated that $HLA\text{-}G^+CD4^+$T cells from ACLF patients were potent suppressors of PBMC proliferation. However, blockade of cell surface HLA-G and to a greater extent blockade of CTLA-4 abrogated this suppression and restored levels of IFN-γ, IL-2 and TNF-α secretion in PBMCs. Additionally, we have shown that IL-35 as well as IL-22 were potent candidate cytokines for immunomodulation of $CD4^+$T cells into immunosuppressive-$CD4^+IL\text{-}35^+HLA\text{-}G^+$T cells
Conclusion: Our data demonstrate evidence of dysregulation of the adaptive arm of the immune system in chronic liver failure mediated by IL-35. This finding will aid in the identification of novel therapeutic targets to reverse immuneparesis in chronic liver failure

SAT-375

Therapeutic interleukin 4 modulates monocyte dynamics and accelerates repair and regeneration following acute liver injury

Ruairi Lynch[1], Calum Bain[1], Cathy Hawley[1], Stuart Forbes[2], Stephen Jenkins[1]. *[1]The Queen's Medical Research Institute, Edinburgh, United Kingdom; [2]The MRC Centre for Regenerative Medicine, The University of Edinburgh, Edinburgh, United Kingdom*
Email: rlynch@ed.ac.uk

Background and aims: Acute liver failure has significant mortality, and in its most severe form, the only treatment is liver transplantation. Murine models of acute liver injury are characterised by dramatic changes in the hepatic macrophage compartment, with an initial accumulation of pro-inflammatory $Ly6C^{hi}$ monocytes and loss of Kupffer cells, followed by the dominance of recruited $Ly6C^{lo}$ macrophages that promote liver repair. IL-4 administered prior to injury with carbon tetrachloride (CCl_4) has been shown to be hepatoprotective by directly promoting hepatocyte proliferation. We aimed to assess the effects of therapeutic IL-4 administered following acute liver injury with CCl_4.
Method: Male C57Bl/6 mice were given CCl_4 intraperitoneally to induce an acute liver injury. IL-4 was administered in the form of an immune complex subcutaneously. To investigate the role of IL-4Rα signalling in bone marrow derived cells, whole-body and tissue-protected chimeras were generated with wild type or $IL\text{-}4R\alpha^{-/-}$ donor bone marrow. Results were analysed using immunohistochemistry of tissue sections, serum biochemistry and flow cytometric analysis of leukocytes.
Results: Therapeutic administration of IL-4 following CCl_4 reduced markers of hepatic injury (ALT and necrotic area) and enhanced hepatic regeneration as measured by hepatocyte proliferation. This was paralleled by profound alterations to the monocyte/macrophage pool, with increases in the number of pro-reparative $Ly6C^{lo}$ macrophages but also a significant reduction in the number of pro-inflammatory hepatic $Ly6C^{hi}$ monocytes. Using chimeras, we have shown that $Ly6C^{lo}$ macrophage accumulation required cell-intrinsic, IL-4Rα-dependent proliferation and the loss of hepatic $Ly6C^{hi}$ monocytes was dependent on cell-intrinsic, IL-4Rα signalling. Importantly, analysis of kidney, spleen and blood revealed that the loss of $Ly6C^{hi}$ monocytes secondary to IL-4 treatment was not limited to the liver and occurred systemically. *In vitro* and *ex vivo* assays showed that the reduction in $Ly6C^{hi}$ monocytes in response to administration of IL-4 was due to IL-4Rα-dependent death of circulating monocytes rather than decreased output from the bone marrow.
Conclusion: This novel therapeutic role of IL-4 in causing death of pro-inflammatory $Ly6C^{hi}$ monocytes and an increase in pro-reparative $Ly6C^{lo}$ macrophages could offer potential therapeutic insights not only for acute liver injury but also other inflammatory pathologies characterised by monocytosis.

SAT-376

Bile acids induce STAT3 and repress FOXP3 expression in hepatic CD4 lymphocytes under cholestatic conditions

Ramesh Kudira[1], Celine Silva-Lages[1], Amy Taylor[1], Tiffany Shi[1], Rebekah Karns[1], Mary Mulen[1], Wujuan Zhang[2], Kenneth Setchell[2], Alexander Miethke[1]. *[1]Cincinnati Children's Hospital Medical Center, Pediatric Gastroenterology, Hepatology and Nutrition, Cincinnati, United States; [2]Cincinnati Children's Hospital Medical Center Location B, Pediatric Pathology and Laboratory Medicine, Cincinnati, United States*
Email: alexander.miethke@cchmc.org

Background and aims: Impaired regulatory T cell (Treg) responses have been identified to predispose to cholangiopathies, including PSC and Biliary Atresia. Immunotherapies targeting Tregs are considered, yet, stability of Tregs in the cholestatic liver is unknown.
Method: Splenic $CD4^+CD25^+Foxp3^+$ Tregs from Foxp3/GFP reporter mice were cultured for 48hrs in presence of either 100 μM Taurocholic acid (TCA) or Taurochenodeoxycholic acid (TCDCA),

αCD3/CD28 and hIL-2 prior to cytometric quantification of Foxp3 expression. $CD4^+CD25^+CD127^{low}$ Tregs separated from PBMCs of healthy donors were cultured with TCDCA and subjected to RNAseq.
Results: Exposure to TCDCA, but not TCA, significantly reduced Foxp3 expression in Tregs and decreased their suppressive capacity when co-cultured with CD8 cells. Quantitative PCR revealed expression of the bile acid (BA) surface receptor S1pr2, but not of Fxr, Pxr, Vdr, or Tgr5. However, blocking S1pr2 with JET-013 did not prevent TCDCA-induced repression of Foxp3. Furthermore, incubation with D4 labelled TCDCA and subsequent mass-spectrometry showed dose dependent intracellular accumulation of BA. Searching for intracellular molecular targets of BA, the role of Stat3 was investigated. TCDCA-treatment increased *Stat3* mRNA expression and pre-treatment of Tregs with the Stat3 inhibitor S31-201 prevented TCDCA effects on Foxp3. Bisulphate sequencing detected hypermethylated CpG sites in the Foxp3 promoter region following TCDCA treatment indicating epigenetic effects of TCDCA/Stat3. Methylation blocker 5-Aza-2'deoxycytidine prevented TCDCA-induced Foxp3 repression in vitro and administration of 20 mg/kg/d for 7 days increased intrahepatic Tregs in cholestatic $Mdr2^{-/-}$ mice (mean ± SEM of % Treg/CD4: 12 ± 1 vs 6.2 ± 1.5 in 5-Aza vs vehicle, $p < 0.01$). Treating $Mdr2^{-/-}$ mice with 10 mg/kg/day of ASBT inhibitor SC-435 for 14 days lowered serum TCDCA-levels (mean: 0.54 vs 45 μM in controls, $p < 0.05$) and expanded hepatic Tregs (#Tregs/100 mg tissue: 1722 ± 208 vs 311 ± 49, $p < 0.01$). RNAseq on human Tregs cultured with TCDCA revealed increased expression of IL17F, IL-17A, AHR and down-regulation of STAT1 and CEBP transcription factors.
Conclusion: TCDCA in concentrations found in the serum of patients with biliary obstruction reduces suppressor function of Tregs via induction of Stat3 and epigenetic silencing of Foxp3. Inhibiting methylation or intestinal BA reuptake restore hepatic Treg responses in murine sclerosing cholangitis. Anti-cholestatic medications may improve the efficacy of Treg-directed immunotherapy for biliary diseases in the future.

SAT-377

Significant reductions in intrahepatic Mucosal Associated Invariant T cells with increased terminal activation marker expression amongst NAFLD patients following a 12 week aerobic exercise program: a paired liver biopsy study

Sara Naimimohasses[1], Philip O'Gorman[2], Ann Monaghan[2], Megan Kennedy[2], Dean Holden[3], Peter Beddy[4], Niall Conlon[3], Stephen Finn[5], Margaret Dunne[6,7], John Gormley[2], Jacintha O'Sullivan[7], Suzanne Norris[1]. Email: naimims@tcd.ie

Background and aims: Exercise has been shown to improve the cardiometabolic profile and reduce hepatic steatosis amongst NAFLD patients. Aerobic exercise programs can lead to decreases in circulating pro-inflammatory cytokines and alterations in circulating immune cell populations. The aim of this study was to evaluate the effect of an aerobic exercise program on circulating and intrahepatic MAITs.
Method: 25 individuals with biopsy proven NAFLD were enrolled in the study. 16 patients were allocated to an exercise intervention (EI) and 9 patients were recruited as controls. Baseline investigations inclusive of bloods, fibroscans and DEXAs were performed and repeated following completion of EI. The EI consisted of a 12 week aerobic exercise program (two supervised and three unsupervised) with increasing intensity. 13 patients in the EI with steatohepatitis on their initial liver biopsy had repeat liver biopsies to re-assess histological stage. Liver tissue and whole blood samples were stained with antibodies specific for CD45, CD3, CD8, CD161, Vα7.2, CD69 and CD95 and were analysed with multi-colour flow cytometry using a BD FACSCanto II (BD Biosciences) and FlowJo software (Tree Star, Asland, OR). Statistical analysis of paired samples was performed using the Wilcoxon matched pair rank test. Patient characteristics: 52% (n = 13) female, 64% (n = 16) diabetes/IGT, median age 58 *(20-71)*, BMI 35 *(27-48)*, ALT 49 *(14-116)*, AST 30 *(19-63)*, HbA1c 42 *(27-106)*.
Results: Following completion of the EI, there was a significant reduction in BMI ($p = 0.0305$), without any significant changes in ALT, AST or HBA1c. On repeat liver biopsy there were significant reductions in NAS score following the EI ($p = 0.0312$) this was attributable to reductions in the histological grade of ballooning ($p = 0.0078$). No significant reductions were observed in the steatosis, lobular inflammation or fibrosis grade. Review of intrahepatic MAITs demonstrated significant reductions in the percentage of intrahepatic MAITs ($p = 0.0215$), with increased MFI of CD95 ($p = 0.0027$) post EI (See figure 1).

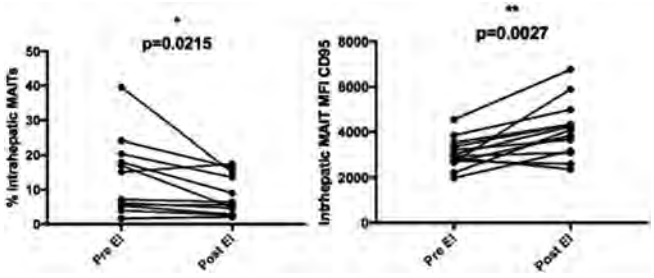

Figure 1:

Conclusion: A 12 week EI resulted in significant improvement in histological NAS score and grade of ballooning. The observed reduction in intrahepatic MAITs combined with increased terminal activation marker may reflect increased MAIT cell apoptosis due to increased oxidative stress and increased FAS signalling.

SAT-378

The NIF mouse as a model for acute, late stage non-alcoholic steatohepatitis

Julia Nilsson[1,2], Anja Schmidt-Christensen[1], Maria Hörnberg[2], Nina Fransén Pettersson[1], Sofia Mayans[2], Dan Holmberg[1,2]. [1]*Lund University, Malmö, Sweden;* [2]*InfiCure Bio, Umeå, Sweden*
Email: julia.nilsson@med.lu.se

Background and aims: NAFLD (Non-alcoholic fatty liver disease) is the most common cause of chronic liver disease in the Western world and is a complex spectrum of liver diseases ranging from steatosis to non-alcoholic steatohepatitis (NASH). Therapeutic advances in treatment of NASH have been slow and NASH has been classified as a medical condition with high, unmet therapeutic need. One barrier to therapeutic development is the lack of preclinical models of progressive NASH that recapitulates human disease. We have developed and characterized the novel animal model, the non-obese diabetic inflammation and fibrosis (NIF) mouse, that spontaneously develops chronic inflammation and fibrosis in multiple organs, as a novel animal model of NASH.
Method: The NIF mouse and its littermate controls were analyzed at six different time points through the ages of 3 to 18 weeks, using histology, flow cytometry, qPCR analysis, cell activation and cytokine analysis, immunohistochemistry, hydroxyproline examination and adoptive transfer experiments.
Results: In the liver, the N-IF mouse displays inflammation and fibrosis particularly evident around portal tracts and central veins, and accompanied with evidence of abnormal intrahepatic bile ducts. The extensive cellular infiltration consists mainly of macrophages and granulocytes, particularly eosinophils. This inflammatory syndrome is mediated by a transgenic population of natural killer T cells (NKT) induced in an immunodeficient NOD genetic background and characterized by the combined production of both Th1 and Th2

cytokines. Through upregulation of TGF-β due to the pro-inflammatory factors and the high levels of Th2 cytokines produced by the transgenic NKT cells, the hepatic stellate cells are activated, leading to the development of severe fibrosis, staged at F3. The disease is transferrable to immunodeficient recipients, while polyclonal T cells from unaffected syngeneic donors can inhibit the disease phenotype.

Conclusion: The disease phenotype of the NIF mouse, although lacking the metabolic factor, resembles the late stages of NASH in several pertinent features, including the temporal heterogeneity of the fibrotic lesions, the progressive nature of the disease and, primarily, the preceding chronic inflammation. This in combination with the early on-set, spontaneous nature and reproducibility, makes this novel mouse model a unique tool to gain further insight into the underlying mechanisms mediating transformation of chronic inflammation into fibrosis and to evaluate intervention protocols for treating conditions of fibrotic disorders such as NASH.

SAT-379

Myeloid cells require gp130 signalling for protective anti-inflammatory functions during sepsis

Sara Dutton Sackett[1,2], Tobias Otto[2], Antje Mohs[2], Leif Erik Sander[2,3,4], Sonja Strauch[2], Roland Sonntag[2], Konrad L. Streetz[2], Daniela Kroy[2], Christian Trautwein[2]. Email: ctrautwein@ukaachen.de

Background and aims: Abdominal infection is a life-threatening complication, especially in patients with chronic liver disease (CLD). In particular, sepsis may trigger acute-on-chronic liver in patients with liver cirrhosis failure leading to rapid mortality. Therefore, new strategies of immunomodulation may not only be beneficial during sepsis but could also improve survival of patients with liver cirrhosis. While IL-6/gp130 signalling has well-defined roles in hepatocytes, herein, we aimed at exploring the role of gp130 signalling in myeloid immune cells during abdominal sepsis.

Method: We employed an established mouse model of polymicrobial sepsis induced by caecal ligation and puncture (CLP). To interrogate the role of gp130 signalling, we analysed mice with gp130 ablation in haematopoietic cells (bone-marrow transplantation from MxCre $gp130^{flox/flox}$ mice), as well as mice with myeloid cell-specific gp130 deletion (LysCre $gp130^{flox/flox}$ mice).

Results: Here, we show that lack of gp130 signalling in myeloid cells leads to defective M2 macrophage polarisation and elevated expression or secretion of pro-inflammatory cytokines such as IL-1β, TNF-α and IL-12. This triggers enhanced immune cell recruitment to the peritoneum followed by increased mortality during sepsis, while bacterial clearance is not impaired. Moreover, we demonstrate that exogenous IL-10 administration elicits activation of the downstream transcription factor STAT3, thereby restoring responsiveness of gp130-deficient macrophages to an M2 phenotype and improving survival in mice lacking gp130 in haematopoietic cells.

Conclusion: In this study, we identify an essential role for gp130 signalling in myeloid cells during M2 macrophage polarisation. Our data provide new insights into the molecular basis of M1/M2 phenotypic dichotomy and identify gp130 as a key regulator of immune homeostasis during sepsis. In addition, our results suggest that IL-10 and gp130 pathways redundantly converge to enhance IL-4-induced M2 polarisation and to counterbalance the profound inflammatory response that occurs in sepsis. Hence, these are also relevant in patients with liver cirrhosis to prevent acute-on-chronic liver failure.

SAT-380

Liver-resident memory CD8 T cells do not egress into hepatic venous blood

Sergio Rodríguez-Tajes[1], Laura J Pallett[2], Mireia Garcia-López[1], Anna Baiges[1], Elena Perpiñán[1], Sabela Lens[1], Nekisa Zakeri[2], David Patch[3], Dominic Yu[3], Juan Carlos García-Pagán[1], George Koutsoudakis[1], Sofía Pérez-del-Pulgar[1], Mala K. Email: sergio.tajes@gmail.com

Background and aims: Emerging evidence suggests that the immunological landscapes of liver tissue and peripheral blood are distinct. Populations of T cells and NK cells have been described that are adapted to the liver microenvironment, remain resident within liver tissue and are therefore absent from the circulation. One example is the highly functional tissue-resident memory CD8 T cell (T_{RM}), recently identified in the human liver. CD8 T_{RM} are characterised by co-expression of tissue retention molecules CD69 and CD103, and are associated with control of chronic HBV infection *(Pallett LJ, et al. J Exp Med 2017)*. Here we sought to provide more definitive evidence for complete sequestration of this population in human liver by excluding low-level egress that would only be detectable by sampling the hepatic vein. We also aimed to investigate whether gut T_{RM} can transit to the liver by sampling portal venous blood.

Method: We isolated mononuclear cells from heparinised blood samples obtained from 13 patients undergoing hepatic vein catheterisation (transjugular liver biopsy or hepatic venous pressure gradient measurement), and 3 patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) procedures. Hepatic and peripheral venous blood samples were obtained from all patients, and portal venous blood samples from the 3 TIPS patients. CD8 T cells were interrogated by multiparametric flow cytometry for the expression of tissue-retention signals.

Results: Sampling hepatic venous blood (with or without balloon inflation), failed to reveal a population of CD8 T cells co-expressing CD69 and CD103; CD8 T_{RM} were essentially undetectable, as in peripheral blood (< 1%). The overall T cell composition as assessed by CD4/CD8 ratio was reflective of the circulation rather than the liver, with a strong intra-donor correlation between the frequencies of CD8 and CD4 T cells in hepatic and peripheral venous blood. Preliminary data also showed no detection of CD8 T_{RM} transiting in portal venous blood from gut to liver. Expression of the prototypic exhaustion marker PD1 and cytotoxic potential (granzyme B expression) of CD8 T cells was similar in all venous blood compartments.

Conclusion: By sampling the human liver vasculature we provide evidence in support of tissue-specific retention of human T_{RM}. This has direct implications for monitoring and targeting these highly functional organ-specific memory CD8 T cell sentinels.

SAT-381

TAA-specific CD8+ T-cell responses are inefficiently induced in hepatocellular carcinoma

Catrin Tauber[1,2], Michael Schultheiss[2], Nico Büttner[2], Christoph Neumann-Haefelin[2], Annette Schmitt-Graeff[3], Maike Hofmann[2], Robert Thimme[2]. [1]*Faculty of Biology, University of Freiburg, Freiburg, Germany;* [2]*Department of Medicine II, University Hospital Freiburg, Freiburg, Germany;* [3]*Institute of pathology, University Hospital Freiburg, Freiburg, Germany*
Email: catrin.tauber@uniklinik-freiburg.de

Background and aims: In hepatocellular carcinoma (HCC), CD8+ T-cell responses targeting tumor-associated antigens (TAA) are considered to be beneficial. However, the molecular profile of TAA-

specific CD8+ T cells in HCC is not well defined due to their low frequency.
Method: By applying peptide/MHCI tetramer-based enrichment, a method of high sensitivity, we now could define the heterogeneity of TAA-specific CD8+ T cells targeting AFP, glypican-3, NY-ESO-1, MAGE-A1 and MAGE-A3.
Results: In this study, we demonstrate that TAA-specific CD8+ T-cell responses are not efficiently induced in HCC patients as supported by the following observations: First, in HCC patients, frequencies of TAA-specific CD8+ T cells were not increased compared to healthy donors or patients with liver cirrhosis. Second, a remarkable proportion of TAA-specific CD8+ T cells exhibited were naive despite the presence of antigen within the tumor tissue. Third, transarterial chemoembolization (TACE) did not enhance TAA-specific CD8+ T-cell responses. In addition, we observed that antigen-experienced TAA-specific CD8+ T cells lack the characteristic transcriptional regulation of exhausted CD8+ T cells, namely $Eomes^{hi}Tbet^{dim}$, and express inhibitory receptors only on a minor proportion of cells. This suggests restricted antigen recognition and further supports the hypothesis of inefficient induction and activation.
Conclusion: Our comprehensive analysis reveals that TAA-specific CD8+ T cells are not properly induced in HCC thereby unravelling new and unexpected insights into TAA-specific CD8+ T-cell biology in HCC. This clearly highlights severe limitations of these potentially anti-tumoral T cells that may hamper their biological and clinical relevance in HCC.

SAT-382
Crosstalk between liver NKT cells and liver sinusoidal endothelial cells
Abdallah Yassin[1], Bastian Höchst[1], Percy A. Knolle[1]. [1]*Institute of Molecular Immunology, School of Medicine, Technical University of Munich, München, Germany*
Email: percy.knolle@tum.de

Background and aims: The liver is known for its tolerogenic microenvironment and organ-resident antigen-presenting cell populations. It also harbors a large number of innate lymphocytes out of which NKT cells constitute a substantial population. While NKT cells are known to exert potent effector functions upon CD1-restricted antigen presentation, it has remained largely unclear which local cell populations in the liver are capable of activating NKT cells in an CD1-specific fashion and whether such antigen-activation of NKT cells is involved in the orchestration of hepatic CD8 T cell immunity. The aim of this study was to characterize the ability of liver sinusoidal endothelial cells as antigen presenting cells to orchestrate NKT cell immunity.
Method: Methods used in this study include high-purity isolation of primary liver cell populations to study their cognate interaction with lymphocytes *ex vivo* using flow cytometry and bead-array based detection of cytokines released upon antigen-specific stimulation.
Results: We isolated primary cell populations from the liver, i.e. liver sinusoidal endothelial cells (LSECs), Kupffer cells and hepatocytes to study which of these cell populations engaged in CD1-restricted antigen presentation to NKT cells. LSECs showed highest CD1 expression that was even further increased upon contact with pro-inflammatory mediators. Dose kinetic studies revealed that LSECs cross-presented minute concentrations of the alpha-galactosyl-ceramide in a CD1-restricted fashion to primary NKT cells. Such cognate interaction resulted in upregulation of activation markers and preferential induction of IL-2 and Interferon gamma from activated NKT cells. Compared with splenic dendritic cells, LSECs proved to be more efficient in CD1-restricted activation of NKT cells. Importantly, cognate interaction between LSECs and NKT cells initiate polyclonal activation of CD8 T cells.
Conclusion: Our results reveal efficient CD1-restricted activation of NKT cells by antigen-presenting LSECs as initiating event in broad local CD8 T cell that may be instrumental in anti-viral immunity in the liver.

SAT-383
Human mesenchymal stem cells-derived exosomes attenuate liver ischemia/reperfusion injury by up regulation of notch-1-related autophagy in CD4 T cell
Xiaomei Zhang[1], Jun Zheng[1], Jianye Cai[1], Liang Chen[1], Wei Liu[1], Yang Yang[1]. [1]*The Third Affiliated Hospital of Sun Yat-Sen University, Department of Hepatic Surgery, Guangzhou, China*
Email: uv1@163.com

Background and aims: Mesenchymal stem cell (MSC)-derived exosomes administration has been identified as a novel and effective cell-free therapeutic tool for several liver diseases through cell-contacted communication. The present study was aimed to investigate the role of umbilical cord MSC (UC-MSC) derived exosome (UC-MSC-Exo) in the treatment of hepatic ischemia-reperfusion injury and further explore the potential mechanisms.
Method: UC-MSC-Exo were utilized to the liver I/R injury mice through intravenous transfusion and their effects were assessed by serum hepatic enzyme and liver histopathologic analysis. Furthermore, the number of CD4+Foxp 3 + regulatory T cells (Tregs) in liver was detected by flow cytometry, and total CD4+ T cells were isolated from the liver of each group to evaluate their changes of autophagy by flow cytometry and transmission electronic microscope (TEM). In order to elucidate the mechanisms of UC-MSC-derived exosomes in CD4+T cells, CD4+T cells were isolated from C57BL/6 spleen and co-cultured with UC-MSC-Exo. The activation of Notch-1 and autophagy-related proteins in CD4+ T cells were determined by Western blot analysis, respectively. The exosomes from Jagged-1-knockdonwded UC-MSCs (UC-MSC-$Exo^{Jagged\text{-}1\text{-}KD}$) were contributed to further confirming the role of Jagged-1 in UC-MSC-Exo-based therapy.
Results: UC-MSC-Exo administration remarkably attenuated I/R-induced liver injury as determined by decreased serum hepatic enzymes [alanine aminotransferase (ALT), aspartate aminotransferase (AST) and lactate dehydrogenase (LDH)] and hepatic inflammatory microenvironment as well as improved hepatocellular apoptosis and hepatic pathologic changes. Further investigations showed that UC-MSC-Exo not only increased the ratio of T-reg cells but also upregulated autophagy in CD4+ T cells. Furthermore, Jagged-1, which can enhance autophagy by targeting the Notch-1 signaling pathway, abundantly expressed on UC-MSC-Exo. While the therapeutic roles of UC-MSC-$Exo^{Jagged\text{-}1\text{-}KD}$ on liver I/R injury were remarkably weakened as they could not availably activate Notch-1-related autophagy and suppress inflammatory activation in CD4+ T cells in vitro and in vivo.
Conclusion: Expression of Jagged-1 on exosomes plays an important role in UC-MSC-Exo therapy for liver I/R injury by targeting the Notch-1 signaling pathway and upregulating autophagy in intrahepatic CD4+ T cells. UC-MSC-Exo-based therapy may be considered as a beneficial approach for upregulating autophagy to alleviate inflammatory liver diseases.

Production and characterization of human liver extracellular matrix hydrogels for in vitro culture of distinct human primary liver cell populations
Niki Alevra Sarika[1,2], Valéry L. Payen[1,2], Maximilien Fleron[3], Véronique Préat[2], Gabriel Mazzucchelli[3], Edwin de Pauw[3], Adil El Taghdouini[1], Anne des Rieux[2], Etienne M. Sokal[1]. [1]*Institute de Recherche Expérimentale et Clinique (IREC), Pediatric Hepatology and*

Cell Therapy Department, Brussels, Belgium; [2]Louvain Drug Research Institute (LDRI), Advanced Drug Delivery and Biomaterial department (ADDB), Brussels, Belgium; [3]Grappe interdisciplinaire de génoprotéomique appliquée (GIGA), Mass spectrometry laboratory and Proteomics platform, Liège, Belgium
Email: niki.alevra@uclouvain.be

Background and aims: The study of human primary liver cell biology is largely hampered by the lack of adequate *in vitro* culture systems that allow the maintenance of the cells' viability and physiologic phenotype for prolonged periods of time. In this context, a growing interest for liver decellularization and for the use of liver extracellular matrix (ECM) in cell culture and tissue engineering applications emerged over the past five years. Whereas several publications describe detailed procedures for animal liver decellularization and ECM-based hydrogel production, few is known about the composition and properties of isolated human liver ECM. In this study, we analyzed the composition of human liver ECM and derived hydrogels, and we further addressed the question of the potential benefits of a liver ECM protein-coated surface for the culture of primary human liver cells.
Method: A combination of thermic and osmotic shock, enzymatic digestion and detergents has been used to decellularize human liver fragments unsuitable for transplantation. Liver ECM was partially digested with pepsin for coating purposes and characterized by histology and mass spectrometry. Primary human liver cells, including hepatocytes, hepatic stellate cells (HSC) and endothelial cells (EC) were seeded on liver-coated culture dishes. Adhesion (2 h), viability (24 h), proliferation (7 days) and phenotypic properties were evaluated and compared to a surface of reference (CellBIND or rat tail collagen coating).
Results: Our protocol led to a residual amount dsDNA below decellularization standards. Coating derived from liver ECM showed no toxicity for primary human liver cells. Mass spectrometry revealed the abundance of type I and type III fibrillar collagen components (COL1A1, COL1A2, COL3A1) as well as elastin in liver ECM hydrogels used for coating. Preliminary results further suggest the benefits of human liver ECM on human primary liver cell properties in 2D culture as compared to surfaces of reference.

Conclusion: Our study provides a first detailed characterization of human liver ECM and derived hydrogels, easily and reproducibly isolated from small human liver fragments. Our results further open the way for the use of human liver ECM as a coating for the culture of primary human liver cells in 2D. In a near future, 3D applications will be developed.

SAT-386

Insulin resistance in NK cells of F4 fibrosis inhibit mTOR expressions and are associated with decreased F-actin and killing ability in NASH patients

Johnny Amer[1], Ahmed Salhab[1], Rifaat Safadi[1]. [1]*Hadassah Hebrew University Hospital, Jerusalem, Israel*
Email: johnnyamer@hotmail.com

Background and aims: In humans, two NK-cell subsets have been characterized according to the cell-surface density of CD56 and expression of CD16. $CD56^{+}CD16^{+}$ NK cells (more cytolytic and produce significant amounts of cytokine when their activating receptors are engaged) compose approximately 90% of circulating NK cells; $CD56^{++}CD16^{-}$ NK cells (Bright NK cells) constitute approximately 10%. We investigated a potential role of NMDAR (an insulin responding *N*-Methyl-D-Asparate Receptor) to modulate NK responses in Non-alcoholic-Fatty-Liver-Disease (NAFLD) progressions.
Method: Flow cytometry analysis was performed in peripheral-blood-lymphocytes from healthy and histology documented NAFLD cases with low and advanced fibrosis.
Results: The NK cytolytic $CD56^{Dim\ (CD16+)}$ showed to be the dominant populations in all studied samples. NAFLD NK^{dim} population had lower insulin receptors ($NK^{dim}\ IR^{low}$), mainly in advanced fibrosis ($p < 0.05$). These patients showed higher HOMA-score while their NK^{dim} population showed lower F-Actin and mTOR expressions. NAFLD $CD56^{Dim}$ CD107a (NK-granzymes-activation marker) tend to increase in low fibrosis NAFLD cases ($p = 0.06$) but was unchanged in advanced fibrosis. In cultures, insulin exposure unleashed the CD107a to increase NK killing. However, insulin resistance of NAFLD NK cells showed lower responses and decreased killing ability. On the other hand, insulin up-regulation of the NMDAR showed to depresses mTOR activity.
Conclusion: NAFLD NK cells exert insulin resistance, mainly the $CD56^{Dim}$ cytolytic population. The NMDAR unit regulates NK activity as a result of metabolic modifications; via an mTOR dependent pathway. It stimulated F-Actin accumulations and NK granzymes complex; indicating a new cellular pathway through which NK cells contribute to the NAFLD progression.

Pharmacological inhibition of P2X7 receptor ameliorates liver injury in nonhuman primates by reducing liver inflammation and fibrosis

Bernat Baeza-Raja[1], Andrew W Goodyear[1], Lynn Yamamoto[1], G. Steven Dodson[2], Toshihiko Takeuchi[2], Matt Mcclure[2], Karim Dabbagh[2]. [1]*Second Genome, Inc, Discovery, South San Francisco, United States;* [2]*Second Genome, Inc, South San Francisco, United States*
Email: bernat@secondgenome.com

Background and aims: Activation of the inflammasome complex has been identified as a major contributor to hepatocyte damage, immune cell activation, and amplification of liver inflammation in non-alcoholic steatohepatitis (NASH). The purinergic receptor (P2X7 receptor) is an ATP-gated ion channel responsible for the activation of the inflammasome complex and the release of IL-1β. Although P2X7 receptor has been suggested to regulate inflammation and fibrosis in murine models, whether it can serve as a therapeutic target for NASH remains unknown.
Method: We have analyzed P2X7 receptor in NASH patients and examined the effects of P2X7 receptor pharmacological inhibition in human primary hepatocytes, Kupffer cells, and hepatic stellate cells *in vitro* and in a chemically-induced fibrosis model in nonhuman primates.
Results: We found that livers from NASH donors showed increased P2X7 receptor expression compared to livers from NAFLD and healthy donors. In addition, P2X7 receptor pharmacological inhibition blocked IL-1β release from human primary Kupffer cells and PBMCs, leading to reduced hepatocyte damage and fibrogenesis in human primary hepatic stellate cells. We also found that

pharmacological inhibition of P2X7 receptor resulted in a marked protection against inflammation and fibrosis in monkey in a chemically-induced model of liver injury.
Conclusion: Taken together, these findings indicate that pharmacological inhibition of P2X7 receptor has the ability to reduce inflammation and fibrosis in both human in vitro primary cells and nonhuman primates. Thus, P2X7 receptor is a promising molecular target for treating liver diseases, including NASH.

SAT-388
How to infuse heterologous human adult liver-derived progenitor cells safely?
Louise Coppin[1], Mustapha Najimi[2], Julie Bodart[2], Marie-Sophie Rouchon[2], Patrick Vandersmissen[2], Eeckhoudt Stephane[3], Géraldine Dahlqvist[4], Castanares Diego[5], Johan Heemskerk[6], Sandrine Horman[2], nathalie Belmonte[7], Etienne Sokal[4], Xavier Stéphenne[4]. *[1]Cliniques Universitaires Saint-Luc, Pediatric gastroenterology and hepatology, Brussels, Belgium; [2]Université Catholique de Louvain, Brussels, Belgium; [3]Cliniques Universitaires Saint-Luc, Clinical biology-hemostasis, brussels, Belgium; [4]Cliniques Universitaires Saint-Luc, Gastroenterology and hepatology, Brussels, Belgium; [5]cliniques Universitaires Saint-Luc, Intensive care, Brussels, Belgium; [6]Maastricht University, Maastricht, Netherlands; [7]Promethera Biosciences, Mont-Saint-Guibert, Belgium*
Email: coppinlouise@gmail.com

Background and aims: Mesenchymal stem cell (MSC) infusions are currently evaluated in numerous clinical trials, but therapy-induced thrombi have been described in several patients. Most MSCs in fact express a procoagulant activity (PCA) linked to tissue factor (TF) expression. The aim of this study was to optimise infusion protocols using Heterologous Human Adult Liver-derived Progenitor Cells (HHALPC) without inducing a thrombogenic risk after the infusion. We studied infusions of high cell doses in metabolic patients and low cell doses in cirrhotic patients, known to a have rebalanced haemostasis.
Method: First cell dose escalation was studied using a xenotransplant animal model (healthy Wistar rat, with or without anticoagulants). Then the crucial role of TF in PCA was confirmed using flow chambers (shear stress model). Finally, we characterized disseminated intravascular coagulation (DIC) induced by HHALPCs *in vitro* and investigated how to control the induced thrombotic and haemorrhagic risks in whole blood of healthy and cirrhotic patients (by fibrin generation model and tubing loops, mimicking blood flow).
Results: *In vivo* we showed that the thrombogenic risk induced by HHALPC infusions is dose dependent. High cell doses such as 50×10^6 cells/kg induced DIC 1 h after transplantation with a significant decrease in platelets ($p < 0.01$), fibrinogen ($p < 0.001$), and coagulation factors II, V and VIII ($p < 0.01$) compared to control rats infused only with PBS. Infusions of lower cell doses, such as 5×10^6 cells/kg did not activate the coagulation cascade. Adding anticoagulants during infusions of high cell doses, such as heparin (300 I.U./5×10^6 cells) or a combination of heparin (10 I.U./5×10^6 cells) and bivalirudin can control the thrombogenic risk. By tubing loop model we showed that HHALPCs activate the coagulation cascade in a less explosive way in decompensated cirrhotic patient's blood compared to healthy volunteers. HHALPCs only induce a significant decrease in platelets ($p < 0.01$) and fibrinogen ($p < 0.01$) and not in coagulation factors.
Conclusion: Low doses of MSCs (5×10^6 cells/kg) expressing TF do not induce a thrombogenic risk, and could thus be used in future clinical trials treating acute decompensated cirrhotic patients while monitoring platelet and fibrinogen levels. The thrombogenic risk induced by infusions of higher cell doses can be controlled by adding anticoagulants and could therefore be used to treat metabolic patients.

SAT-389
Obeticholic acid reduces matrix metalloproteinases activity via iNOS modulation in hepatic ischemia/reperfusion injury
Laura Giuseppina Di Pasqua[1], Giuseppina Palladini[1,2], Clarissa Berardo[1], Veronica Siciliano[1], Luciano Adorini[3], Plinio Richelmi[1], Massimiliano Cadamuro[4], Luca Fabris[4], Stefano Perlini[1,2], Mariapia Vairetti[1], Andrea Ferrigno[1]. *[1]University of Pavia, Internal Medicine and Therapeutics, Pavia, Italy; [2]Fondazione IRCCS Policlinico San Matteo, Pavia, Italy; [3]Intercept Pharmaceuticals, San Diego, United States; [4]University of Padua, Molecular Medicine (DMM), Padua, Italy*
Email: lauragiuseppin.dipasqua01@universitadipavia.it

Background and aims: We have previously shown that the Farnesoid×Receptor (FXR) agonist obeticholic acid (OCA) decreases inducible NOS (iNOS) content in ischemia/reperfusion (I/R)-treated rats (Ferrigno A et al., 2018). iNOS is known to regulate the activity of matrix metalloproteinases (MMPs) in liver I/R injury (Hamada T et al., 2009). In this study, we evaluated the effects of OCA on MMP-2 and MMP-9 gelatinase activity in liver, bile and serum after hepatic I/R.
Method: Male Wistar rats (n = 20) were orally administered 10 mg/kg/day of OCA (Intercept Pharmaceuticals) for 5 days or vehicle and subjected to a 60-min partial-hepatic ischemia or sham-operated. After a 60-min reperfusion bile flow was quantified, and serum, bile and tissue samples were collected for MMP-2 and MMP-9 analysis by zymography. Serum levels of AST and ALT as well as biliary levels of LDH, γGT and glucose were quantified. Liver morphology was evaluated by HandE staining as well as Western blot analysis of iNOS.
Results: I/R induced increase in both iNOS expression ($p<0.01$) and MMP-2 and MMP-9 activity ($p<0.005$ and $p<0.01$, respectively) in the liver. OCA administration reduced MMP-2 and MMP-9 in liver ($p<0.009$ and $p<0.05$, respectively) and bile ($p<0.03$ and $p<0.01$, respectively); the same trend, although not significant, was observed in serum samples. OCA did not change liver morphology, while less pyknotic cells in liver specimens from OCA-treated rats were found. Although not significantly, OCA administration reduced hepatic serum enzyme levels in the I/R group. Biliary levels of LDH, γGT and glucose were significant lower in I/R rats treated with OCA compared with I/R group treated with vehicle ($p<0.05$, $p<0.008$ and $p<0.05$, respectively). No difference in bile flow were detectable in I/R groups.
Conclusion: In liver submitted to I/R a reduction in MMPs activity by OCA administration was found. For the first time, we have shown an MMPs biliary content that was modulated by the treatment with OCA. These data are also associated with lower levels of biliary markers of cholangiocyte injury and biliary reabsorption of glucose, this last index of cholangiocyte function (Tabibian JH et al., 2013). The present data suggest that OCA is involved in the reduction of bile duct injury by the MMPs activity modulation and the decrease of hepatic gelatinase activity observed using this FXR agonist appears to be mediated by iNOS.

SAT-390
Dengue virus protein NS3 activates hexokinase activity in hepatocytes to support virus replication
Marianne Figl[1], Clémence Jacquemin[1], Laure Perrin-Cocon[1], Patrice Andre[1], Vincent Lotteau[1], Olivier Diaz[1]. *[1]Centre International de Recherche en Infectiologie (CIRI), INSERM U1111-CNRS UMR5308 Université Lyon 1, ENS de Lyon, LYON cedex 07, France*
Email: olivier.diaz@inserm.fr

Background and aims: Viruses modulate central carbon metabolism in the infected cell but the underling molecular mechanisms are poorly described. We have previously demonstrated that NS5A of hepatitis C virus directly interacts with the first glycolysis enzyme hexokinase and increases its activity to support HCV replication (ramiere et al, 2014). To test if this was a common mechanism shared by flaviviruses, we looked whether dengue virus (DENV) proteins were capable of modulating hexokinase activity. Because clinical evidences point to a more pronounced infection of the liver in the

severe forms of infection, we analyzed the dependence of DENV to glycolysis and hexokinase activity in relevant hepatocyte models.
Method: Interaction between DENV proteins and the four hexokinase isoenzymes was studied by protein-complementation assays and coimmunoprecipitation. Like virtually all cancer cells, the hepatocarcinoma cell line Huh7 express the "cancer-type" HK2 isoenzyme whereas in vivo hepatocytes express the HK4 isoenzyme (or Glucokinase, GCK). Therefore, we invalidated HK2 expression in Huh7 cells by CRISPR-Cas9 and restored the expression of the hepatocyte-specific hexokinase isoenzyme, GCK. Dependence of viral replication to glycolysis was evaluated in the two cell models.
Results: We showed that DENV-NS3 interacts with all hexokinase isoenzymes, suggesting a potential impact of DENV-NS3 on the glycolytic activity of infected cells. Expression of DENV-NS3 enhanced glucose consumption and lactate secretion in both Huh7-HK2 and Huh7-GCK and in the none hepatic cell line A549 expressing HK1. In cellular homogenates we analyzed the modulation of catalytic parameters of the enzyme by DENV-NS3. We observed that DENV-NS3 decreased the apparent Km of GCK and abolished the normal allosteric activity of the enzyme. DENV infection was drastically increased in Huh7-GCK compared to Huh7-HK2. Interestingly, using the subgenomique DENV-GFP+ replicon we observed that GFP expression was dependant of glucose concentration in culture medium confirming the direct impact of glycolysis activity on viral replication. Moreover, stimulating GCK activity by direct synthetic activators resulted in an increased replication of the replicon and GFP expression.
Conclusion: DENV controls hepatic glycolysis through the interaction between NS3 and Glucokinase. This interaction modifies the catalytic parameters of the enzyme and favours replication of the virus. This observation suggests that liver infection by DENV is highly dependent on the control of glycemia in vivo.

SAT-391
The influence of Caveolin-1 on hepatocyte metabolism

Mei Han[1], Zeribe Chike Nwosu[1], Weronika Pioronska[1], Matthias Ebert[1], Steven Dooley[1], Christoph Meyer[1]. [1]*Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany*
Email: Mei.Han@medma.uni-heidelberg.de

Background and aims: The membrane protein caveolin-1 (CAV1) has been associated with metabolism in hepatocytes, adipocytes, cancer-associated fibroblasts, and is thought to contribute to cancer progression by altering biochemical pathways. However, the impact of CAV1 expression on metabolic profile is still poorly understood. Here, we aimed to determine novel metabolic gene alterations altered by CAV1 in murine hepatocytes and whole liver.
Method: Freshly isolated murine hepatocytes were transfected with siRNA to knock down CAV1 expression, followed by microarray profiling. The differentially altered genes were used for functional annotation analysis (DAVID, GSEA bioinformatics platforms), to predict molecular functions, biological processes and cellular components altered by CAV1. In addition, we evaluated consistency of altered genes by *in vivo* profiling of *Cav1-/-* mice liver.
Results: Knockdown of CAV1 significantly altered ~1350 genes, topmost of which were *Ifit3*, *Ly6a*, *Zbp1* (upregulated) and *Tnc*, *Nes*, *Fhl1, and Cav1 (as proof of principle),* (downregulated). Pathway annotation analysis revealed that loss of CAV1 induced upregulation of a plethora of metabolic processes and the downregulation of cancer-related pathways. We observed a similar annotation pattern in a dataset of *Cav1-/-* mice liver. Interestingly, 229 of the altered genes were specifically metabolic genes had not been previously associated with CAV1. The novel CAV1-altered genes belong mostly to amino acid metabolism (e.g. *Gcat, Scly*), fatty acid metabolism (e.g. *Acad11, Acadvl*), glycan metabolism (e.g. *Alg6, Galnt7*), nucleotide metabolism (e.g. *Nme5, Nt5c2*), or ion/small molecule transporters (e.g. *Ndufb8, Atp7a*).
Conclusion: Our data reveals that CAV1 affects many metabolic processes in hepatocytes. These changes may have significant implications in liver pathophysiology.

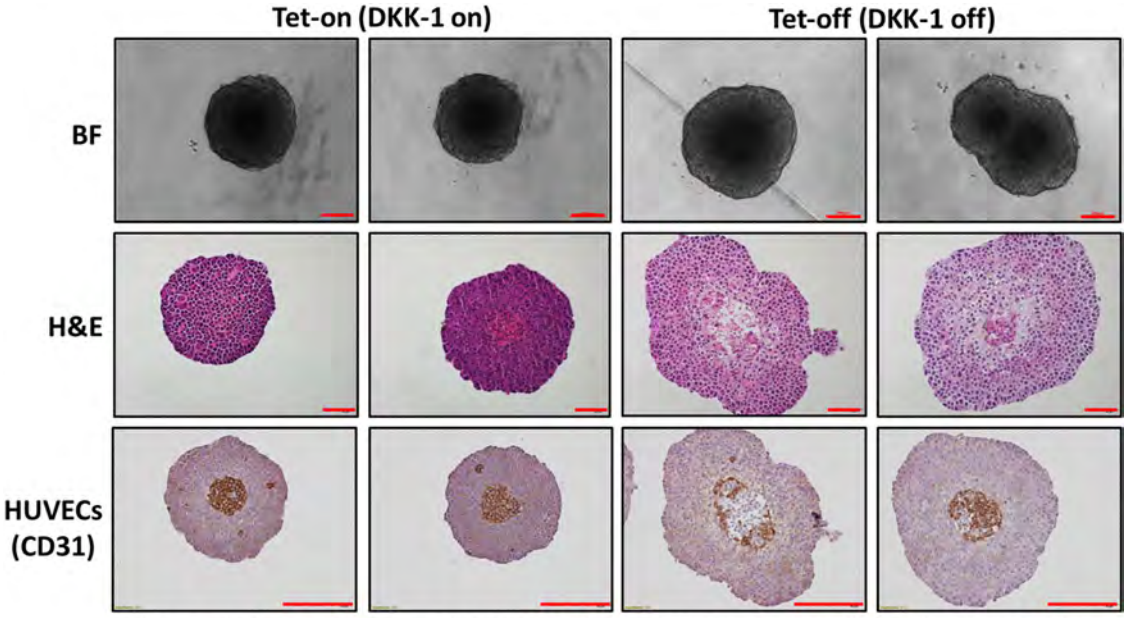
SAT-392
Dickkopf-1 from hepatocellular carcinoma cells promotes the angiogenic potential of endothelial cells by activating the VEGFR-2 signaling pathway

Bora Jin[1,2], Yechan Jeong[2], Beom Kyung Kim[2,3], Jun Yong Park[2,3], Do Young Kim[2,3], Kwang-Hyub Han[2,3], simon W Ro[1,2], Seung Up Kim[2,3], Sang Hoon Ahn[2,3]. [1]*Yonsei University College of Medicine, Brain Korea 21 Plus Project for Medical Science, Seoul, Korea, Rep. of South;* [2]*Severance Hospital, Yonsei Liver Center, Seoul, Korea, Rep. of South;* [3]*Yonsei University College of Medicine, Department of Internal Medicine, Institute of Gastroenterology, Seoul, Korea, Rep. of South*
Email: ksukorea@yuhs.ac

Background and aims: Dickkopf-1 (DKK-1) is an antagonist of Wnt signaling. Several reports have shown an association between the elevated expression of DKK-1 and tumor angiogenesis. However, the biological function of DKK-1 in angiogenesis of hepatocellular carcinoma (HCC) is not well documented. We investigated the phenotypical changes of vascular endothelial cells after interactions with HCC cells expressing DKK-1 using two-dimensional (2D) and three-dimensional (3D) co-culture systems.
Method: The cell lines Huh7 and Hep3B, with low and high DKK-1 expression, respectively, were selected. The tetracycline-inducible DKK-1 expression cell line (Tet-on Huh7) and a DKK-1 knockout cell line using CRISPR/Cas9 (KO Hep3B) were established. The angiogenic potential of human umbilical vein endothelial cells (HUVECs) was investigated using wound scratch, transwell, and tube formation assays. HUVECs were co-cultured with Tet-on/off Huh7, or KO Hep3B for 3D spheroid models, where cells were seeded in a 10:1 ratio (HCC cells:HUVECs) in non-adhesive, round-bottom 96-well plates. After 3 days, spheroids were harvested for quantitative polymerase chain reaction, western blotting, and immunohistochemistry staining.
Results: The angiogenic potential of HUVECs significantly increased after being treated with human recombinant DKK-1. When HUVECs were treated with Tet-on/off Huh7 and KO Hep3B-conditioned media in an indirect 2D co-culture system, Tet-on Huh7 increased the angiogenic potential of HUVECs, which was not increased with Tet-off Huh7 and KO Hep3B. When 3D spheroids were constructed to mimic the in vivo environment, spheroids with HUVECs and Tet-on Huh7 were constructed faster and more packed than those mixed with Tet-off Huh7. When HUVECs in spheroids were stained, HUVECs mixed with Tet-on Huh7 cells exhibited greater viability than those mixed with Tet-off Huh7 cells (Figure). The biological morphology of spheroids with KO Hep3B was similar to those with Tet-off Huh7. Furthermore, the expression levels of vascular endothelial growth factor receptor 2 (VEGFR-2) signaling factors significantly increased when HUVECs were mixed with Tet-on Huh7 cells in 3D spheroids.
Conclusion: We confirmed that DKK-1 from HCC cells promoted the angiogenic potential of HUVECs by activating the VEGFR-2 signaling pathway. Thus, further studies should determine whether blockade of DKK-1 may represent a novel therapeutic target for HCC treatment.

SAT-393
Melatonin attenuates dysregulation of the circadian clock pathway in liver fibrosis and progression to hepatocarcinoma

Diana Isabel Sánchez[1], Bárbara González Fernández[1], Irene Crespo[1], Beatriz San Miguel de Vega[1], Francisco Jorquera[2], Javier González-Gállego[1], María Jesús Tuñón González[1]. [1]*Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd). Institute of Biomedicine (IBIOMED), University of León., León, Spain;* [2]*Department of Gastroenterology. University Hospital Complex of León., León, Spain*
Email: mjtung@unileon.es



DKK-1, dickkopf-1; Tet, tetracycline; BF, bright-field; H&E, hematoxylin and eosin; HUVECs, human umbilical vein endothelial cells. Scale bar indicates 200 μm.

Figure: (abstract: SAT-392)

Background and aims: Disruption of circadian rhythm, which is regulated by Clock genes, results in pathological processes including fibrosis and progression to hepatocarcinoma (HCC). Melatonin exhibits antifibrotic and oncostatic features, but it is unknown if these effects are mediated by the regulation of Clock genes.
Method: Fibrosis was induced in C57BL/6J mice with CCl4 twice a week for 4 or 6wk; melatonin was given at 5 or 10 mg/kg/day i.p. beginning 2wk after the start of CCl4 administration. HCC was induced in ICR mice receiving DEN once a week for 8wk; melatonin was given (5 or 10 mg/kg/day i.p.) 4wk after the onset of DEN administration and ending at 10, 20, 30 and 40wk. We investigated whether melatonin has its effect through the modulation of the nuclear receptor REV-ERB, using the agonist SR9009, in human stellate cells LX2 and Hep3B cells. Cells were exposed to SR9009 (10 μM for 24 h) and treated with melatonin (0.1-0.5 mM and 0.5-1 mM respectively). To study the effect of melatonin on the pathway, BMAL1 was silenced in Hep3B cells, treated or not with the indole (0.1 and 0.5 mM), for 24 h after silencing. The expression of fibrosis markers, proliferation, apoptosis and Clock genes were analyzed by Western-blot, qRT-PCR, immunohistochemistry and cell proliferation assays.
Results: The expression of the main Clock genes, BMAL1 and CLOCK, the transcriptional repressors, PER and CRY, and the nuclear receptors, REV-ERB and RORα, were disrupted in both animal models from the first time-periods reaching higher differences at 6 and 40wk, respectively. Melatonin prevented these altered expressions dose-dependently. To aim if the melatonin antifibrotic and oncostatic effects were through the modulation of REV-ERB, LX2 and Hep3B cells were exposed to SR9009. The ligand was able to modulate the pathway in a similar way to that observed after melatonin administration in LX2 cells, and potentiating melatonin effects in Hep3B cells. The elevated expression of fibrosis markers α-SMA and COL1 were reduced in LX2 cells after SR9009 exposure. BMAL1 silencing resulted in a decreased cell proliferation and an increased expression of the apoptotic markers Bax, cleaved caspase 3 and PARP1/2. Pro-apoptotic and antiproliferative melatonin effects were attenuated in BMAL1-depleted cells.
Conclusion: Melatonin modulates the expression of dysregulated Clock genes, and this could contribute to its beneficial effects in liver fibrosis and the progression to HCC.

SAT-394
Genetic Features Associated with 18F-FDG uptake in intrahepatic cholangiocarcinoma
Koo Jeong Kang[1], Keun Soo Ahn[1], Yong Hoon Kim[1], Tae-Seok Kim[1], Bong-Il Song[2], Hae Won Kim[2], Daniel O'Brien[3], Lewis R Roberts[4], Kwok Kei Mak[5], Kyoung Sook Won[2]. *[1]Keimyung University Dong-San Medical Center, Surgery, Daegu, Korea, Rep. of South; [2]Keimyung University Dong-San Hospital, Nuclear medicine, Daegu, Korea, Rep. of South; [3]Mayo Clinic, Biomedical Statistics and Informatics, Rochester, United States; [4]Mayo Clinic, Gastroenterology and Hepatology, Rochester, United States; [5]Keimyung University, College of Natural Science, Statistics, Daegu, Korea, Rep. of South*
Email: kjkang@dsmc.or.kr

Background and aims: In intrahepatic cholangiocarcinoma (iCCA), genetic characteristics on ^{18}F-FDG-PET scans are not yet clarified. If they are evaluated, we can predict molecular features based on the FDG uptake. We analyzed RNA sequencing in iCCA patients to evaluate gene expression signatures associated with FDG uptake patterns.
Methods: We performed RNA sequencing of 22 cases iCCA who underwent preoperative ^{18}F-FDG- PET, and analyzed the clinical and molecular features according to the maximum standard uptake value (SUVmax). Genes and biological pathway which are associated with SUVmax were analyzed.
Results: Patients with SUVmax higher than 9.0 (n = 9) had poorer disease-free survival than those with lower SUVmax (n = 13, P = 0.035). Genes related to glycolysis and gluconeogenesis, phosphorylation and cell cycle were significantly correlated with SUVmax (| r | ≥ 0.5). RRM2, which is related to the toxicity of Gemcitabin was positively correlated with SUVmax, and SLC27A2 which is associated with Cisplastin response was negatively correlated with SUVmax. Cell cycle, hypoxia and metabolism-related pathways were enriched in high SUVmax patients.

Conclusion: The genomic features of gene expression and pathways can be predicted by FDG uptake features in iCCA. Patients with high FDG uptake have enriched cell cycle, metabolism and hypoxic pathways, which may lead to a more rational targeted treatment approach.

SAT-395

Bone marrow-mesenchymal stem cells of cirrhosis patients show insulin resistance and bioenergetic exhaustion

dhananajay Kumar[1], Deepanshu Maheshwari[1], Smriti Shubham[1], Nidhi Nautiyal[1], Sheetalnath Rooge[1], Lovkesh Anand[2], Ashish Vyas[1], Rekha Kumari[1], Shwetank Sharma[1], Rakhi Maiwall[2], Sujata Mohanty[3], Chhagan Bihari[4], Anupam Kumar[1], Shiv Kumar Sarin[2]. *[1]Institute of Liver and Biliary Sciences, Department of Molecular and Cellular Medicine, New Delhi, India; [2]Institute of Liver and Biliary Sciences, Department of Hepatology, New Delhi, India; [3]All India Institute Of Medical Sciences, New Delhi, Stem Cell Facility, New Delhi, India; [4]Institute of Liver and Biliary Sciences, Department of Pathology, New Delhi, India*
Email: shivsarin@gmail.com

Background and aims: Autologous bone marrow MSC therapy in cirrhotics has shown varied clinical response. Cirrhosis is a state of chronic inflammation and metabolic stress which can adversely affect the BM and stem cell population. We hypothesized that chronic liver injury may result in metabolic dysfunction of BM-MSCs and compromise their therapeutic potential.
Method: We isolated MSC from BM of cirrhotic patients (n = 10) and compared with matched healthy BM (n = 8). All the cells were characterized for MSCs as per criteria of International Society Cell and Gene Therapy (ISCT). Global-transcript profiles of cells were done by Next Generation Sequencing (NGS). Bioenergetics was studied using Seahorse Extracellular Flux Analyzer. Cellular glucose uptake was measured using Glucose Uptake Assay kit.
Results: In isolated cells from both cirrhotic and healthy BM fulfilling the minimal criteria for MSCs, mRNA sequencing showed significant upregulation of genes linked to insulin resistance, TNF signaling and down regulation of genes linked to oxidative phosphorylation, glutathione metabolism, longevity and nucleotide excision repair (fig 1a). In comparison to healthy BM-MSCs, cirrhotic BM-MSCs showed significant decrease in both baseline glycolysis ($p < 0.001$) (fig 1b) and glycolytic reserve ($p < 0.001$). In NGS data, though cirrhotic BM MSCs showed increased expression of Glycolytic genes they showed significant decrease in glucose uptake ($p < 0.001$) (fig 1c). Further analysis of oxidative phosphorylation showed significant decrease in baseline respiration, ATP production and spare respiratory reserve capacity in cirrhotic BM-MSCs in comparison to control (fig 1d). Cirrhotic BM-MSCs also showed decreased expression of genes associated with oxidative phosphorylation (fig 1a) and showed significant increase in mitochondrial ROS ($p < 0.01$) in comparison to control (fig 1e), suggesting compromised oxidative phosphorylation and mitochondrial dysfunction in cirrhotic BM-MSCs.
Conclusion: Cirrhotic BM-MSCs have impaired metabolic profile characterized by compromised glycolysis and oxidative phosphorylation due to insulin resistance. This might adversely affect their therapeutic potential and requires attention and modulation in ex-vivo cultures.

SAT-396

Heat activation of hepatocytes is sufficient to account for post radiofrequency ablation induced tumorigenesis

Aurelia Markezana[1], Muneeb Ahmed[2], elina zorde-khavlevsky[1], liao haixing[1], Svetlana Gourevich[1], Eithan Galun[1], S. Nahum Goldberg[1,2,3]. *[1]The Goldyne Savad Institute of Gene therapy, Hadassah Hebrew university hospital, Jerusalem, Israel; [2]Beth Israel Deaconess medical center, Radiology, Boston, United States; [3]Division of image-guided therapy and interventional oncology Hadassah Hebrew university hospital, Radiology, Jerusalem, Israel*
Email: aureliahakoune@gmail.com

Background and aims: Radiofrequency ablation (RFA) is an image-guided minimally invasive treatment commonly used to treat a wide range of focal primary and metastatic tumors in the liver, lung, kidney, bone, and other sites. Yet, RFA in some cases can also cause increased cancerous effects. Thus, RFA induced tumor progression remains a substantial barrier to clinical efficacy due to the poorly characterized mechanism of periablational and distant effects.
We have previously demonstrated in an in vivo rodent model that RFA of normal liver can induce growth of distant tumor. Moreover, following liver ablation an increased inflammatory response has been observed including cellular recruitment of neutrophils, macrophages, and activated myofibroblasts to the ablated zone. Additionally, several cytokines with potential pro-tumorigenic properties, including IL-6, HGF, STAT-3, and VEGF, are increased following RFA. These and additional factors may be expressed and secreted either by liver parenchymal or non-parenchymal cells. Yet, the main mechanistic pathway that drives RFA's pro-oncogenic effects has yet to be fully elucidated. Therefore, our purpose is to determine the role of the heat damaged hepatocytes in this process.
Method: In order to identify mechanisms of tumor recurrence and progression post RFA, we established an in vitro model to determine which parenchymal and recruited/non-parenchymal cells within the periablational zone activate pro-tumorigenic pathways post RFA.
Results: Our results demonstrate that primary hepatocytes subjected to moderate hyperthermia induce accelerated cell growth of several cancer cell lines (R3230 rat mammary adenocarcinoma, CT26 and MC38 mouse colorectal cancer, BNL.CL2 mouse hepatoma) that can be reduced by the c-Met inhibitor, PHA. Protein microarray of heated hepatocytes medium indicated secretion of proteins implicated pathways involved in tumor progression and immune system activation including multiple members of the fibroblast growth factors family, VEGFC, and CSF-1. Significant upregulation in mRNA expression of HSP70, IL-6, STAT3 and HGF were detected in the heated hepatocytes.
Conclusion: These results may indicate that heat damaged hepatocytes in the ablated zone by themselves can induce proliferation of tumor by releasing pro-tumorigenic factors post RFA. Elucidation of these pathways may allow us to uncover methods to eliminate these unwanted secondary effects of an otherwise robust clinical therapy.

SAT-397

HIC-5 and GARP expression is upregulated by hydrogen peroxide and TGF beta in primary human hepatic stellate cells cultured on decellularized human liver 3D ECM scaffolds

Simona Onali[1], Elisabetta Caon[1], Kessarin Thanapirom[1], Martina Marrali[2], Maria Giovanna Vilia[1], Luca Frenguelli[1], Walid Al-Akkad[1], Giuseppe Mazza[1], Massimo Pinzani[1], Krista Rombouts[1]. *[1]University College London, Institute for Liver and Digestive Health, London, United Kingdom; [2]Engitix Limited, London, United Kingdom*
Email: simona.onali@yahoo.it

Background and aims: Transforming growth factor beta (TGFb) plays a crucial role in the activation of hepatic stellate cells (HSC). This study aims to investigate the expression of three TGFb1-modulated proteins, namely Hydrogen peroxide Inducible Clone-5 (HIC-5), NADPH oxidase 4 (NOX4) and Glycoprotein A Repetitions Predominant protein (GARP), in primary human HSC cultured in a novel 3D model based on decellularized healthy and cirrhotic human liver extracellular matrix (ECM) scaffolds.
Method: Decellularized human liver 3D scaffolds were repopulated with primary human HSC ($0.25*10^6$) for 10 days. HSC were exposed to H_2O_2 (10uM-100uM) and TGFb1 (5 ng/ml) for 24 h, w/wo pre-treatment of H_2O_2/TGFb1. HSC engraftment/proliferation was assessed histologically and by immunohistochemistry and viability was quantified by PrestoBlue. 2D and 3D experiments were

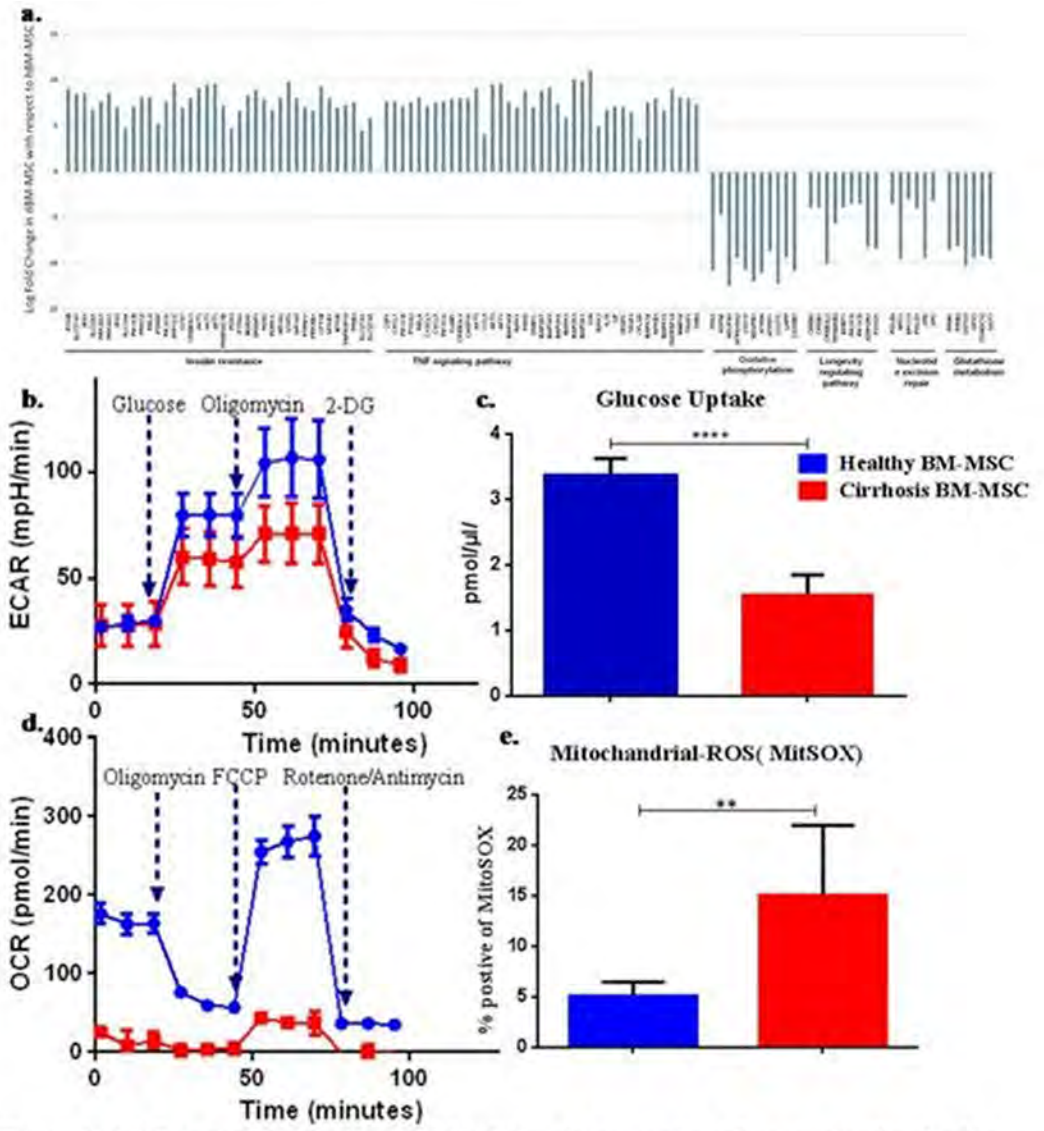


Figure 1: (a.) Bar graphs showing log fold change in expression of genes associated with Insulin Resistance, TNF signaling , Oxidative Phosphorylation , Longevity Regulating, Nucleotide Excision Repair and Glutathione Metabolism pathway in cirrhotic BM-MSCs with respect to healthy BM-MSCs. Figure: (abstract: SAT-395)

performed in parallel to compare pro-fibrogenic and pro-inflammatory gene expression as assessed by qPCR.

Results: Engraftment/proliferation in healthy 3D scaffolds were demonstrated histologically and with Ki67 and PDGFB-R IHC staining. Prestoblue assay showed that H_2O_2 did not affect HSC viability. HIC-5 mRNA expression in HSC cultured on healthy 3D scaffolds was induced upon exposure to H_2O_2 (50um and 100um). In contrast, H_2O_2 exposure did not affect the mRNA expression of NOX-4, GARP, TGFb1, TGFbR1. When comparing 3D with 2D cultures, HIC-5 mRNA expression was significantly upregulated in 3D indicating a specific 3D ECM-induced effect. Moreover, HIC-5 mRNA expression was further increased upon TGFb1 exposure in 3D in contrast to the corresponding 2D model. NOX4 and GARP were upregulated by TGFb1 in both models, however the effect of TGFb1 on gene expression was greater in HSC cultured in 3D compared to 2D. HSC in 3D healthy scaffolds pre-treated with TGFb1 and exposed to H_2O_2 induced significantly HIC-5, GARP and Col1a1 mRNA expression in comparison to simultaneous treatment with H_2O_2/TGFb1. This indicated a TGFb1 positive feedback as was shown by TGFb-R1 upregulation. NOX4 was not affected by pre-treatment with H_2O_2/

TGFb1. Experiments using HSC cultured in cirrhotic 3D scaffolds are ongoing.
Conclusion: Primary human HSC express differently HIC-5, NOX-4 and GARP when cultured in 3D ECM scaffolds derived from healthy human liver in comparison to 2D culture. Human tissue-specific 3D scaffolds offer a more realistic pathophysiological model to further define the specific role and modulation of the TGFb1 signalling pathway in hepatic fibrogenesis.

SAT-398

Pterostilbene reduces liver steatosis associated with obesity

Sara Palacios[1], Leixuri Aguirre[2], Elizabeth Hijona[3], Luis Bujanda[4], Saioa Gómez-Zorita[5], María P. Portillo[6]. [1]*Doisy Research Center. Saint Louis University, Biochemistry and Molecular Biology Department., St Luois (Missouri), United States;* [2]*Universidad del País Vasco. CIBEROBN, Nutrition and Food Sience, Vitoria-Gasteiz, Spain*
Email: mariapuy.portillo@ehu.eus

Background and aims: Excessive fat accumulation within the liver is known as simple hepatic steatosis, the most benign form of non-alcoholic fatty liver disease. Our aim was to determine whether pterostilbene, a phenolic compound belonging to the group of stilbenes, improves this hepatic alteration in a rodent model of genetic obesity.
Method: Zucker (*fa/fa*) rats were distributed in 2 experimental groups. Rats in the pterostilbene group were orally given this compound at a dose of 15 mg/kg/d through an orogastric catheter for 6 weeks. Histological liver analysis was carried out. Enzyme activities were assessed by spectrophotometry or fluorimetry, gene expression by RT-PCR and protein expression by western blot.
Results: Obese Zucker rats showed a grade 2 steatosis, according to Brunt scale, and pterostilbene partially reduced this to grade 1. No effects were observed in pterostilbene-treated rats in the activity of *de novo* lipogenesis enzymes. In contrast, an increase was observed in carnitine palmitoyltransferase 1a (CPT-1a) and microsomal triglyceride transfer protein (MTP) activities in PT group. Gene expression of the transporter *cd36* was decreased by pterostilbene and that of respiratory electron transport chain complex IV (*cox-2*) was increased. Pterostilbene administration did not modify protein expression of sterol regulatory element-binding protein-1 (SREBP-1c), but increased that of peroxisome proliferator-activated receptor α (PPARα) and mitochondrial transcription factor A (TFAM), and decreased that of diacylglycerol O-acyltransferase 2 (DGAT2).
Conclusion: Pterostilbene is a useful molecule to reduce liver steatosis. Its delipidating effect is due, at least in part, to reduced fatty acid availability and triacylglycerol synthesis, as well as increased very low density lipoprotein assembly and increased fatty acid oxidation.

SAT-399

The profile on intracellular gangliosides correlates with the malignant phenotype of cholangiocarcinoma cells and modulates cells adhesion

Chiara Raggi[1], Antonella Mannini[1], Margherita Correnti[2], Elisabetta Rovida[1], Jesper Andersen[3], Cedric Coulouarn[4], Fabio Marra[1]. [1]*University of Florence, Florence, Italy;* [2]*Humanitas, Rozzano, Italy;* [3]*Biotech Research and Innovation Centre (BRIC), University of Copenhagen, Copenhagen, Denmark;* [4]*Inserm, Inra, University Rennes, UMR 1241, Rennes, France*
Email: chiara.raggi@unifi.it

Background and aims: Identification of cancer stem cell (CSC) has opened the way to the design of innovative diagnostic and therapeutic strategies in neoplastic diseases. Gangliosides (GS) a family of sialic acid-containing glycosphingolipids, have been associated with malignant phenotype of several cancers (i.e. breast, melanoma, glioblastoma, ovary). In particular, GD2, a complex GS, has been proposed as a novel CSC-marker. Nonetheless, limited information is available for many tumor types including human cholangiocarcinoma (CCA). This study aims to obtain a GS profiling of human CCA stem-like subset and their parental cells.
Method: Stem-like compartment was enriched by sphere culture (SPH) in two lines of established human intrahepatic CCA cells (HUCCT1, CCLP1). CCA GS composition was performed by chromatographic analytical techniques and revealed by resorcinol-HCl reagent. GD2 detection as well as its co-expression with CD133 CSC-marker was carried out by FACS analysis. The role of the GM3 GS on cell adhesion was investigated using D-threo-1phenyl-2-palmitoylamino-3-N-morpholine-1-propanol (PPMP), a GM3 synthase inhibitor.
Results: In contrast to parental cells grown as adherent monolayers (MON), CCA-SPH showed strong expression of GD2. The time course of SPH-growth revealed a remarkable GD2 expression along with CD133 levels just few days after plating. Overall, CCA-SPH showed a GM1/GM2 reduction in parallel with an increase in GM. Notably, a cell-line specific GS profile was revealed. MON-CCA exhibited high levels of simple GS such as GM3 and GM2 in HUCCT1 and in CCLP1, respectively. Moreover, HUCCT1 showed a GM3-dependent adhesion capacity on fibronectin. Remarkably, since GM2 and GD2 biosynthesis is driven by the enzyme beta-1, 4 N-acetylgalactosaminyltransferase-1 (B4GALNT1) and GD3 by alpha-N-acetylneuraminide alpha-2, 8-sialyltransferase (ST8SIA1), mRNA expression of both enzymes were analyzed by transcriptomic data from surgically resected CCA samples. Both B4GALNT1 and ST8SIA1 were significantly increased in tumor samples compared to paired non-tumoral liver tissue. Strikingly, B4GALNT1 expression considerably correlated with recurrence, perineural invasion and presence of satellite nodules in CCA patients.
Conclusion: We show for the first time that the GS composition is modulated in the CCA stem-like subset. GD2 should be explored as a candidate biomarker for CCA. GS composition may affect pivotal characteristics of CCA cells such as adhesion.

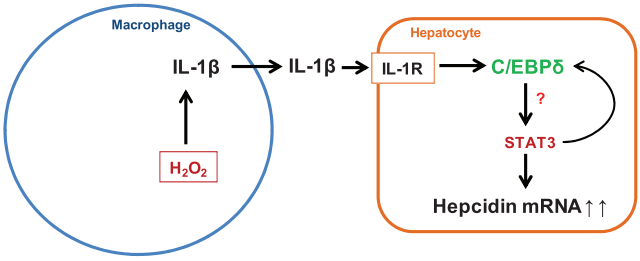
SAT-400

IL-1 beta-mediated macrophage-hepatocyte crosstalk upregulates hepcidin under physiologic low oxygen levels

Ines Silva[1], Teresa Peccerella[1], Gunda Millonig[1], Sebastian Mueller[1], Vanessa Rausch[1]. [1]*University of Heidelberg, Center for Alcohol Research and Salem Medical Center, Heidelberg, Germany*
Email: ines.silva@uni-heidelberg.de

Background and aims: Liver-secreted hepcidin is the systemic masterswitch of iron homeostasis and its dysregulation leads to iron accumulation in most of chronic liver diseases. Hepcidin is strongly upregulated by iron, inflammation or H_2O_2 but the role of monocyte-derived macrophages on hepcidin regulation under (patho)physiological conditions is poorly understood. We here investigate the cellular crosstalk involved in hepatic hepcidin regulation by using macrophage/hepatocytes co-cultures mimicking physiological cell ratios and oxygen levels.
Method: Huh7 cells and THP-1 monocytes differentiated into macrophages were co-cultured at different physiological cell ratios (10:1 or 4:1) under normoxia (21% O_2) or hypoxia (1 or 5% O_2). The exposure of Huh7 cells to macrophage-conditioned medium was also investigated. Hepcidin, IL-1β, IL-6 and C/EBPδ mRNA level were assessed by qRT-PCR and the expression of STAT3 and SMAD proteins was analyzed by western blot. A cytokine array identified several macrophage-secreted cytokines, however studied using IL-1 receptor antagonist evidenced the role of IL-1β. Signaling pathways involved in hepcidin regulation were studied by using truncated hepcidin promoter constructs and siRNA-mediated knockdown of STAT3 or C/EBPδ.

Results: We demonstrated that the presence of macrophages leads to significantly increased hepatic hepcidin mRNA levels. This effect was even potentiated when co-cultures were maintained under 1 or 5% O_2. Interestingly, hepcidin was also upregulated in Huh7 cells exposed to macrophage-conditioned medium under 1% O_2 suggesting the role of a secreted factor in mediating hepatic hepcidin induction. Western Blot analysis, as well as studies with truncated hepcidin promoter constructs suggested the involvement of the STAT3 but not BMP signaling pathway. Among all the secreted cytokines analyzed, IL-1β was identified as important mediator of macrophage-induced hepcidin upregulation and found to act independent of IL-6. Moreover, we demonstrate an involvement of C/EBPδ in mediating IL-1β-STAT3 signaling with subsequent hepcidin induction.



Conclusion: Our findings underscore the importance of the hepatocyte/macrophage crosstalk for hepatic hepcidin regulation including IL-1β as macrophage-released cytokine, which is rapidly expressed during acute or chronic liver injury. We highlight the induction of hepcidin by IL-1β via STAT3, independent of IL-6-mediated signaling, which may result in hepatic iron accumulation in chronic liver disease.

SAT-401

Necroptosis signaling molecules regulate hepatic stellate cell activation via MLKL oligomerization-cell death independent pathway

Joo Hyun Sohn[1], Dae Won JUN[2], Jinhwa Park[2], Bo-Kyeong Kang[3], Mi Mi Kim[3], Jaeyoon Jeong[1], Hyunwoo Oh[4], Hyo Young Lee[5], Sang Bong Ahn[6], Yong Kyun Cho[7], Dong Hee Koh[8]. *[1]Hanyang University School of Medicine Guri, Internal Medicine, Guri, Korea, Rep. of South; [2]Hanyang University School of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [3]Hanyang University School of Medicine, Radiology, Seoul, Korea, Rep. of South; [4]Medical corp, 7th division, Republic of Korea army, Hwacheon, Korea, Rep. of South; [5]Seoul National University College of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [6]Eulji University School of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [7]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [8]Hallym University College of Medicine, Internal Medicine, Hwaseong, Korea, Rep. of South*
Email: noshin@hanyang.ac.kr

Background and aims: Necroptosis, a type of regulated cell death, is dependent on kinase activities of receptor interacting proteins (RIPs). We evaluated the role of necroptosis in hepatic stellate cells regulation via cell death independent pathway, and as well as its potential for target in hepatic fibrosis.
Method: Up-regulation of mixed lineage kinase domain like pseudokinase (MLKL) was evaluated in In-vitro liver fibrosis model. Morphology of stellate cells activation were analyzed by immunofluorescence and TEM. Necroptosis molecules and MLKL oligomerization was confirmed by immuno-blotting.
Results: Necroptosis stimulation with TNF-α and zVAD treatment on stellate cells caused stellate cell activation, and fibrosis markers including α-SMA, collagen1 and TIMP1 were significantly increased after necroptosis stimuli. Contrary, MLKL inhibitor (necrosulfonamide) reduced stellate cells activation markers including α-SMA, vimentin, and collagen1α. However, necroptosis stimulation or overexpression of MLKL did not lead to cell survival and number of stellate cells unexpectedly. MLKL phosphorylation, oligomerization, and cell membrane rupture of stellate cell did not observe after necroptosis stimulation. Our results show that the hepatic stellate cells did not form necrosome in the necrosome formation stage, unlike other cells (ex. hepatocyte). Instead, necroptosis stimulation regulated ICAM-1, VCAM-1, and chemokine C-X-C motif ligand-1/2 expression in hepatic stellate cell.
Conclusion: Necroptosis pathway activates hepatic stellate cell. But MLKL oligomerization and necroptotic cell death did not develop in stellate cell. Necroptosis stimulation seems to be differently act on stellate cell via oligomerization-cell death independent pathway.

SAT-402

Hepamine 2.0: Visualization and data-mining resource for liver disease

Timo Itzel[2], Matthias Evert[3], Andreas Teufel[1]. *[1]University Hospital Mannheim, Division of Hepatology, Department of Internal Medicine II, Mannheim, Germany; [2]University Hospital Mannheim, Division of Clinical Bioinformatics, Department of Internal Medicine II, Mannheim, Germany; [3]University of Regensburg, Department of Pathology, Regensburg, Germany*
Email: Timo.Itzel@medma.uni-heidelberg.de

Background and aims: Throughout the past two decades, numerous gene expression profiling data on literally all liver diseases were generated and stored in public databases. These data are thought to contain deep insights into the molecular development of liver diseases, support the development of molecular diagnostics and ultimately promote precision medicine in hepatology. However, once published the majority of these data remain idle. Only very few data were used for additional analyses or comparative projects by the hepatology research community. This may mostly be due to the limited bioinformatics knowledge on how to obtain and analyze the stored raw data by most biomedical research personnel. In order to overcome this barrier and to support an easy translation of bioinformatics data into translational hepatology research, we created Hepamine, a liver disease microarray database, visualization platform and data-mining resource.
Method: Microarray data were obtained from the ArrayExpress Archive of Functional Genomics Data (http://www.ebi.ac.uk/arrayexpress). Pre-analysis of expression data was performed using R statistical software and microarray analysis packages from the Bioconductor repository (https://www.bioconductor.org). Expression data were stored locally in a MySQL database.
Results: We have generated Hepamine, a web-based repository of pre-analyzed microarray data for various liver diseases. Among these are HCC, CCC, liver fibrosis/cirrhosis, chronic hepatitis, autoimmune liver disease, fatty liver disease and many more. Further development was influenced by optimization the access and visualization of the data. By restructuring the frontend, the data access is know more comfortable. Filtering and visualization of the data are know configure able separately. Genes may be searched on the basis of specific expression patterns across diverse samples. We also provide predefined gen sets to select pathways from KEGG and wikipathways. Results are furthermore visualized in simple three color tables indicating up-, down-, or no differential expression in multiple experiments. To enlarge the scope of the Hepamine, all data were linked to common functional and genetic databases, in particular offering information on the respective gene, signaling pathway analysis and evaluation of biological functions by means of gene ontologies.
Conclusion: Hepamine provides comprehensive data and easy access to various hepatologic gene expression data. It will open this widely unused resource particularly to hepatologists without bioinformatics or microarray profiling experience and substantially facilitate the translation of these data to molecular hepatology research. Hepamine is accessible at: http://www.hepamine.de.

SAT-403

Polycyclic aromatic hydrocarbons can trigger a hepatocyte release of cytotoxic extracellular vesicles

Nettie van Meteren[1], Martine Chevanne[1], Isabelle Gallais[1], Fabienne Gauffre[2], Soizic Chevance[2], Agnès Burel[3], Dominique Lagadic-Gossmann[1], Eric Le Ferrec[1], Odile Sergent[1]. *[1]Univ Rennes, Inserm, EHESP, Irset (Institut de recherche en santé, environnement et travail)-UMR_S 1085, Rennes, France; [2]Univ Rennes, CNRS, ISCR (Institut des Sciences Chimiques de Rennes)-UMR 6226, Rennes, France; [3]Univ Rennes, Plate-forme MRic-TEM, Biosit-UMS3480, Rennes, France*
Email: nettie.vanmeteren@univ-rennes1.fr

Background and aims: Extracellular vesicles (EVs), membrane enclosed nanostructures released by cells into the extracellular environment, have been described as mediators in several pathogenic processes including liver diseases. In regards to xenobiotic liver injury, EVs emerge as potential actors of DILI (Drug Induced Liver Injury), but nothing is known concerning TAFLD (Toxicant-Associated Fatty Liver Disease) and TASH (Toxicant-Associated SteatoHepatitis) progression. Therefore the aim of this work was to study the impact of polycyclic aromatic hydrocarbons (PAHs) on hepatocyte-derived EV production with a special attention to hepatocyte death, as a key characteristic of TASH. PAHs are major environmental pollutants formed during incomplete combustion of organic materials and can be found in cigarette smoke and contaminated food, the main exposure in non-smokers.
Method: WIF-B9 and primary rat hepatocytes were treated by three different PAHs at a concentration of 100 nM : benzo (a)pyrene (BP), dibenzo (a, h)anthracene (DBA) or pyrene (PYR). They were selected based upon their various affinities for the AhR (Aryl hydrocarbon Receptor) and their various concentrations in common food. Then, EVs were isolated from extracellular medium by differential ultracentrifugation.
Results: PAHs were able to increase the release of EVs and to induce apoptosis of both types of hepatocytes. EVs released were mainly composed of exosomes. EV production, as well as cell death, involved oxidative stress, CYP metabolism and activation of cytosolic transcription factors such as AhR (Aryl hydrocarbon Receptor) or CAR (Constitutive Androstane Receptor), depending on the PAH type. Moreover, PAHs changed exosome protein marker expression in WIF-B9 hepatocytes. In addition, changes in membrane fluidity of EVs occurred with all tested PAHs, but bulk cellular membrane fluidization was only involved in BP- or DBA-induced EV release and cell death. PAHs modified also cholesterol levels both in cells and EVs, but only the cholesterol depletion due to BP or DBA was implicated in EV release and cell death. Finally, EVs released by PAH-treated hepatocytes were internalized by untreated hepatocytes causing cell death.
Conclusion: PAHs caused release of exosomes by hepatocytes in the extracellular environment that could participate in the process of hepatocyte death.

SAT-404

Discordant NS5a but not NS3 RASs profile in liver and plasma compartments of HIV/HCV genotype 1a/4d infected patients

Riccardo Vercesi[1,2], Giulia Morsica[1], Hamid Hasson[1], Emanuela Messina[1], Adriano Lazzarin[1], Caterina Uberti-Foppa[1,3], Sabrina Bagaglio[1]. *[1]IRCCS, Ospedale San Raffaele, Division of Infectious Diseases, Milan, Italy; [2]Università degli Studi di Milano, Bicocca, Dept. of Biotechnology, Milan, Italy; [3]University Vita-Salute, Milan, Italy*
Email: morsica.giulia@hsr.it

Background and aims: Naturally occurring resistance-associated substitutions (RASs) in the NS3 and NS5a DAAs target regions may be present in liver, the major site of HCV replication, irrespective of un detectability in plasma compartment. This finding may have implication for the response to treatment with direct acting antivirals (DAAs). We evaluated the RAS profile of NS3 and NS5a in liver and plasma of HIV/HCV coinfected patients (pts) harboring genotype (GT) 1a/4d.
Method: Twenty-one HIV/HCV coinfected pts naïve to anti-HCV treatment who performed liver biopsy for diagnostic purposes were included in the study. Fourteen pts harbored HCV GT1a and 7 pts harbored GT4d. Median age was 41 years (inter quartile-range, IQR 38-43); 14 were males and 7 females; median alanine amino transferase (ALT) and aspartate amino transferase (AST) values were 66 IU/L (IQR 41-200, normal values < 59 IU/L), 65 IU/L, (IQR 49-137, normal values < 35 IU/L), respectively. CD4 cells count was 486 (IQR 443-614) HCV-RNA load was 5.6 Log IU/ml (IQR 5.5-6). The study was conducted in accordance with ethical principles stated in the Declaration of Helsinki and the patients gave written informed consent. NS3 and NS5a RASs profile was investigated by viral population sequencing in liver tissues and plasma, according to Lontok, 2015, Sarrazin, 2016 and Carrasco, 2018.
Results: RASs in the NS3 were detected in 9/21 (43%) coupled liver tissues and plasma samples. NS3 mutated strains in GT1a exhibited Q80 K in plasma and liver. In GT4d infected pts, NS3 protease region resulted conserved in plasma and liver. The analysis of the NS5a domain showed RASs in 10/21 (47.6%) liver tissues and 6/21 (28.5%) corresponding plasma samples; in GT1a, 3/14 sequences from liver had RASs [M28R/Q30P/L31R in 1 pt, Q30R/L31R in one other pt, H58E in the remaining pt] while RASs were not revealed in the corresponding plasma. Interestingly, in GT4d 7/7 (100%) liver tissues and 6/7 plasma samples (85.7%) showed the amino acid substitution T58P at site of resistance.
Conclusion: We detected a different profile of RASs in the compartments explored concerning the NS3 and NS5a target regions. So, in particular for GT1a the liver compartment could be responsible for the emergence of resistant variant not detected in the corresponding plasma sample by viral population analysis. This finding may have implication especially for GT1a patients with virological failure and absence of RASs in plasma sample at re-treatment.

SAT-405

Genomic expression in circulating PBMCs of patients with hepatocellular carcinoma: Effect of ablative treatment

Palmieri Vincenzo[1], annamaria gesualdo[1], Marica Cariello[2], Antonio Moschetta[2], Francesca Passerini[1], Fabiana D'Onofrio[1], Enrica Settimo[1], Lucia Donatella Grimaldi[1], Piero Portincasa[1]. *[1]Clinica Medica "A. Murri", Biomedical sciences and Human Oncology, Bari, Italy; [2]Interdisciplinary Department of Medicine of University of Bari, Bari, Italy*
Email: v.o.palmieri@gmail.com

Background and aims: Genomic profiling of HCC has a significant clinical and prognostic role and novel correlations with clinical features, therapeutic response, survival and follow-up are expected. The aims of the work are: to find out the role of the analysis of gene expression profile of PBMCs as a surrogate approach for the assessment of local HCC-infiltrating mononuclear inflammatory cells and its main clinical features; To find out whether ablative treatment of HCC may affect the genomic expression in circulating PBMCs.
Methods: 30 patients affected by HCC, classified on the basis of Child Class and staged by BCLC criteria; all of them underwent to ablative treatment (radiofrequency 16, chemoembolization 14); the effect of treatment has been evaluated by mRECIST criteria. Blood samples have been collected at time 0, before treatment, and at time 1 (three months after the ablative procedure). RNA profiling: microarray expression profiling on PBMCs has been performed in order to identify upregulation and down-regulation of specific gene expression pathways at the basis of the phenotypic identity card of the individualized patient. Experiments have been performed on high-throughput iSCAN illumina facility using the HumanHT-12 v3 Expression BeadChip Kit; PCR Quantitative Real Time (RT-qPCR);

RTqPCR primers were designed using Primer Express software (Applied Biosystems, Foster City, CA).
Results: The genomic evaluation by microarrays analysis on circulating PBMCs has been completed on all subjects (11 with complete response, CR; 12 with partiale response, PR; 7 stable or progression disease, SD, PD).
After preliminary microarrays analysis, the RTqPCR identified the following significant ($p < .05$) variations of genes expression in the comparison between time 0 and time 1 (data are expressed as relative mRNA, M+SEM):
Down-regulated genes: KLF9 in all (0.96+0.07 vs 0.74+0.04) and RP (1.27+0.21 vs 0.78+0.04); in RC subjects CCDC88C (1.07+0.04 vs 0.87+0.01), CORO7 (0.99+0.01 vs 0.22+0.04), LTBR4 (1.54+0.31 vs 0.35 +0.13), PREX1 (1.11+0.06 vs 0.72+0.07);
Up-regulated genes: in RC subjects: EAF2 (0.91+0.10 vs 1.59+0.07).
Furthermore, in the comparison RC vs RP at time 0, ENTPD1 (0.91 +0.08 vs 1.31+0.07) and ICOS (2.11+0.55 vs 0.92+0.16) resulted different.
Conclusions: Finding of down and up-regulation of genes in circulating PBMCs in HCC patients after ablative procedure represents a novel result with possible diagnostic and prognostic implications.

SAT-406

Elevated biliary cholesterol in spite of hepatic ABCG5/G8 deficiency: Biliary lipid secretion in conditional knock-out mice

Friederike Poppenborg[1], Caroline Bopp[1], Annika Nicklas[1], Frank Lammert[1], Susanne N Weber[1]. [1]*Saarland University Medical Center, Department of Medicine II, Homburg, Germany*
Email: susanne.weber@uks.eu

Background and aims: Gallstone disease is one of the most common gastrointestinal diseases worldwide. It results from biliary cholesterol supersaturation, which is the necessary condition for the nucleation of cholesterol crystals that grow into mature gallstones. Cholesterol is transported across the hepatocanalicular membrane in an ATP-dependent, regulated manner by the heterodimer ABCG5/G8. Besides its function in the liver, *Abcg5/g8* is also expressed in enterozytes, where it transports plant sterols and cholesterol back into the intestinal lumen. The aim of this study was to analyze the biliary lipid composition when the transporter is inactivated selectively in the liver but not the intestine.
Method: Using BAC-based recombineering, we have generated conditional *Abcg5/g8* knock-out mice that allow tissue-specific deletion of the first 2 exons of *Abcg5* and the first exon of *Abcg8*, respectively, by cre-mediated recombination. *Abcg5/g8* flox mice were crossed to albumin-cre mice expressing cre in the liver under the control of the albumin promoter (*Abcg5/g8*-Hep-KO). Hepatic bile was obtained after cannulation of the common bile duct, and bile flow and biliary lipid secretion rates were measured during the first hour of the acute bile fistula. In addition, expression analyses of cholesterol metabolism regulating genes were performed.
Results: All animals developed normal, were fertile and showed no gross abnormalities. Total biliary lipids in hepatic bile were significantly reduced in the knock-out mice compared to wild-type controls (1.1 ± 1.0 g/dl vs. 1.5 ± 1.0 g/dL), and the cholesterol saturation index (CSI) was significantly elevated (2.3 ± 0.3 vs. 0.9 ± 0.1). Analysing bile consumption during the first hour of the acute bile fistula, we demonstrated that bile acid output was significantly decreased (66.95 ± 6.8 vs. 124.6 ± 18.7 µmol/hr/kg), while both cholesterol and phospholipids were elevated (10.26 ± 1.2 vs. 4.8 ± 0.8 µmol/hr/kg and 33.1 ± 4.6 vs. 27.7 ± 3.7 µmol/hr/kg, respectively). Expression of *Abcg5* and *Abcg8* was not detectable in the liver but unaffected in the intestine. The alternative cholesterol transporter *Abcg1*, which is expressed in endothelial cells, macrophages and monocytes, was significantly induced.
Conclusion: Our results show that the liver-specific deletion of *Abcg5/g8* does not protect against gallstone formation, rather it leads to supersaturation of cholesterol in bile and a markedly increased CSI in the conditional knock-out mice. These changes occur in the setting of decreased bile acid and total lipids, all of which increase gallstone susceptibility. Further studies need to determine the mechanistic changes of biliary lipid secretion at the level of the hepatocanalicular membrane as well as adaptive responses.

SAT-407

The Wilson's disease mouse (Atp7b-/-) has profound alterations in the hepatic metabolome and improved insulin sensitivity

Ruth Wooton-Kee[1], Alli Nuotio-Antar[2], David Moore[1]. [1]*Baylor College of Medicine, Molecular and Cellular Biology, Houston, United States;* [2]*Baylor College of Medicine, Pediatrics-Nutrition, Houston,*
Email: wootenke@bcm.edu

Background and aims: Inactivating mutations in the copper transporter Atp7b result in Wilson's disease (WD). The *Atp7b*$^{-/-}$ mouse develops hallmarks of WD, including elevated hepatic copper accumulation preceding pathology, high urinary copper excretion, and development of necrosis, inflammation, steatosis, and bile duct proliferation. We previously reported that hepatic metabolic nuclear receptor activity is disrupted in *Atp7b*$^{-/-}$ mice and WD patients, suggesting an unexpected mechanism for WD pathology. Hepatic nuclear receptors, in particular FXR and PPARα, are critical for maintaining metabolic homeostasis, and activity of these nuclear receptors is decreased in the Atp7b$^{-/-}$ mice. Therefore, we hypothesized that decreased nuclear receptor activity in *Atp7b*$^{-/-}$ mice correlates with altered glucose and lipid homeostasis.
Methods: Following 10 weeks on either a chow or Western diet (40% kcal fat), body and liver weights, lean and fat mass, glucose sensitivity (glucose tolerance testing), insulin sensitivity (insulin tolerance testing), and gluconeogenesis (pyruvate tolerance testing) were assessed in *Atp7b*$^{-/-}$ mice and wild-type (WT) littermate controls. Hyperinsulinemic-Euglycemic clamp was also performed to further assess insulin sensitivity. Hepatic glycolytic, TCA, and amino acid metabolites were measured by LC-MS. Microarray analysis was performed with GeneChip Mouse 430 2.0 (Affymetrix), and gene mRNA expression was measured by real-time PCR.
Results: Body, liver, and lean mass were not different between WT and *Atp7b*$^{-/-}$ mice on chow diet, whereas, fat mass was 50% less in *Atp7b*$^{-/-}$ mice on chow diet. Unlike WT mice, *Atp7b*$^{-/-}$ mice did not exhibit Western diet induced increases in body, liver, or fat mass. *Atp7b*$^{-/-}$ mice showed decreased gluconeogenesis and had improved insulin sensitivity on chow or Western diet compared with WT mice. Hepatic glucose, pyruvate, and lactate levels were decreased in *Atp7b*$^{-/-}$ mice; however, the glycolytic intermediates glucose-6 phosphate, 3 phosphate-glycerate, and phosphoenolpyruvate were significantly increased. TCA metabolites citrate, fumarate, malate, and oxaloacetate were increased, whereas α-ketoglutarate was decreased. Interestingly, concentrations of asparagine, proline, methionine, and glutamic acid were increased; however, glutamine concentration was decreased in *Atp7b*$^{-/-}$ mice. Metabolite-gene associated changes were identified from the microarray analysis, indicating an association between changes in gene expression and metabolite enrichment.
Conclusions: *Atp7b*$^{-/-}$ mice exhibited changes in glucose and insulin sensitivity that accompanied complementary alterations in hepatic metabolites and metabolic gene expression. Taken together, these significant metabolic changes are likely due to copper-mediated dysfunctional nuclear receptor activity in *Atp7b*$^{-/-}$ mice.

Non-invasive assessment of liver disease except NAFLD

SAT-409

Hepatic vein arrival time assessed by contrast-enhanced ultrasound in the non-invasive evaluation of portal hypertension

Irene Andaluz[1], Marta Abadía[1], Dolores Ponce[2], María Luisa Montes[3], Teresa Hernández[2], Consuelo Froilán[1], Miriam Romero[1], Araceli García[1], Joaquín Poza[1], Joan Novo[2], Lucía Fernández[2], Pilar Castillo[1], Javier García-Samaniego[1,4], José Carlos Erdozaín[1], Pedro Mora[1], Antonio Olveira[1]. *[1]Hospital Universitario La Paz, Gastroenterology Department, Madrid, Spain; [2]Hospital Universitario La Paz, Interventional Radiology, Madrid, Spain; [3]Hospital Universitario La Paz, Internal Medicine. HIV Unity., Madrid, Spain; [4]Instituto de Salud Carlos III, CIBERehd, Madrid, Spain*
Email: irene.an.gar@gmail.com

Background and aims: There is a growing interest in the non-invasive assessment of hepatic venous pressure gradient (HVPG) due to its invasiveness and limited accessibility. Transient elastography (TE) is the most used technique, with good results determining clinically significant portal hypertension (CSPH: HVPG ≥ 10 mmHg), nevertheless it yields worse results with higher HVPG cut-offs (> 12 mmHg: bleeding risk portal hypertension [BRPH]). Intrahepatic shunts developed in cirrhosis with portal hypertension leads to hemodynamic changes that correlate with disease severity, and are worse assessed by TE. Measurement by other techniques, such hepatic vein arrival time (HVAT), could be clinically useful.
Method: Prospective, single-center study. Inclusion criteria: liver cirrhosis, clinical need for HVPG measurement. Exclusion criteria: portal vein thrombosis, prehepatic hypertension, cardiopathy. On the same day, and prior to the HVPG, TE and ultrasound measurement (Toshiba Aplio 500, Japan) of HVAT from the cubital vein was performed (10% increase in hepatic vein signal compared to baseline after injection of contrast [Sonovue®, Bracco, Italy]). Beta-blocked patients had their medication withdrawn five days before testing. The reliability of HVAT and TE in the prediction of CSPH and BRPH was evaluated by determining the areas under receiver operating characteristic curves (AUROC) and the percentage of correctly classified patients.
Results: 56 patients were included. 6 were excluded from analysis of HVAT because of poor echo window and 10 of TE due to invalid results (89% vs 82% applicability) In the 50 patients with HVAT (medians): 61 years, 70% male, BMI 26.6 kg/m^2, Child-Pugh A/B/C 70/28/2%, MELD 10, 87% varices, 14% ascites. Linear correlation (Pearson) of HPVG with HVAT: –0.55 (p < 0.001).
The AUROC of CSPH by TE was 0.86 (95%CI: 0.72–1; p = 0.008) with optimal cut-off (OC) of 15.2 kPa (Se 91.4%, Sp 80%, PPV 97%, NPV 57%) and by HVAT was 0.94 (95%CI: 0.85–1; p = 0.001) with OC of 17 seconds (Se 93%, Sp 66%, PPV 95%, NPV 57%). The AUROC of BRPH by TE was 0.74 (95%CI 0.58–0.89; p = 0.013) with OC of 22 kPa (Se 65.4%, Sp 71.4%, PPV 81%, NPV 52.6%) and by HVAT was 0.8 (95%CI 0.67–0.93; p = 0.001) with OC of 14 seconds (Se 82%, Sp 62%, PPV 82%, NPV 62%). For HVPG ≥ 12 mmHg, TE correctly classified 67.5%, HVAT 76% and sequential use (HVAT > TE) 85% of patients.
Conclusion: HVAT assessed by contrast-enhanced ultrasound is an excellent non-invasive method to evaluate the existence of CSPH, and superior to TE in the assessment of BRPH.

SAT-410

Higher spleen iron content estimated by MRI T2* signal is associated with lower insulin-resistance in patients with dysmetabolic iron overload syndrome

Rayer Cassandra[1], Paisant Anita[2], Morcet Jeff[1], Gandon Yves[1], Deugnier Yves[1], Laine Fabrice[1], Edouard Bardou-Jacquet[1]. *[1]CHU Rennes, Rennes, France; [2]CHU Anger, Angers, France*
Email: rayer.cassandra@gmail.com

Background and aims: Dysmetabolic Iron Overload (DIOS) is the most common cause of liver iron overload. It is defined as moderately increased hepatic and body iron stores with at least one feature of the metabolic syndrome without other cause of iron overload. The significance of a predominant parenchymal or mesenchymal distribution of iron overload in this context is discussed. Abdominal T2* MRI is the gold standard to quantify Liver Iron Content (LIC). It also allows estimation of Splenic Iron Content (SIC) which may provide insight on iron overload distribution. The goal of this study is to evaluate the clinical relevance of SIC estimated by MRI in patients with DIOS.
Method: MRI of patients with DIOS included in our center in a prospective randomized trial evaluating the benefit of bloodletting (Laine Hepatology 2017), were reviewed to estimate SIC at inclusion. Patients with diabetes were excluded. SIC was estimated by T2* MRI similarly to LIC (d'Assignies Eur Radiol 2018), and T2* signal converted in µmol/g to ease understanding. Clinical and biological data were collected in the prospective study. Association between LIC and SIC was assessed by Spearman correlation. Factors associated with SIC were studied by univariate and multivariate analysis, with SIC divided in two classes according to median value.
Results: 101 patients were included. Mean age was 56.6 (± 9.5) years, 87% were men, and mean BMI was 27.7 (± 2.7). Mean serum ferritin (Frt) was 813 (± 290)µg/L, mean LIC 88.9 (± 42.5) µmol/g and mean SIC 57.2 (± 42.7)µmol/g. The mean HOMA index was 2.1 (± 1.3).
In univariate analysis SIC was correlated to LIC (r = 0.33, p < 0.001), transferrin saturation (TSat) (r = -0.18, p = 0.08), and mean corpuscular volume (MCV) (r = -0.32, p < 0.01). SIC ≥ 50µmol/g was associated to higher LIC (p = 0.01), higher alkaline phosphatases (ALP) (p = 0.04), lower fasting insulin (p = 0.04), lower HOMA index (p = 0.05), and high blood pressure (HBP) (p = 0.04).
In Multivariate analysis SIC ≥ 50µmol/g was associated to LIC ≥ 100µmol/g (OR = 7.0; IC:2.0–24.8), HOMA ≥ 2.4 (OR = 0.20; IC:0.06–0.60), HBP (OR = 3.1; IC:1.0–9.0), ALP > 70UI/L (OR = 4.8; IC:1.6-13.8), Frt > 650 µg/L (OR = 3.2; IC:1.0-9.7), TSat ≥ 35% (OR = 0.32; IC:0.11-0.95), and MCV ≥ 95fL (OR = 0.19; IC:0.06-0.63)
Conclusion: In patients with DIOS spleen iron content estimated by T2* MRI may identify patients with lower insulin resistance, suggesting differential toxicity of iron overload depending on its localization. The relevance of SIC to the clinical management of these patients should be further investigated.

SAT-411

Clinical comparison and conversion of international normalized ratio and prothrombin index

Paul Cales[1], Marie Tuffigo[2], Frédéric Oberti[1], Virginie Planche[3], Jerome Boursier[1], Isabelle Fouchard Hubert[1], Lannes Adrien[1], Alban Godon[2], Christophe Corpechot[4,5], Valérie Ugo[2]. *[1]University Hospital, Hepatology, Angers, France; [2]University Hospital, Blood biology laboratory, Angers, France; [3]Hôpitaux Universitaires Est Parisien (AP-HP), Blood biology laboratory, Paris, France; [4]Saint-Antoine Hospital, Assistance Publique-Hôpitaux de Paris, Hepatology Department, Reference Center for Inflammatory Biliary Diseases and Autoimmune Hepatitis, Paris, France; [5]Sorbonne University, INSERM UMR_S938, Paris, France*
Email: paul.cales@univ-angers.fr

Background and aims: Coagulation tests are often used in hepatology. The main test is Quick time (QT) expressed as INR or prothrombin index (PI, % vs normal). Our first aim was to compare the

clinical performance of PI and INR. Our second aim was to develop a direct conversion between INR and PI since intermediate variables (QT or ISI) are often unavailable.
Method: Evaluation was performed in three steps detailed in results.
Results: ***First step***: clinical comparison. In a 1st study, we evaluated the accuracy for Metavir F staging by liver biopsy in 949 patients with chronic liver disease (CLD) of various etiologies. PI was superior to INR in 12 out 13 judgement criteria. For example, the mean values between F2 vs F1 were significantly different for PI (p = 0.001) and not for INR (p = 0.110). In a 2nd study, we evaluated the prognosis for survival in 2387 patients with CLD of various etiologies (follow-up: 9.9 ± 5.9 years). PI was more predictive (Harrell C-index: 0.727) than INR (0.726). Then, we evaluated AUROC for large esophageal varices (EV) in 487 patients: PI: 0.704, INR: 0.695. The reproducibility, tested by intra-class correlation coefficient (ICCC), between 17 laboratories in 20 CLD was, PI: 0.92, INR: 0.83. Thus, in almost all comparisons, PI was superior to INR. Finally, INR and PI interacted for the diagnosis of fibrosis or EV. The PI/INR ratio solved this interaction and increased the accuracy for fibrosis or EV. ***Second step***: conversion. In a 1st study performed in 29.690 patients with various pathologies, we developed 2 mathematical formula of conversion between PI and INR. We provide the results for the conversion from INR to PI that includes 8 terms. ICCC was 0.9998 between measured PI (mPI) and estimated PI (ePI) by INR. The formula was validated in other 6185 patients with various pathologies and different ISI (ICCC: 0.9995) or in 1674 patients with CLD (ICCC: 0.9942) or in 1574 patients with various pathologies from another center with different ISI and 4 analyzers (ICCC: 0.9933). ***Third step***: clinical validation of conversion formula. This was evaluated with accuracy of a fibrosis test (FibroMeter V2G) in the 1st population with 949 CLD. AUROCs of FibroMeters were, respectively calculated with mPI and ePI for F ≥ 2: 0.8168 vs 0.8169, for F ≥ 3: 0.8277 vs 0.8271, for F = 4: 0.8751 vs 0.8753.
Conclusion: PI is superior to INR in terms of liver fibrosis or EV diagnosis, prognosis and reproducibility in CLD. The PI/INR ratio is useful by increasing accuracy. Conversion formula between PI and INR (freely available on a calculator) provide excellent accuracy.

SAT-412

The utility of the enhanced liver fibrosis test in alcoholic liver disease

Declan Connoley[1,2,3], Preya Patel[2,3], Brian Hogan[2], Sudeep Tanwar[2], Freya Rhodes[2,3], Julie Parkes[4], William Sievert[1,5], William Rosenberg[2,3]. *[1]Monash University, Clayton, Australia; [2]University College London, Institute for Liver and Digestive Health, London, United Kingdom; [3]Royal Free Hospital NHS Foundation Trust, Hepatology, London, United Kingdom; [4]University of Southampton, Southampton, United Kingdom; [5]Monash Health Australia, Melbourne, Australia*
Email: w.rosenberg@ucl.ac.uk

Background and aims: Alcohol is the main cause of chronic liver disease (CLD) in the UK, the third commonest cause of death in 18-65 year-olds. Liver fibrosis severity correlates with prognosis. The Enhanced Liver Fibrosis (ELF) test is a serological biomarker able to stratify fibrosis severity in CLD, however its utility in alcoholic liver disease (ALD) warrants further validation. We assessed the diagnostic and prognostic performance of ELF in ALD.
Method: Paired ELF tests and liver biopsies from 786 patients were assessed. Results were compared between ALD (n = 81) and non-ALD aetiologies (n = 705). Prognostic data were available for 70 ALD patients for a median of 5.9 years. ELF cut-offs of < 8.3, ≧9.8, ≧10.5 and ≧11.3 were assessed and area under receiver operator characteristic (AUROC) curves used to determine diagnostic utility in histologically staged moderate fibrosis (Ishak F≧3) and cirrhosis (F≧5). Survival data were assessed using Cox Proportionate Hazard Ratios (HR) adjusted for age, sex and treatment centre; and logistic regressions adjusted for age and sex.
Results: Median age in the ALD cohort was 50. Biopsies staged as; F0: 5, F1: 7, F2: 6, F3: 4, F4: 5, F5: 10, F6: 44. ELF identified cirrhosis and moderate fibrosis in ALD independently of inflammation, AUROCs = 0.895 and 0.923 respectively, and was non-inferior to non-ALD aetiologies (Figure 1A and B). The overall diagnostic accuracy of ELF was assessed using the Obuchowski Method: AUROC in ALD = 0.934; non-ALD = 0.907. Using ELF < 9.8 to exclude and ≧10.5 to diagnose cirrhosis, 87.7% of ALD cases could have avoided biopsy, with a sensitivity of 91% and specificity of 85%. A unit increase in ELF was associated with a 2.6 times greater risk of a liver related event (LRE) at 6 years. ELF ≧11.3 was associated with a Cox HR of 8.6 for LREs compared to ELF < 9.8.
Conclusion: ELF accurately stratifies liver fibrosis in ALD independently of inflammation. Its use may improve detection of alcoholic cirrhosis in primary and secondary care. Prognostically, ELF performs as well as biopsy in ALD with performance similar to that observed in other aetiologies of CLD.

SAT-413

Selected cytokines associated with chronic hepatitis b histological activity and fibrosis: A 78-week prospective study

Xiao-Qin Dong[1], yongqiong Deng[1], Jiyuan Zhou[1], Linlin Yan[1], Zhao Wu[1], liang miao[1], Wanna Yang[1], Tiantian Yao[1], Hong Zhao[1], Gui-Qiang Wang[1]. *[1]Peking university first hospital, Infectious disease, Beijing, China*
Email: john131212@126.com

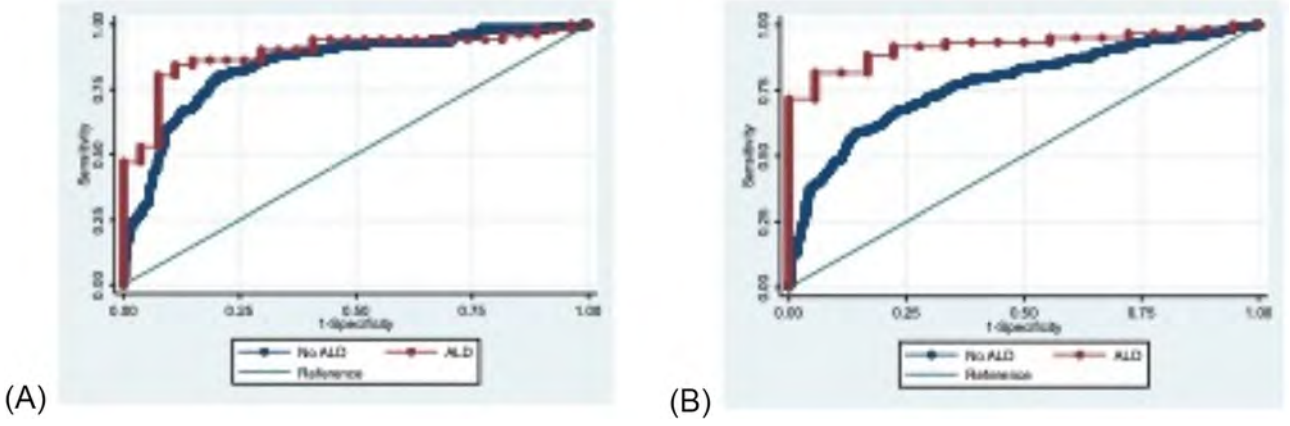


Figure 1: (abstract:SAT-412): AUROC for ALD (red) and non-ALD (blue) for (A) cirrhosis and (B) moderate fibrosis. AUROC for cirrhosis was 0.895 (95% CI: 0.823-0.968) in ALD and 0.846 (95% CI: 0.807-0.885) in non-ALD aetiologies (p = 0.307). AUROC for moderate fibrosis was 0.775 (95% CI: 0.739-0.811) in non-ALD and 0.919 (95% CI: 0.859-0.980) in ALD (p < 0.001).

Background and aims: Previous studies of small cohorts have revealed that several circulating cytokines are involved in the progression of chronic hepatitis B (CHB). And little reliable data is available about these cytokines for liver fibrosis monitoring in CHB patients on antiviral therapy. We aimed to investigate associations between circulating cytokines and liver histopathological activity and fibrosis in a large cohort, and explore the performance of selected cytokines in monitoring liver histopathology change following 78-week antiviral treatment in CHB patients.

Method: Based on Ishak system, we prospectively assessed liver biopsies from 734 CHB patients and serially in 233 patients before and after 78-week enticavir-based treatment. Circulating cytokines were measured by Luminex screening system. Univariate and multivariate analyses were conducted to analyse data. The detailed clinical trial protocol has been registered (NCT01962155 and ChiCTR-DDT-13003724).

Results: Before treatment, anti-hepatitis B virus core antibody (anti-HBc) ($p = 0.000$), Collagen IV alpha 1 (COL4A1) ($p = 0.028$), Hyaluronic Acid (HA) ($p = 0.040$), Interferon- gama -inducible T-cell alpha chemoattractant (I-TAC) ($p = 0.004$) and Angiopoietin-like protein 2 (Angptl2) ($p = 0.049$) were independently associated with at least moderate inflammation (Histology activity index ≥ 5), and Interferon-gama-inducible protein-10 (IP-10) ($p = 0.000$), COL4A1 ($p = 0.033$), HA ($p = 0.004$), Laminin (LN) ($p = 0.006$), and Angptl2 ($p = 0.011$) independently correlated with significant fibrosis (Ishak fibrosis score ≥ 3). After 78-week antiviral therapy, the decline of COL4A1, HA, IP-10 and LN were much greater in patients with inflammation improvement, and greater decline of HA, IP-10 and LN in patients with histological improvement was also observed (Figure). Further analysis found that change in COL4A1, HA, I-TAC, Angptl2, IP-10 and LN were correlated with change in liver histological necro-inflammatory activity, but not with the change in liver fibrosis after 78-week antiviral therapy.

Conclusion: Anti-HBc and I-TAC were independently associated with at least moderate inflammation, COL4A1, HA and Angptl2 were independent markers of at least moderate inflammation and significant fibrosis, whereas IP-10 and LN were independent indicators of significant fibrosis. Changes in these selected cytokines, which could be related to change in liver inflammation, were unreliable to reflect fibrosis change after 78-week antiviral treatment.

Email: horia.stefanescu@irgh.ro

Background and aims: Baveno VI criteria state that high risk esophageal varices (HRV) can be safely ruled-out if liver stiffness (LS) by transient elastography (TE) is < 20 kPa and platelets count (PLT) is > 150×10^3. However, TE's applicability is limited in some patients. Realtime shear-wave elastography (2D-SWE) is a novel ultrasound-based technique that estimates LS. Our group recently demonstrated the good performance of 2D-SWE from General Electric (2D-SWE.GE) to estimate clinically significant portal hypertension: for a cut-off 11.3 kPa, the diagnostic accuracy is > 80% for HVPG ≥ 10 mmHg.
The aim of this study was to test and validate the performance of LS estimated by 2D-SWE.GE to predict the presence of HRV, alone or in association with PLT.
Method: In this bicentric study, all consecutive cirrhotic patients due to various etiologies were enrolled in a training (center 1) and a validation set (center 2). All patients underwent in the same day LS assessment by both TE and 2D-SWE.GE and usual lab test, including PLT. All patients also had endoscopy within 6 months from inclusion for assessment of variceal status (HRV-grade II and III varices, or grade I with red signs or Child-Pugh C cirrhosis).
Results: In the training set [n = 103; median age = 56 (20-74) years; 41.7% prevalence of HRV] LS was feasible by TE in 97/103, while by 2D-SWE.GE in all patients. Mean LS values by 2D-SWE.GE were higher in patients with HRV (16.79 vs. 13.15 kPa, p = 0.008). AUC for the prediction of HRV was 0.76 (95%CI:0.65-0.86) for TE and 0.65 (95% CI:0.53-0.76) for 2D-SWE.GE, (deLong test p = ns) and the proportion of correctly classified patients was 57/93 (61.3%) and 58/98 (59.2%), respectively. The best cut-off for 2D-SWE.GE-LSM was again 11.3 kPa, with 0.8 Se and 0.45 Sp. By using together 2D-SWE.GE-LS < 11.3 kPa and PLT > 150×10^3, the missed HRV rate is 5% (1/18) and the spared endoscopies rate is 29.3% (17/58). The classic Baveno VI criteria, however, showed a higher rate of missed HRV (1/14, 7%) and lower rate of spared endoscopies (13/56, 23%).
In the validation set [n = 82; median age = 60 (38-75) years; 25.6% HRV prevalence] the AUC of 2D-SWE.GE-LS for predicting HRV was 0.68 (95%CI: 0.55-0.81) vs. 0.73 (95%CI: 0.61-0.85) for TE-LS, deLong test p = ns. The combination between 2D-SWE.GE-LS < 11.3 kPa and PLT > 150×10^3 had a 0% (0/12) missed HRV rate and 19.7% (12/61) spared endoscopy rate. The original Baveno VI criteria had similar performance: 0/15 missed HRV rate and 15/61 (24.5%) spared endoscopies rate.
Conclusion: LS by 2D-SWE.GE can predict the presence of HRV in patients with cirrhosis. The best cut-off (which also predicts CSPH) has modest diagnostic accuracy, but used in conjunction with PLT, in a Baveno VI approach, leads to better performance, low missed HRV rates and good proportion of spared endoscopies. Therefore, 2D-SWE.GE is a good and alternative for TE for LS assessment in patients with advanced liver diseases.

SAT-415
High levels of basement membrane remodelling (C4M) and low activity of wound healing (FPA) reflect fibrosis in alcoholic liver disease

Natasja Gudmann[1], Maja Thiele[2,3], Mette Juul Nielsen[1], Bjørn Stæhr Madsen[2,3], Sönke Detlefsen[4], Linda S. Moeller[2,3], Maria Kjærgaard[2,3], Diana Leeming[1], Morten Karsdal[1], Aleksander Krag[2,3]. *[1]Nordic Bioscience, Biomarkers and Research A/S, 2730 Herlev, Denmark; [2]Odense University Hospital, Department of Gastroenterology and Hepatology, 5000 Odense C, Denmark; [3]Odense University Hospital, OPEN, Odense Patient Data Exploratory Network, 5000 Odense C, Denmark; [4]Odense University Hospital, Department of Pathology, 5000 Odense C, Denmark*
Email: nsg@nordicbio.com

Background and aims: Alcoholic liver disease (ALD) is characterized by a long symptom free phase which is difficult to diagnose. If undetected, development of liver fibrosis may lead to liver-related complications and mortality. Thus, there is a need for non-invasive diagnostics to evaluate dynamics of liver fibrosis and progression at an early stage of disease. One approach may be assessment of neo-epitopes released from extracellular matrix or wound healing. We assessed whether fibrosis stage was associated with serological levels of fibrinopeptide a (FPA), a peptide fragment released when fibrinogen is converted to fibrin, together with C4M, a marker of MMP mediated type IV collagen degradation of the basement membrane.
Method: In this study 302 asymptomatic, compensated ALD patients were recruited prospectively. FPA and C4M were measured in serum by competitive ELISAs. We used liver biopsy as reference, with central scoring of fibrosis (Kleiner stage F0-4) and non-alcoholic fatty liver disease (NAFLD) Activity Score: ballooning 0-2, lobular inflammation 0-3 and steatosis 0-3. The association between C4M or FPA and clinical, demographic and liver histologic data was evaluated by Mann Whitney test, Kruskal Wallis tests and Receiver operating characteristics (ROC) analysis.
Results: C4M levels were 35% higher in patients with hepatocyte ballooning scores of 2 compared to 0 ($p < 0.001$), 36% higher in patients with lobular inflammation score 3 compared to 0-1 ($p = 0.004$) and 16% higher in patients with portal inflammation than in those without ($p = 0.003$). In contrast, FPA was 36% lower in patients with hepatocyte ballooning score 2 compared to 0 ($p = 0.001$), 34% lower in patients with a lobular inflammation score 3 compared to 0 ($p < 0.001$) and 22% lower in patients with portal inflammation than in those without ($p = 0.003$). C4M concentrations were 45% higher and FPA levels were 38% lower in patients with a fibrosis score 4-5 compared to 0-1 (both $p < 0.0001$). ROC analyses revealed that C4M was able to discriminate between F0-1and F3-4 with an AUC of 0.69, for FPA the AUC was 0.71 whereas C4M and FPA combined improved the AUC to 0.80.
Conclusion: The present findings suggest that degradation of basement membrane in the presence of decreased wound healing capacity is highly associated with fibrosis stage, inflammation and ballooning in early stage alcoholic steatohepatitis. Basement membrane damage in the absence of relevant wound heling may lead to increased fibrogenesis.

SAT-416
Transient elastography in normal pregnancies: A prospective cohort study

Marcus Stenberg Ribeiro[1], Per Stal[1], Hannes Hagström[1], Gunilla Ajne[1]. *[1]Karolinska Institutet, Stockholm, Sweden*
Email: hannes.hagstrom@ki.se

Background and aims: Transient elastography is a valuable tool to detect liver fibrosis by estimation of liver stiffness. Results can be falsely high when blood flow to the liver is increased. A normal material of transient elastography results during a normal pregnancy, when blood flow from the abdomen is high in late stages is currently not available.
Method: We recruited 28 women with normal singleton pregnancies in a prospective cohort study. Women with an abnormal elastography result (> 7.9 kPa), signs of liver disease prior to conception or a BMI > 25 kg/m^2 at the first trimester were excluded. All women underwent transient elastography during the first, second and third trimester, and additionally three months postpartum. There were complete and reliable data from all four visits on 24 women on liver stiffness, this group was used as the analytical sample.
Results: Mean age at baseline was 30.6 years (SD 4.1), and mean BMI was 22.3 kg/m^2 (SD 1.9). 14 women (58%) were nulliparous. All

women underwent a normal pregnancy without signs of preeclampsia or gestational diabetes. Mean gestational length was 284 days (SD 7.1). Mean liver stiffness increased from 3.8 kPa during the first trimester to 5.9 kPa during the third trimester (p = 0.002). At the third trimester, 2 women (8%) had an elastography measurement of > 7.9 kPa. At the final examination, results were normalized (5.9 to 3.8 kPa, p = 0.002), with no woman with more than 7.9 kPa at elastography (Figure 1). Likewise, mean CAP increased from 186 dB/m in the first trimester to 215 dB/m in the third trimester (p = 0.01) and then fell postpartum (215 to 193 dB/m, p = 0.03). All pregnancies ended with normal results.

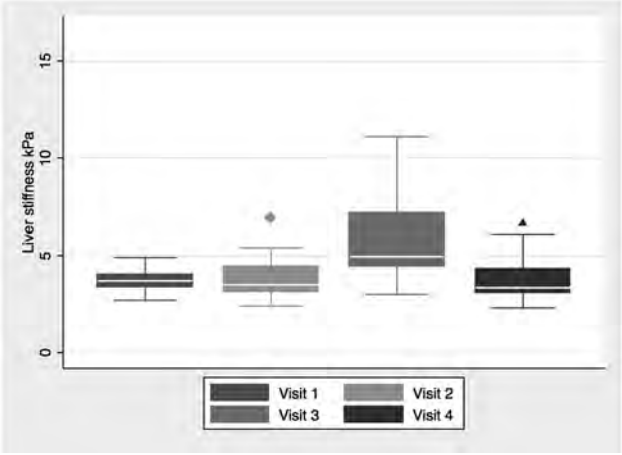

Figure 1. Results from transient elastography measurements in 24 normal pregnancies.

Conclusion: Transient elastography can be pathologic during the third trimester in normal pregnancies but slightly elevated levels can be considered a normal finding.

SAT-417

Serum levels of keratin 19 fragments (CYFRA 21-1) are elevated in advanced liver disease and predict poor survival

Karim Hamesch [1], Nurdan Gueldiken[1], Aly Mahmoud[1,2], Norbert Hueser[3], Daniel Hartmann[3], Christian Trautwein[1], Sebastian Mueller[4], Pierre Rufat[5], Pierre Nahon[6], Marianne Ziol[7], Tony Bruns[8], Pavel Strnad[1]. *[1]University Hospital RWTH Aachen, Medical Clinic III, Gastroenterology, Metabolic diseases and Intensive Care, Aachen, Germany; [2]Faculty of Veterinary Medicine, University of Sadat City, Department of Medicine and Infectious Diseases, Sadat City, Egypt; [3]Technical University of Munich, School of Medicine, Department of Surgery, Munich, Germany; [4]University of Heidelberg, Salem Medical Center and Center for Alcohol Research, Heidelberg, Germany; [5]Hopital Jean Verdier, Biostatistics, Bondy, France; [6]Hopital Jean Verdier, Service d'Hépatologie, Bondy, France; [7]Université Paris 13, Sorbonne Paris Cité, UFR SMBH, Bobigny, France; [8]Jena University Hospital, Department of Internal Medicine IV, Jena,*
Email: khamesch@ukaachen.de

Background and aims: Keratins (Ks) are tissue-specifically expressed proteins. Among them, K18 is produced in hepatocytes while K19, the most widely used ductular reaction (DR) marker, is found in cholangiocytes and progenitor cells of the liver. While the K18-based serum fragments M30/M65 are commonly used liver disease predictors, K19 fragments as detected via CYFRA 21-1 (fragments of cytokeratin 19) are established tumor markers but their usefulness in liver disease remains unknown. Therefore, we systematically evaluated K19 in different liver disease settings.
Method: Hepatic expression of DR markers was analyzed in liver biopsies of 63 patients with chronic liver disease. Serum CYFRA 21-1 levels were measured in: (i) 52 German alcohol misusers prior and after detoxification therapy, (ii) 280 German patients with decompensated cirrhosis, (iii) 231 French patients with alcoholic cirrhosis.
Results: Hepatic K19 levels were comparable in F0-F3 (no/intermediate fibrosis stages), but significantly increased in F4 (cirrhosis). Hepatic K19 mRNA correlated strongly with expression levels of other DR-specific keratins (i.e. K7/K23). In active alcohol misusers, CYFRA 21-1 levels were increased in patients with higher liver stiffness (i.e. LSM ≥ 15 kPa; a surrogate of advanced liver disease) compared to patients with LSM < 15 kPa (3.71 (2.20-4.53) vs. 1.42 (0.23-2.33) ng/ml, p = .002). Similar CYFRA 21-1 levels were seen before and after alcohol detoxification therapy (median duration 7 days). The strong correlation between both values (r = .744, p <.0001) indicated that CYFRA 21-1 constitutes a rather stable parameter. In patients with decompensated cirrhosis, serum CYFRA 21-1 predicted 90-day transplant-free survival (HR = 2.97 [1.92-4.60], p <.0001) and its diagnostic accuracy was comparable to the composite scores MELD and ACLF (AUROC 0.64, 0.70 and 0.68, respectively). CYFRA 21-1's usefulness was confirmed in patients with alcoholic cirrhosis, where elevated serum CYFRA 21-1 prognosticated liver-related death (HR = 2.59 [1.64-4.09], p <.001) and HCC occurrence (HR = 1.74 [1.02-296], p = .039).
Conclusion: Hepatic K19 and serum CYFRA 21-1 levels rise in cirrhotics. In the latter, increased CYFRA 21-1 levels associate with a poor prognosis. Hence, CYFRA 21-1 constitutes a novel, DR-related prognostic marker in advanced liver disease.

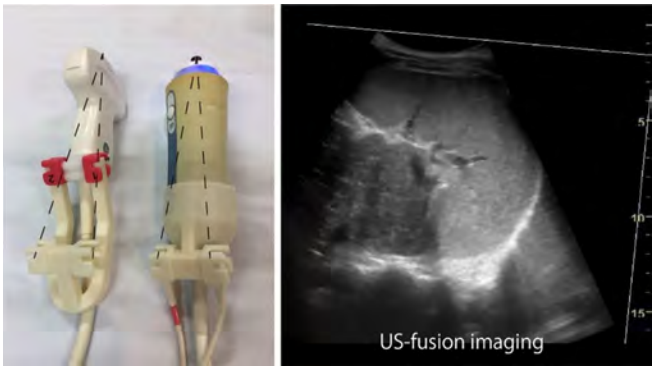
SAT-418

Splenic stiffness measurement using the ultrasound-fusion method

Masashi Hirooka[1], Yohei Koizumi[1], Takaaki Tanaka[1], Kotaro Sunago[1], Atsushi Yukimoto[1], Yusuke Imai[1], Takao Watanabe[1], Osamu Yoshida[1], Masanori Abe[1], Yoichi Hiasa[1]. *[1]Ehime University Graduate School of Medicine, Gastroenterology and Metabology, Touon, Japan*
Email: masashih@m.ehime-u.ac.jp

Background and aims: Recently, it has been recognized that spleen stiffness measurement can be used to stratify the degree of portal hypertension and rule out high-risk varices. However, performing spleen stiffness measurement adequately by transient elastography with A- and M-mode images is difficult. Thus, we developed a new method of transient elastography with B-mode images. We aimed to assess the diagnostic performance of spleen stiffness measurement using our method.
Method: We enrolled 60 patients (mean age, 66.9 ± 10.8 years; male: female, 42:18) and 18 healthy volunteers without hepatic venous pressure gradient measurements in this study and performed transient elastography and esophagogastroduodenoscopy. The hepatic venous pressure gradient was measured in patients with chronic liver disease. To perform transient elastography with virtual B-mode images using the ultrasound-fusion method, new attachments printed on a 3D-printer were used (shown as picture). Using these attachments, the distance between the top of the convex probe and the position sensors was made equivalent to the distance between the top of the transient elastography probe and sensors. First, the 3D-ultrasound volume was determined by scanning the spleen in a manual sweeping manner, using the convex probe with the new attachment and sensor, in the magnetic field. Second, the sensors were replaced with the transient elastography probe's attachment, and transient elastography was performed. The diagnostic accuracy in the presence and absence of the attachments was assessed.
Results: The median volume of the spleen was 170 ml (range 70-1727ml). The median success rates of transient elastography were 76.9% with the new attachment and 55.6% without the new attachment (p < 0.001). Especially in patients without splenomegaly (< 100 ml), the median success rates of transient elastography were 76.9% and 35.0% with and without the new attachment, respectively (p < 0.001). Correlation coefficients for spleen stiffness measurement

and hepatic venous pressure gradient were better with (r = 0.72, p = 0.007) than without (r = 0.62, p = 0.014) the new attachment. To predict ERV, the area under the receiver operator characteristic curve was 0.921 and 0.858 with and without the new attachment, respectively (p = 0.043). The positive likelihood ratios were 5.4% and 3.4% with and without the new attachment, respectively. Cut-off values of spleen stiffness measurement were 53.3 and 45.0 kPa with and without new attachment, respectively.



Conclusion: In conclusion, the spleen stiffness could be measured easily by virtual B-mode imaging using the new attachment. Moreover, the potential for ERV detection improved.

SAT-419

Endotrophin, a fragment of collagen type VI formation (PRO-C6) is associated with progression free survival and mortality in patients with hepatocellular carcinoma

Signe Holm Nielsen[1,2], Raj Uchila[3], Mohammed Eslam[3], Mette Juul Nielsen[1], Diana Leeming[1], Roslyn Vongsuvanh[3], David Van Der Poorten[3], Morten Karsdal[1], Jacob George[3]. *[1]Nordic Bioscience, Fibrosis Biology and Biomarkers, Herlev, Denmark; [2]Technical University of Denmark, Biomedicine and Biotechnology, Kgs. Lyngby, Denmark; [3]Westmead Hospital, Department of Gastroenterology and Hepatology, Westmead, Australia*
Email: shn@nordicbio.com

Background and aims: Hepatic fibrosis develops in response to chronic injury and is characterized by excessive accumulation of extracellular matrix (ECM) proteins. Injury may lead to cirrhosis and progress further to hepatocellular carcinoma (HCC). Small fragments of ECM proteins, known as neo-epitopes are generated during liver injury and released into the circulation. Collagen type VI (COL6) is known to be over-expressed in progressive fibrosis and cancer. PRO-C6 is a COL6 fragment which reflects formation of COL6 and was recently proposed to be a pro-fibrotic signaling molecule, endotrophin, that induces fibrosis directly through fibroblasts. We investigated PRO-C6 as a diagnostic and prognostic biomarker of HCC.
Method: PRO-C6 was measured in plasma from 86 biopsy-proven HCC patients, age and sex-matched cirrhotic (n = 86), non-cirrhotic HBV (n = 86) patients, and healthy controls (n = 86). Demographic data, liver parameters and AFP were gathered. The HCC patients were followed for up to 17-years after diagnosis. Progression free survival (PFS) were defined as time from diagnosis to objective tumour progression or death. Associations between PRO-C6 levels for progression and mortality in HCC patients was assessed by Kaplan-Meier and Cox Regression analysis.
Results: PRO-C6 was able to separate healthy controls, non-cirrhotics and cirrhotics from HCC patients (p < 0.0001, p < 0.0001 and p = 0.007 respectively). Within a 17-year follow-up period, seventy-five (75%) of 82 patients experienced disease progression. PRO-C6 levels above the median was significantly associated with PFS time (p = 0.011), whereas AFP was borderline significant (p = 0.051). PRO-C6 was included in the final model for prediction of whether the patient had an event (HR [95% CI]; 1.06 [1.01-1.11], p = 0.020). Both PRO-C6 and AFP were significantly associated with overall survival (p = 0.003 and p = 0.006, respectively), and both were included in the final model for prediction of mortality (PRO-C6: HR [95% CI]; 1.08 [1.02-1.13], p = 0.007; AFP: HR [95% CI]; 1.00 [1.00-1.00], p = 0.017).
Conclusion: The novel biomarker PRO-C6 was shown to be a marker of disease severity in patients with hepatic fibrosis and HCC. PRO-C6 was independently associated with progression and overall survival, superior to AFP. The role of PRO-C6 and its potential as a prognostic biomarker for HCC should be further investigated, as well as the role of Endotrophin in hepatic fibrosis progression and conversion into HCC.

SAT-420

The value of liver stiffness to platelet ratio and liver stiffness to spleen diameter to platelet ratio score compared with hepatic venous pressure gradient to predict the portal hypertension in patients with alcoholic and viral cirrhosis

Se Ri Ryu[1], Seong Hee Kang[2], Jeong-Ju Yoo[3], Soung Won Jeong[1], Moon Young Kim[2], Sang Gyune Kim[3], Jae Young Jang[1], Young Seok Kim[3], Soon Koo Baik[2], Yong Jae Kim[1], Su Yeon Park[1]. *[1]Soonchunhyang University Seoul Hospital, Seoul, Korea, Rep. of South; [2]Yonsei University Wonju College of Medicine, Wonju, Korea, Rep. of South; [3]Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South*
Email: jeongsw@schmc.ac.kr

Background and aims: The hepatic venous pressure gradient (HVPG) well reflects portal hypertension but its measurement is relatively invasive. Transient elastography (TE) is a non-invasive method for evaluating liver stiffness (LS), but the readings are higher in those with alcoholic than viral liver cirrhosis, rendering it difficult to predict the HVPG.. Here, we explored whether the HVPG could be deduced from the LS to platelet ratio (LPR) and the LS to spleen diameter-to platelet ratio score (LSPS) in patients with alcoholic and viral liver cirrhosis.
Method: Between January 2008 and March 2017, 556 patients who underwent HVPG and TE were consecutively enrolled at three Korean tertiary medical centers. HVPG and TE were performed within 1-month intervals. The causes of liver cirrhosis, and the cutoffs of TE, the LPR, and the LSPS were analyzed for all patients.
Results: All non-invasive methods for evaluating LS afforded significantly lower sensitivities and specificities when the HVPG value was ≥ 16mmHg; this was also true of the LPR and LSPS. However, at HVPG values ≥ 6, ≥ 10, and > 12mmHg, the cutoffs facilitated estimation of HVPG values. Unlike what was found using TE, when the LPR and LSPS were used to calculate cutoffs, these were significant in patients with viral liver cirrhosis (for HVPG values ≥ 6, ≥ 10, and > 12 mmHg; all TE cutoffs were 18.0; but were 0.09, 0.32, and 0.40, respectively, for the LPR, and 1.04, 4.47, and 4.65 for the LSPS).
Conclusion: TE, LPR, and LSPS usefully predicted HVPG levels except when the HVPG was > 16 mmHg. HVPG estimation via the LPR and LSPS was useful for patients with either viral or alcoholic liver cirrhosis; this was not true of TE.

SAT-421

A novel score to select patients for treatment in chronic hepatitis B: Results from a large Ethiopian cohort

Asgeir Johannessen[1], Hanna Aberra[2], Hailemichael Desalegn[2], Bitsatab Mekasha[2], Emmanuel Gordien[3], Frédéric Le Gal[3], Athenaïs Gerber[3], Segolene Brichler[3], Kathrine Stene-Johansen[4], Nega Berhe[5]. *[1]Oslo University Hospital Ullevål, Centre for Imported and Tropical Diseases, Oslo, Norway; [2]St Paul Hospital Millennium Medical College, Addis Ababa, Ethiopia; [3]Centre National de Reference des Hepatites B, C et Delta, Bobigny, France; [4]Norwegian Institute of Public Health, Dept. of molecular biology, Oslo, Norway; [5]Addis Ababa University, Aklilu Lemma Institute of Pathobiology, Addis Ababa, Ethiopia*
Email: johannessen.asgeir@gmail.com

Background and aims: Modern treatment guidelines for chronic hepatitis B (CHB) require viral load measurement and liver fibrosis assessment to determine treatment eligibility, but such tools are rarely available in low- and middle-income countries. Recently, a simple score (TREAT-B), based on alanine aminotransferase (ALT) and hepatitis B e-antigen (HBeAg), was suggested as an alternative tool to determine treatment eligibility in resource-limited settings. The aim of the present study was to evaluate the diagnostic performance of TREAT-B in a large cohort of CHB patients in Ethiopia.
Method: Out of 1303 CHB patients enrolled at a public hospital in Addis Ababa, 964 treatment-naïve patients aged 18 years and older were included in this analysis. Patients with hepatitis C/D and HIV co-infections, hepatocellular carcinoma, pregnancy or decompensated cirrhosis were excluded. All patients underwent a standardized evaluation at recruitment, including blood tests and transient elastography (Fibroscan 402, Echosense, France). The most recent guidelines from the European Association for the Study of the Liver (EASL) was considered the "gold standard," using a Fibroscan result > 7.9 kPa to define significant fibrosis and > 9.9 kPa to define cirrhosis. The diagnostic accuracy of the TREAT-B score was estimated by calculating the area under the receiver operating characteristics curve (AUROC). A TREAT-B score of 2 and above (HBeAg positive and ALT ≥ 20 U/L, or HBeAg negative and ALT ≥ 40 U/L) was used as the treatment threshold.
Results: One-hundred-and-ninety-seven patients (20.4%) were eligible for treatment based on the EASL 2017 guidelines and 220 (22.8%) based on the TREAT-B score. The AUROC of the TREAT-B score was 0.72 (95% confidence interval 0.68-0.77), yielding a sensitivity, specificity, positive predictive value and negative predictive value of 52.8, 84.9, 47.3 and 87.5%, respectively. By applying a TREAT-B score of 3 and above to determine treatment eligibility, the specificity increased to 97.0% but at the cost of a reduced sensitivity at only 26.9%.

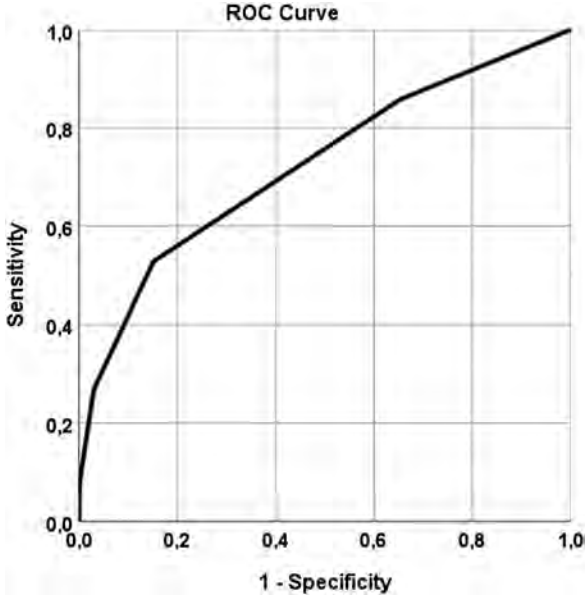


Figure: Receiver operating curve for TREAT-B to determine treatment eligibility in patients with chronic hepatitis B in Ethiopia

Conclusion: The performance of the TREAT-B score was only modest in a large CHB cohort in Ethiopia.

SAT-423

Spleen extracellular volume fraction and platelet count/spleen volume ratio are accurate non-invasive markers of portal hypertension

Christina Levick[1,2], Michael Pavlides[1,2], David J Breen[3], Kathryn Nash[3], Gideon Hirschfield[4], Dhiraj Tripathi[4], Matthew Robson[5], Stefan Neubauer[2], Eleanor Barnes[1,6]. *[1]University of Oxford, Translational Gastroenterology Unit, Oxford, United Kingdom; [2]University of Oxford, Oxford Centre for Clinical MRI Research, Oxford, United Kingdom; [3]University Hospitals Southampton NHS Foundation Trust, Southampton General Hospital, Southampton, United Kingdom; [4]University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Birmingham, United Kingdom; [5]Perspectum Diagnostics Ltd, Oxford, United Kingdom; [6]University of Oxford, Peter Medawar Department, Oxford, United Kingdom*
Email: christina.levick@gmail.com

Background and aims: Non-invasive markers of portal hypertension are needed. In portal hypertension, splenic venous congestion and fibrosis may increase splenic extracellular water content. Whilst a magnetic resonance imaging (MRI) measure of total spleen water content, spleen cT1, correlates with hepatic venous pressure gradient (HVPG, r = 0.68), specific measures of splenic extracellular water content have not been tested. This multicentre study explores markers of portal hypertension including splenic extracellular fluid volume fraction (ECV).
Method: Twenty healthy volunteers and 122 patients with cirrhosis of mixed aetiologies had spleen MRI with gadoxetic acid contrast and blood assessment. All patients with cirrhosis had endoscopy within median 31 days (IQR 12-93) of MRI. Portal hypertension was defined as the presence of varices, ascites or HVPG > 5 mmHg. MRI was analysed for spleen ECV, native T1, native cT1 and size. Spleen ECV was calculated as (1-haematocrit)*ΔR1spleen/ΔR1blood, where ΔR1 = 1/T1native-1/T1post gadoxetic acid. Diagnostic accuracy for portal hypertension was assessed by area under the receiver operator curve (AUROC).

Table 1: Diagnostic accuracy of non-invasive markers for the identification of portal hypertension in 122 patients with cirrhosis

	AUROC (95% CI)	p	Cut off	Sensitivity (%)	Specificity (%)
Candidate MR markers					
Spleen ECV	0.79 (0.71-0.87)	< 0.001	0.36	78	72
Native spleen T1 (ms)	0.71 (0.62-0.80)	< 0.001	1332	63	79
Native spleen cT1 (ms)	0.73 (0.63-0.82)	< 0.001	1274	73	73
Spleen volume (ml)	0.77 (0.69-0.86)	< 0.001	480	77	67
Platelet/spleen volume ($x10^9$/l/ml)	0.79 (0.71-0.87)	< 0.001	0.28	74	71
Platelets ($x10^9$/l)	0.73 (0.64-0.81)	< 0.001	117	55	84
Spleen diameter (mm)	0.74 (0.65-0.83)	< 0.001	152	58	82
Platelet/spleen diameter ($x10^9$/l/mm)	0.76 (0.68-0.85)	< 0.001	0.71	53	94

Abbreviations: AUROC, area under the receiver operator curve; ECV, extracellular volume fraction.

Results: Patients had median age 61 years, 78% were male and 65% had portal hypertension. Healthy volunteers had median age 56 years and 60% were male. Median spleen ECV was higher with portal hypertension (0.402 (IQR 0.364-0.457)) than without (0.343 (IQR 0.319-0.368), p < 0.001) in patients with cirrhosis, and similar between healthy subjects (0.338 (IQR 0.324-0.352)) and patients with cirrhosis without portal hypertension (p = 0.302). In patients

with cirrhosis, spleen ECV and platelet/spleen volume ratio identified portal hypertension with the highest accuracy (AUROC 0.79 each, table 1) of all measures tested.
Conclusion: Spleen ECV and platelet/spleen volume ratio can identify portal hypertension accurately and non-invasively.

SAT-424

Spleen transient elastography and suprahepatic vein dumping index can be useful to identify patients without acute and chronic response to beta-blockers

Elba Llop[1], Christie Perelló[2], Teresa Fontanilla[3], Juan De la Revilla[2], Marta Hernández Conde[2], Marta López-Gómez[2], Javier Minaya[3], Carlos Ferre[2], Javier Abad Guerra[2], José Luis Martínez Porras[2], Natalia Fernández Puga[2], Maria Trapero[2], José Luis Calleja Panero[2].
[1]Hospital Universitario Puerta de Hierro., Gastroenterology and Hepatology., Majadahonda, Spain; [2]Hospital Universitario Puerta de Hierro., Gastroenterology and Hepatology. IDIPHIM. CIBERHD., Majadahonda, Spain; [3]Hospital Universitario Puerta de Hierro., Radiology., Majadahonda, Spain
Email: elballop@gmail.com

Background and aims: Monitoring of acute (AR) or chronic (CR) response to beta-blockers in patients with liver cirrhosis is based on the measurement of the hepatic venous pressure gradient (HVPG). Our aim was to evaluate AR and CR to beta blockers with non-invasive techniques.
Method: Prospective observational study. Consecutive patients with indication of primary or secondary prophylaxis of variceal bleeding were included. Patients with multicentric hepatocellular carcinoma, complete portal vein thrombosis, active alcohol consumption or active viral hepatitis were excluded. AR (> or equal 10% decrease in HVPG after e.v. propranolol) and CR (> or equal 20% or GPVH < 12mmHg after 3 months of treatment) were evaluated. Baseline and after AR and CR hepatosplenic measurements of transient elastography (TE) and ARFI and Doppler ultrasound with contrast were obtained.

	Baseline measurements (n = 41)
HVPG (mmHg)	17 (6)
Righ atrial pressure (mmHg)	3.9 (2.6)
Inferior cava vein pressure (mmHg)	7.5 (3.5)
Free suprahepatic vein pressure (mmHg)	9.2 (4.7)
Wedge suprahepatic vein pressure (mmHg)	25.9 (6.6)
SBP/DBP (mmHg)	136.3/76.3 (24.5/12.5)
HR (bpm)	74.3 (9)
Liver TE (KPa)	38.3 (18.6)
Spleen TE (KPa)	65.0 (19.4)
Liver ARFI (m/s)	2.7 (0.7)
Spleen ARFI	3.3 (0.5)
Portal vein diameter (mm)	13.1 (2.6)
Portal vein speed (cm/s)	19.3 (5.3)
Hepatic artery speed (cm/s)	74.2 (40.0)
Resistance index	0.7 (0.2)
Suprahepatic contrast wash time (s)	21.6 (6.6)
Dumping index (> 0.6) (n;%)	16 (42.1%)

Results: From June 2015 to May 2018, 55 patients (14 with exclusion criteria) were included. We analyzed 41 patients, mean age 57 (SD8), 82.9% males, alcohol 43.9%, Child A/B/C 78%/17.1%/4.9% and 87.8% on primary prophylaxis. In all AR was performed and in 68.3% (CI 55%-85%) was positive. The CR was performed in 30 (73.2%) and was positive in 36.7% (CI18%-55%). The baseline measurements are shown in Table 1. Basal measurements related significantly with AR were: spleen TE (STE) (responders (R) 58.4 (SD 23.0) KPa vs non-responders (NR) 75 (SD0) KPa; p = 0.04) and suprahepatic vein dumping index (SHVDI) (> 0.6 greater flattening) (R30.8% vsNR63.6%, p = 0.06), and with CR, the STE (R58.1 (SD21.4) KPavsNR73.2 (SD5.5) KPa; p = 0.02) and SHVDI (R18.2% vs NR58.8%, p = 0.03). A STE > or equal to 74KPa showed 100% sensitivity and 60% specificity for AR, and 88% sensitivity and 70% specificity for CR (AUC 0.8 and 0.8). The SHVDI (> 0.6) showed an AUC of 0.7 in AR and 0.8 in CR. AR was not observed in 6 (66.7%) vs 3 (33.3), p = 0.01 patients with STE > or equal to 74KPa and SHVDI > 0.6. CR was not observed in 9 (100%) vs 0 (0%), p = 0.03 patients with STE > or equal to 74KPa and SHVDI > 0.6.
Conclusion: STE and SHVDI identify a subgroup of patients without AR or CR to beta-blockers.

SAT-425

Serum metabolites as diagnostic biomarkers for cholangiocarcinoma, hepatocellular carcinoma and primary sclerosing cholangitis

Email: rociorm@usal.es

Background and aims: Early and differential diagnosis of intrahepatic cholangiocarcinoma (iCCA) and hepatocellular carcinoma (HCC) by non-invasive methods represents a current clinical challenge. The analysis of low-molecular weight metabolites by new high-throughput techniques is a novel strategy for identifying biomarkers. Here, we have investigated whether serum metabolome can provide useful biomarkers in the diagnosis of iCCA and HCC and could discriminate iCCA from HCC. Since primary sclerosing cholangitis (PSC) is a risk factor for CCA, serum metabolomic profiles of PSC and CCA have also been compared.
Method: Chloroform/methanol and methanol extracts obtained from the serum of patients with PSC, iCCA, or HCC and healthy individuals were analyzed using ultra-performance liquid chromatography coupled to mass spectrometry (UHPLC-MS).
Results: The analysis of the levels of lipids and amino acids in the serum of patients with iCCA, HCC, PSC and healthy individuals (n = 20/group) showed differential profiles. Several metabolites presented high diagnostic value for iCCA vs control, HCC vs control, and PSC vs control, with areas under the receiver operating characteristic curve (AUC) greater than those found in serum for the non-specific tumor markers carbohydrate antigen 19-9 (CA19-9) and alpha-fetoprotein (AFP), commonly used to help in the diagnosis of iCCA and HCC, respectively. The development of an algorithm combining glycine, aspartic acid, SM (42:3) and SM (43:2) permitted to accurately differentiate in the diagnosis of both types of tumors (biopsy-proven). The proposed model yielded 0.890 AUC, 75% sensitivity and 90% specificity. Another algorithm by combination of PC (34:3) and histidine accurately permitted to differentiate PSC from iCCA, with an AUC of 0.990, 100% sensitivity and 70% specificity. These results were validated in independent cohorts of 14-15 patients per group and compared with profiles found in NAFLD/NASH patients.

Conclusion: Specific changes in serum concentrations of certain metabolites are useful to differentiate iCCA from HCC or PSC, and could help in the early diagnosis of these diseases.

SAT-426

Abnormal liver function tests: Current waiting times and comparison to iLFTs

Iain Macpherson[1], Matthew Priest[2], Ellie Dow[3], John F Dillon[4], Andrew Fraser[2]. [1]*NHS Forth Valley, Forth Valley Royal Hospital, Larbert, United Kingdom;* [2]*NHS Greater Glasgow and Clyde, Queen Elizabeth University Hospital, Glasgow, United Kingdom;* [3]*NHS Tayside, Ninewells Hospital and Medical School, Dundee, United Kingdom;* [4]*University of Dundee, Gut Group, Ninewells Hospital and Medical School, Dundee, United Kingdom*
Email: iain.macpherson3@nhs.net

Background and aims: At present patients referred to secondary care with abnormal LFTs are seen at a nurse-led pre-assessment clinic, where a serological liver screen and Fibroscan are performed. They are then discussed at a Multi-Disciplinary Team (MDT) meeting and discharged or appointed to a consultant-led clinic. "Intelligent Liver Function Tests" (iLFTs) provide a diagnostic pathway, stratifying referrals to primary or secondary care. If referrers provide data on alcohol intake, BMI and comorbidities, those with abnormal LFTs have reflex tests without further venepuncture or clinical interview. We aimed to identify how long the current process takes, and how iLFTs could impact this.
Method: A retrospective analysis of 135 cases discussed at MDT from February-August 2018 was performed. Time from abnormal LFTs to referral; and times from referral to completion of serological liver screen and discussion at MDT were recorded. The diagnosis recorded at MDT was compared to the diagnosis and outcome had iLFTs been used.
Results: 93 of the 135 patients were referred due to abnormal LFTs. Figure 1 shows the timescales involved. The median time from identifying deranged LFTs to referral was 15 days (range 1-32). The median time from referral to completion of liver screen was 83 days (range 0-264). The median time to MDT discussion was 95 days (range 23273).
6 patients did not attend pre-assessment. 3 (50%) did not require referral if the iLFT protocol was followed.
37 patients (39.9%) were discharged by the MDT. MDT diagnosis matched iLFTs diagnosis in 30 cases (81%). 23 patients (24.7%) would not have been referred if iLFTs were used.
50 patients were referred for review at a consultant clinic. In 41 cases (82%), the diagnosis proposed at MDT was the same if the GP had used iLFTs. Only 2 (2.1%) patients would not have been referred if iLFTs had been used: one diagnosed as NAFLD with low fibrosis risk, and one with NAFLD with F3 fibrosis whom iLFTs would have diagnosed as ARLD with low fibrosis risk.

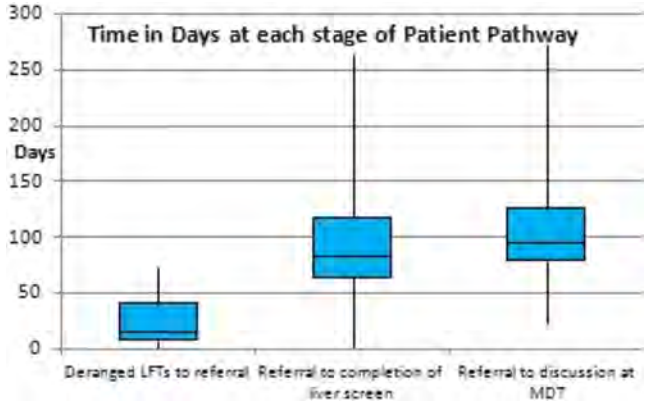

Figure: Duration of each stage of the pathway

Conclusion: iLFTs rapidly and safely identify patients with elevated liver enzymes requiring referral to secondary care. If iLFTs were used by referrers, the time to completion of the liver screen would be reduced by 83 days on average. In addition 24.7% of patients would not require referral to secondary care. This represents a substantial cost saving in terms of clinic appointments and unnecessary investigations.

The role of liver and spleen stiffness measurement in predicting hepatic decompensation after HCV eradication with direct antiviral agents therapy

Elton Dajti[1], Federico Ravaioli[1], Antonio Colecchia[2], Giovanni Marasco[1], Maria Letizia Bacchi Reggiani[1], Luigina Vanessa Alemanni[1], Mariarosa Tamé[1], Stefano Brillanti[1,3], Francesco Azzaroli[1], Giuseppe Mazzella[1], Davide Festi[1]. [1]*University of Bologna, Bologna, Italy;* [2]*Borgo Trento University Hospital, Verona, Italy;* [3]*University of Siena, Research center for the study of hepatitis, Siena, Italy*
Email: antonio.colecchia@aovr.veneto.it

Background and aims: To date few evidences are available on the risk of hepatic decompensation (HD) related to portal hypertension (PH) after therapy with new direct-acting antivirals (DAAs) in patients with HCV-related advanced chronic liver disease (ACLD). Furthermore, the predictive role of non-invasive markers of PH, such as liver (LSM) and spleen (SSM) stiffness measurement after DAA therapy is still debated and should be clarified. We previously reported that SSM ≥ 54 kPa was able to predict HD in untreated HCV patients, better than LSM. Our aim was to assess the role LSM and SSM in HD prediction after sustained virologic response (SVR).
Method: A cohort study in 146 ACLD patients treated with DAAs and with available LSM and SSM both before and 6 months after end-of treatment (EOT) was performed in our centre. Patients were prospectively followed up from EOT and PH related events were registered. Time-dependent models for HD prediction after SVR were applied to account for changes in LSM and SSM after DAA therapy.

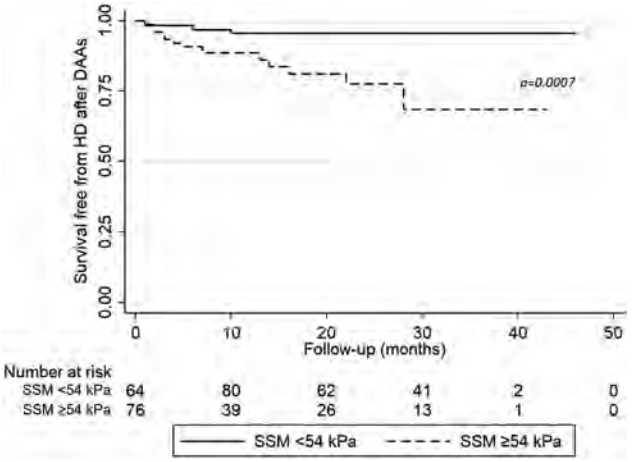

Figure 1: Kaplan Meier HD-free survival curves by SSM cut-off (54 kPa) after time-dependent predictive modelling.

Results: During a follow-up of 33, 5 months a total of 20 (13.7%) patients developed at least one episode of HD (among these, 3 presented a second HD event). The first decompensating event was ascites in the majority (17/20, 85%) of patients. Three patients developed a second episode of HD. Besides HD development, 18 (12.3%) patients developed hepatocellular carcinoma after DAA therapy; 3 (2.1%) developed portal vein thrombosis, 4 (2.7%) underwent high-bleeding risk varices prophylaxes, 3 (2.1%) underwent liver transplantation and 7 (4.8%) patients died. At the multivariate analysis, previous HD (HR, 8.065; 95%CI 2.806-23.180)

and SSM ≥ 54 kPa (HR, 4.678; 95%IC 1.307-16.744) were independently associated with a higher risk of HD development after DAAs treatment. Kaplan-Meier curves were estimated and drawn by the SSM cut-off of 54 kPa (Figure 1); in term of survival, the difference between the two curves was statistically significant (p = 0.0007). The time-dependent model including SSM values at baseline and at 6 months after EOT predicted post-SVR HD development better than the models including LSM and its changes after therapy.
Conclusion: SSM is confirmed to be an accurate surrogate of portal hypertension also after SVR achieved with DAA therapy. Moreover, SSM is able to stratify for the risk of HD development after DAA therapy more accurately than LSM.

SAT-428
Prediction of liver stiffness by serum indexes in HCV-infected patients with or without HIV coinfection
Nicolas Merchante[1], Álvaro Mena de Cea[2], Juan Manuel Pascasio[3], Andrés Marco[4], Manuel Rodríguez[5], Miguel Angel Simón[6], Manuel Hernández Guerra[7], Ángeles Castro[2], Álvaro Giráldez[3], Elisabet Turu[4], Carmen A. Email: nicolasmerchante@gmail.com

Background and aims: Assessment of liver stiffness (LS) prior to therapy is recommended in HCV-infected patients, mainly with the aim of identify those with advanced fibrosis/cirrhosis. As transient elastography (TE) is not available in all settings, this could be a barrier for achieving the goal of HCV elimination. Our aim was to analyse the diagnostic accuracy of serum indexes for the prediction of liver stiffness.
Method: Cross-sectional retrospective study conducted in 6 hospitals and a prison program of health in Spain (2017-2018). Patients were included provided they met the following inclusion criteria: a) Chronic hepatitis C (with or without HIV infection); b) Undergoing a LS assessment by TE as part of pre-treatment evaluation; and c) Availability of routine blood test by the time of TE examination. Liver cirrhosis was diagnosed by a LS ≥ 12.5 kPa and advanced fibrosis was considered if LS was ≥ 9.5 kPa. The predictive accuracy of APRI and FIB4 indexes was assessed by means of AUROC curves and the diagnostic accuracy was determined by estimating the sensitivity, specificity and the negative (NPV) and positive (PPV) predictive values.
Results: 1391 patients (25% HIV-coinfected; 53% previous injection drug users; 13% incarcerated) were included. Median (Q1-Q3) time between blood test and TE was 0 (−4; +4) days. 557 (40%) patients had a LS ≥ 9.5 kPa and 351 (25%) patients had a LS ≥ 12.5 kPa. The AUROC (95% CI) for APRI and FIB for predicting a LS ≥ 12.5 kPa was 0.83 (0.81-0.85) and 0.84 (0.82-0.87), respectively. The respective figures for predicting a LS ≥ 9.5 kPa were 0.78 (0.76-0.81) and 0.79 (0.77-0.82). APRI < 0.5, present in 595 (43%) individuals, had a 95% NPV for excluding cirrhosis. The combination of a FIB4 < 1.45 with an APRI < 0.5, present in 467 (34%) patients, had an 87% NPV for excluding a LS ≥ 9.5 kPa. The combination of APRI > 2 with FIB4 > 3.25, present in 134 (10%) patients, had an 89% PPV for a LS ≥ 9.5 kPa. Globally, this approach could avoid the need of TE in 53% patients, with only 5% of cirrhotic patients incorrectly classified as non-cirrhotic. Accuracy of the proposed cut-off values was not influenced by HIV-coinfection.
Conclusion: Simple serum indexes confidently identify the absence of cirrhosis and the presence of advanced fibrosis in HCV infected patients with or without HIV. Our diagnostic approach could avoid the need for TE assessment prior to starting therapy in a half of the patients. As HIV coinfection does not impact on the diagnostic yield of serum indexes, the same algorithm can be adopted when evaluating these patients.

SAT-429
Von Willebrand factor a non-invasive serum biomarker of portal pressure in cirrhosis: Evidence in human and rodent
Xiaolong Qi[1,2,3], Wenda Li[2], Pinzhu Huang[2], Xinlong Lin[1], Xiangbo Zeng[1], Yanna Liu[1,3], Ruizhao Qi[4], Fuquan Liu[5], Yu Wang[6], Chunqing Zhang[7], Popov Yury[2]. *[1]Nanfang Hospital, Southern Medical University, CHESS Group; Hepatic Hemodynamic Lab, Institute of Hepatology, Guangzhou, China; [2] Beth Israel Deaconess Medical Center, Harvard Medical School, Division of Gastroenterology and Hepatology, Boston, China; [3] Lanzhou University, CHESS Frontier Center, Lanzhou, China; [4]The Fifth Medical Center of Chinese PLA General Hospital, Department of General Surgery, Beijing, China; [5] Beijing Shijitan Hospital, Capital Medical University, Department of Interventional Therapy, Beijing, China; [6]Beijing Friendship Hospital, Capital Medical University, Institute of Hepatology, Beijing, China; [7]Shandong Provincial Hospital, Shandong University, Department of Gastroenterology, Jinan, China*
Email: qixiaolong@vip.163.com

Background and aims: Endothelial dysfunction and inflammation-associated markers has been shown to correlate significantly with portal pressure and the increase level of them is associated with poor outcomes in patients with cirrhosis. However, there is still no evidence on whether these serum biomarkers correlate with portal pressure in cirrhotic experimental animal models. Therefore, we aimed to assess the correlation between serum biomarkers and portal pressure in both cirrhotic patients and rodents.
Method: This prospective multicenter trial (ClinicalTrials.gov ID: NCT03713606) included cirrhosis patients scheduled to undergo transjugular hepatic venous pressure gradient (HVPG) measurement in 4 centers of China between September 2018 and November 2018. Plasma levels of the nineteen serum biomarkers (Fas, VCAM-1, von Willebrand Factor [vWF], heat shock protein 70 [HSP70], sCD163, T cell immunoglobulin and mucin domain-3 [TIM-3], CD28, CD137, CD27, CD152, herpesvirus entry mediator, indoleamine 2, 3-dioxygenase [IDO], lymphocyte-activation gene 3, B and T lymphocyte attenuator, glucocorticoid-induced tumor necrosis factor receptor [GITR], CD80, PD-1, PD-L1, and PD-L2) that were previously reported to associate with liver cirrhosis in other studies were detected. The correlation between HVPG and the abovementioned markers was analyzed. For the animal experimental study, plasma levels of VCAM-1, vWF, and HSP70 were detected in cirrhotic rats and mice (n = 78 and 37, respectively) induced by carbon tetrachloride to study the correlation with portal venous pressure (PVP).
Results: A total of 74 eligible patients with cirrhosis were recruited with 40 of them were HBV-related cirrhosis patients. There were significant correlations between HVPG and VCAM-1, vWF, HSP70, TIM-3, CD28, CD137, CD152, IDO, GITR, CD80, and PD-L2 (all p < 0.05). Notably, in HBV-related cirrhosis sub-group, vWF had the strongest correlation with HVPG (r = 0.571, p < 0.001) (Figure 1A) among the 19 biomarkers. Additionally, in cirrhotic rodent animal models, only vWF presented a significant correlation with PVP in rats and mice groups (r = 0.608 and 0.405, respectively, both p < 0.001) (Figure 1B and 1C). Besides, the expressions of vWF in cirrhotic liver tissue were obviously higher than that of the healthy tissues of rats and mice (Figure 1D).

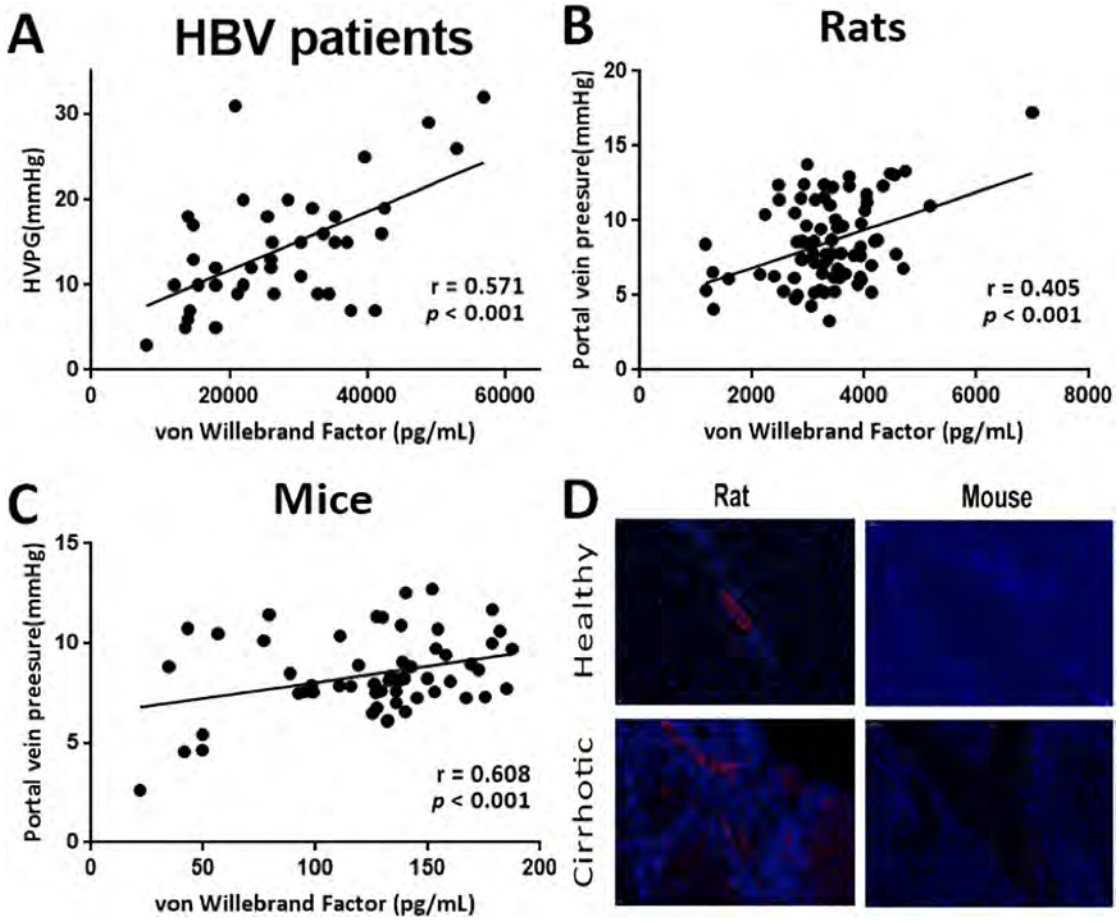

Figure: (abstract:SAT-429)

Conclusion: vWF had the potential to serve as a non-invasive cross-species predictor for diagnosis and monitoring of portal pressure in cirrhosis.

SAT-430

Spleen stiffness measured with ElastPQ point shear wave elastography has a good performance in predicting clinically significant portal hypertension in patients with primary sclerosing cholangitis

Davide Roccarina[1], Francesca Saffioti[1,2], Matteo Rosselli[1], Anna Mantovani[1,3], Roberta Stupia[1,4], Aileen Marshall[1], Massimo Pinzani[1], Douglas Thorburn[1]. *[1]Royal Free London NHS Foundation Trust and UCL Institute for Liver and Digestive Health, University College of London, Sheila Sherlock Liver Centre, London, United Kingdom; [2]University of Messina, Department of Clinical and Experimental Medicine, Division of Clinical and Molecular Hepatology, Messina, Italy; [3]Azienda Ospedaliera Universitaria Integrata, University of Verona, Division of General Medicine and Hypertension, Department of Medicine, Verona, Italy; [4]University of Messina, Division of Clinical and Molecular Hepatology, Messina, Italy*
Email: davideroccarina@gmail.com

Background and aims: Large efforts have been made to identify non-invasive surrogates as markers of clinically significant portal hypertension (CSPH), defined as the presence of gastro-oesophageal varices on upper endoscopy. The correlation of spleen stiffness measurement (SSM) with portal hypertension (PH) as measured by hepatic venous pressure gradient has been reported, but data regarding its reliability are still controversial. We assessed the performance of liver stiffness measurement (LSM) and SSM as performed by point-shear wave elastography (pSWE) in detecting the presence of CSPH in primary sclerosing cholangitis (PSC).

Method: Predictors of CSPH were investigated in 46 PSC patients who underwent an upper-GI endoscopy within 12 months of the elastographic assessment. Demographics, biochemistry and ultrasonographic data were prospectively collected. Fibroscan transient elastography (F-TE), liver and spleen pSWE were obtained on the visit date. Receiver operating characteristics (ROC) curves were constructed to establish the performance of elastographic techniques in predicting CSPH.

Results: Mean age 47 ± 16y, 74% male, CSPH was detected in 18 cases (1 at high-risk of bleeding). Variables significantly associated with CSPH on univariate analysis were: cirrhosis, Child-Pugh, MELD and Mayo risk score, spleen area and length, platelet, albumin, bilirubin, AST, GGT, INR, F-TE, liver and spleen ElastPQ, LSPS (LSM*spleen diameter/platelet). SSM remained the only independent predictor of CSPH on multivariate models (OR 1.13; 95% CI 1.02-1.25; p < 0.025). F-TE and ElastPQ LSM showed a good performance [AUROC, 95%CI, Sensitivity (Se) and Specificity (Sp)]: 0.82, 0.68-0.96, 92% and 64%, and 0.83, 0.70-0.97, 92% and 68%, respectively. Best cut-off was 18.5 and 21.1 kPa, respectively. However, Sp was < 70% for both tests. ElastPQ SSM showed a better performance in predicting OVs (0.87, 0.76-0.99, 92% and 77%), cut-off 40.2 kPa. However, the best diagnostic performance was obtained by combining ElastPQ SSM, spleen diameter and platelet count (0.92, 0.83-1.00, 92% and 81%) which was better than LSPS (0.90, 0.81-0.99, 94% and 67%) (**Fig1**). ElastPQ SSM was superior to BavenoVI and Expanded BavenoVI criteria (Se 92%, for both; Sp 54% and 59%, respectively).

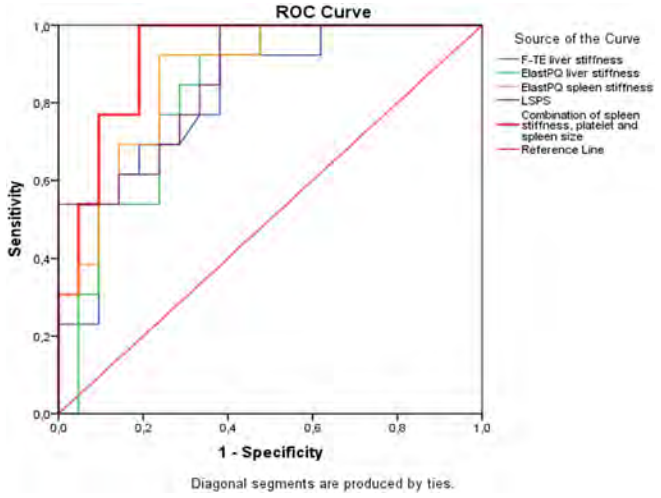

Figure 1: Receiver operating characteristic analysis of the ability of the non-invasive tests to predict the presence of oesophageal varices. Abbreviations: F-TE, transient elastography performed by Fibroscan; LSPS, liver stiffness X spleen diameter/platelet count.

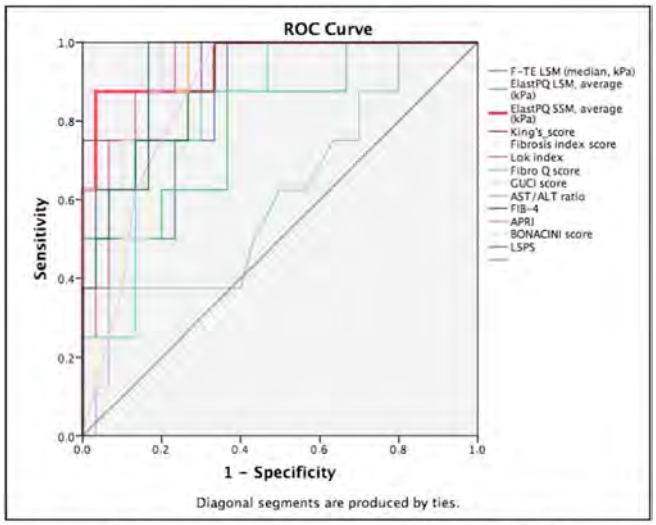
Conclusion: We provide evidence that ElastPQ SSM, particularly in combination with spleen diameter and platelet count, can be used as a reliable tool for the non-invasive diagnosis of CSPH in patients with PSC.

SAT-431

Spleen stiffness measurement with ElastPQ point shear wave elastography has an excellent performance in predicting the presence of clinically significant portal hypertension in primary biliary cholangitis

Francesca Saffioti[1,2], Davide Roccarina[1], Matteo Rosselli[1], Roberta Stupia[3], Aileen Marshall[1], Massimo Pinzani[1], Douglas Thorburn[1]. *[1]Royal Free London NHS Foundation Trust and UCL Institute for Liver and Digestive Health, University College of London, Sheila Sherlock Liver Centre, London, United Kingdom; [2]University of Messina, Department of Clinical and Experimental Medicine, Messina, Italy; [3]University Hospital of Messina, Division of Clinical and Molecular Hepatology, Messina, Italy*
Email: fsaffioti.83@gmail.com

Background and aims: There is an ongoing effort to identify non-invasive surrogates for staging liver disease and detecting clinically significant portal hypertension (CSPH), defined as the presence of gastro-oesophageal varices on endoscopy. The correlation of spleen stiffness measurement (SSM) with portal hypertension measured by hepatic venous pressure gradient has been reported, but data regarding its reliability are controversial. We assessed the ability of liver stiffness measurement (LSM) and SSM performed by point-shear wave elastography (pSWE) to detect CSPH in primary biliary cholangitis (PBC).
Method: Predictors of CSPH were evaluated in 53 PBC patients who had an upper-GI endoscopy within 12 months of the elastographic assessment. Demographics, biochemical and ultrasonographic data were prospectively collected. Transient elastography (Fibroscan, Echosens) [F-TE], liver and spleen pSWE (ElastPQ, Philips Affiniti70G), and the most common clinical fibrosis scores were obtained. ROC curves were constructed to establish the performance of elastographic techniques and fibrosis scores in predicting CSPH.
Results: Mean age 57 ± 12 years, 91% female. OVs were detected in 12 (23%) cases (4 at high-risk of bleeding). Variables significantly associated with CSPH at univariate analysis were: diagnosis of cirrhosis, Child-Pugh, MELD and Mayo risk score, spleen area and longitudinal diameter, platelets, albumin, ALT, INR, F-TE, ElastPQ LSM and SSM, LSPS (LSM*spleen diameter/platelets). SSM remained the only independent predictor of CSPH in all the multivariate models (OR 1.101; 95%CI 1.14-1.20; p < 0.022). F-TE and ElastPQ LSM showed good AUROCs (95%CI): 0.85 (0.72-0.99) and 0.80 (0.62-0.98), with best cut-off 14.3 and 13.8 kPa, respectively. However, specificity (Sp) was < 70% for both tests. ElastPQ SSM showed the best performance in predicting CSPH (AUROC 0.95, 95%CI 0.87-1.00, sensitivity (Se) 88%, Sp 97%), with optimal cut-off 50.1 kPa (PPV 0.89, NPV 0.97), followed by GUCI, King's score and LSPS [AUROC (95%CI): 0.94 (0.87-1.00), 0.94 (0.85-1.00), 0.93 (0.85-1.00), respectively] (**Fig. 1**). In this cohort, the diagnostic performance of ElastPQ SSM in detecting CSPH was superior to the recently validated Baveno VI and Expanded Baveno VI criteria, which showed good Sp (77% and 87%, respectively) but low Se (67%, for both).



Abbreviations: F-TE, transient elastography performed by Fibroscan; LSM, liver stiffness measurement; SSM, spleen stiffness measurement; GUCI, Göteborg University Cirrhosis Index; AST, aspartate aminotransferase; ALT, alanine aminotransferase; APRI, aspartate aminotransferase-to-platelet ratio index, AST to Platelet Ratio Index; LSPS, liver stiffness X spleen diameter/platelet count.

Figure 1: Receiver operating characteristic analysis of the ability of the non-invasive tests of liver fibrosis, liver and spleen elastography to predict the presence of oesophageal varices.

Conclusion: We provide evidence that transient elastography, in particular ElastPQ SSM, can be used as a reliable tool for the detection of CSPH in PBC.

SAT-432

The CT1 multi-parametric MRI value is more sensitive and reliable than transient elastography for the non-invasive monitoring of intra-hepatic inflammation/fibrosis response to DAA therapy in CHC patients

Antonio Salvati[1], Nicola Martini[2], Andy Mckay[3], Barbara Coco[1], Piero Colombatto[1], Gabriele Ricco[1], Filippo Oliveri[1], Veronica Romagnoli[1], Francesco Faita[2], Ferruccio Bonino[4,5], Dante Chiappino[2], Maurizia Rossana Brunetto[4]. *[1]Hepatolgy Unit, Department of Clinical and Experimental Medicine, Pisa, Italy; [2]National Research Council, Institute of Clinical Physiology, Pisa, Italy; [3]Perspectum diagnostic, Oxford, United Kingdom; [4]Univerity of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy; [5]Fondazione Italiana Fegato, Trieste, Italy*
Email: salvatiantonio@hotmail.com

Background and aims: The eradication of HCV infection is supposed to resolve intra-hepatic inflammation and to ameliorate fibrosis, metabolic alterations and steatosis. Nevertheless, accurate non-invasive methods for liver inflammation/fibrosis/steatosis quantification remain a major unmet need. We investigated the impact of DAAs on systemic metabolic alterations, liver inflammation/fibrosis and steatosis assessed by new multi-parametric magnetic resonance (MRI)

Method: 45 consecutive genotype 1b chronic hepatitis C patients (M: F = 22:23, median age 56 ± 28, 75; F0-F2:35; F3-F4:10) received 12-week PAR/OMB/DAS (41)or SOF+VEL (3)or SOF+LED (1) according to the Italian-Drug-Regulatory-Agency-criteria and were enrolled in an observational pilot study.Assessments at baseline (BL) and 6 months after end of treatment follow-up (FU) were: HCV-RNA, AST, ALT, GGT, p-glucose, Insulin, HOMA-index, total-cholesterol, LDL, HDL, triglycerides, Transient Elastography (TE, Fibroscan®);liver inflammation/fibrosis quantification [MRI (corrected T1, cT1) and steatosis (Proton Density Fat Fraction, PDFF) LiverMultiscan™, Perspectum Diagnostics, Oxford, UK]. Wilcoxon test was applied to analyse significant BL/FU modifications (significant if $p < 0.05$).
Results: All patients showed week-12-SVR.Significant reduction from BL to FU was observed for AST ($p < 0.01$), ALT ($p < 0.01$), GGT ($p < 0.01$), p-glucose ($p = 0.04$), HOMA ($p = 0.023$), TE ($p = 0.004$), cT1-MMR ($p = < 0.01$).On the contrary total-cholesterol ($p < 0.01$)and LDL ($p < 0.01$) increased. PDFF values remained stable ($p = 0.48$).Overall median cT1 values declined significantly from BL to FU [811 (663-1133) Vs 791 (652-960) $p < 0.01$]. cT1 values decline significantly in 35 patients ($p < 0.01$] in whom TE presents a significant decrease ($p = 0.002$). Whilst in 10 patients cT1 BL/FU increase significantly (0.005); in this subgroup TE does not change significantly ($p = 0.678$).Overall TE median levels showed a BL/FU significant reduction ($p = 0.004$). TE did not decrease (Δ BL/FU < 1 kPa) in 24 patients in whom cT1 declined significantly ($p = 0.008$).Their BL TE values were significantly lower than those of 21 patients with TE decline [4.8 (3.4-9.3) vs 9.2 (4.9-14) kPa, $P < 0.001$]. Overall TE and cT1 correlated at BL ($p = 0.032$ $r = 0.320$), but not at FU. ($p = 0.503$ $r = 0.104$)
Conclusion: Multi-parametric MRI cT1 appears more accurate than TE in detecting the reduction of liver inflammation/fibrosis after DAAs SVR, that shows a positive impact on glycemic profile but causes a significant increase of total cholesterol and LDL

SAT-433

Portal venous velocity and platelet count as a simple non-invasive tool to rule out the presence of varices needing treatment in patients with compensated cirrhosis

Francesco Santopaolo[1,1], leonardo baiocchi[1], Piera Rossi[1], Alessandra Pecchioli[1], Alessandra Bosa[1], Simona Francioso[1], Arianna Brega[1], Ilaria Lenci[1], Chiara Masetti[1], Martina Milana[1], Francesca Antenucci[1], Benedetto Neri[1], Angelico Mario[1]. *[1]Tor Vergata Hospital University, Liver and Transplant Unit, Rome, Italy*
Email: santopaolofrancesco@gmail.com

Background and aims: Esophagogastroduodenoscopy (EGDS) is the main tool to evaluate the risk of bleeding in cirrhotic patients. Recently a combination of non-invasive methods (transient elastography and platelet count) has been proposed as a simple way to rule out the presence of varices needing treatment (VNT) in patients with liver cirrhosis. We investigated whether portal venous velocity (PVV) can predict the presence of VNT in patients with compensated liver cirrhosis.

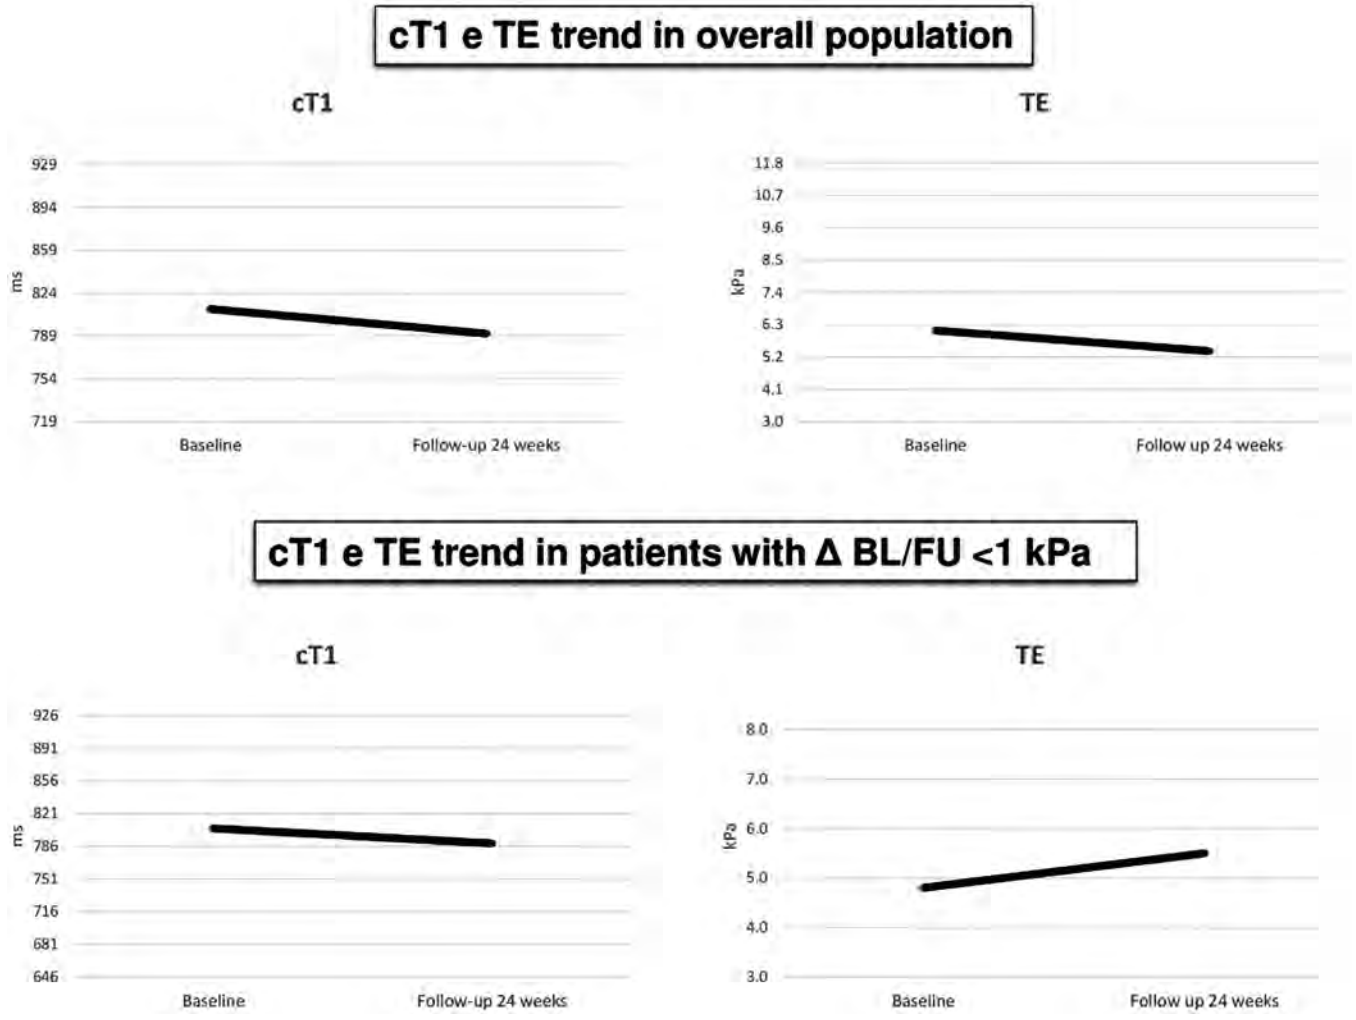


Figure: (abstract: SAT-432)

Method: We retrospectively assessed 246 patients (mean age 60.3, 77.6% males) with compensated liver cirrhosis who had EGDS performed within 6 months from a Doppler ultrasound examination of the portal system. Liver cirrhosis was virus-related in 128 (52%), alcohol-related in 52 (21.1%), NASH-related in 46 (18.7%) and multifactorial in 20 (8.1%). Portal venous velocity (PVV), estimated by Doppler ultrasound, was measured in cm/s. All EGDS and Doppler ultrasound examinations were performed by an expert hepatologist with at least 10 years of experience in a single tertiary center. We also measured platelet count within 6 months of Doppler examination.
Results: VNT were present in 46.6% of patients (122/246). No difference in age, sex and etiology were found between patients with or without varices. Patients with VNT had lower PVV (15.65 cm/s vs 23.53 cm/s; $p < 0.00001$) and lower platelet count (72, 000/cc vs 122, 000; $p < 0.00001$) compared to those without VNT. At logistic regression analysis, PVV ($p < 0.00001$) and platelet count ($p = 0.00001$) were significantly associated with the presence of VNT. Using ROC curves analysis, a cut-off levels of 20 cm/s for PVV and 125, 000 platelets had the highest predictive accuracy for the presence of VNT (AUROC: 0.82). In our cohort 49 of 246 (19.7%) patients met the above criteria (platelets count > 125000 and PPV > 20 cm/s) and none had VNT.
Conclusion: In the present study, a combination of PVV and platelet count measurement allowed to identify a subgroup of patients with compensated cirrhosis (approximately one fifth of the whole cohort) who may avoid undergoing EGDS with a 100% of accuracy. We speculate that a combination of PPV and transient elastometry could be an even better non-invasive tool to rule out the presence of VNT in compensated cirrhosis.

SAT-434

Liver stiffness measurement by transient elastography for the prognosis of hepatic carcinoma, decompensation, and death in patients with chronic liver diseases: A systematic review and meta analysis

Yue Shen[1], Sheng-Di Wu[1], Si-Qi Wang[1], Wei Jiang[1]. [1]*Zhongshan Hospital, Department of Gastroenterology, Shanghai, China*
Email: jiang.wei@zs-hospital.sh.cn

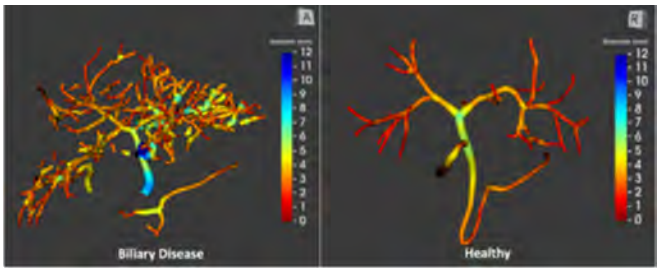
Background and aims: Liver stiffness measurement (LSM) by transient elastography (TE), a non-invasive method, has been assessed for the evaluation of clinical relevant outcomes in patients with chronic liver diseases (CLD) while with variable results. This systematic review and meta-analysis aims to study the relationship between baseline live stiffness (LS) measured by TE and the development of clinical relevant outcomes.
Method: The systematic review identified eligible cohorts reporting the association between baseline LSM by TE and risk of hepatic carcinoma (HCC), hepatic decompensation (HD), all-cause and/or liver-related mortality and liver-related events (LREs) in CLD patients. Summary relative risks (RRs) with 95% confidence intervals (CIs) were estimated using a random-effect model. The dose-response association was evaluated by generalized least squares trend estimation and restricted cubic splines. Commands of GLST, MKSPLINE, MVMETA were applied for statistical analysis.
Results: 62 observational cohort studies were included in the final analysis. Compared with the lowest category, subjects with a highest category of baseline LS were associated significantly with risk of HCC (n: 14 studies; RR: 5.31; 95%CI: 3.76-7.51), all-cause mortality (n: 8 studies; RR: 4.30; 95%CI: 2.85-6.50), HD (n: 11 studies; RR: 7.33; 95% CI: 3.84-14.00), or LREs (n: 11 studies; RR: 9.16; 95%CI: 4.14-20.30), thus suggesting for further dose-response analysis. For one kPa increment in baseline LS, the pooled RR (95%CI) was 1.08 (n: 16 studies; 95%CI: 1.05-1.11) for HCC, 1.08 (n: 7 studies; 95%CI: 1.06-1.11) for all-cause mortality, 1.11 (n: 6 studies; 95%CI: 1.05-1.17) for liver-related mortality, 1.08 (n: 17 studies; 95%CI: 1.06-1.10) for HD and 1.07 (n: 13 studies; 95%CI: 1.04-1.09) for LREs, respectively. Evidence of a non-linear association was found between baseline LS and HCC, all-cause mortality, HD, LREs as well as a composite of all these outcomes ($p < .05$). The non-linear dose-response meta-analysis showed that a significant increase in the risk of corresponding clinical relevant outcomes turned to a stable increase or a slight decrease with increasing baseline LS.
Conclusion: The dose-response meta analysis presents a combination between the levels of baseline LS and RRs for each clinical relevant outcome. TE, which is non-invasive, might be a novel strategy for risk stratification and identification of patients at high risk of developing these outcomes.

SAT-435

Quantitative MRCP imaging (MRCP+): Accuracy, repeatability and reproducibility evaluation in healthy and liver disease patients

Gary Woodward[1], Neelam Hassanali[1], Marija Mavar[1], Ged Ridgway[1], Andrea Borghetto[1], Carlos Ferreira[1], Hayley Simpson[1], Matt Kelly[1], Rajarshi Banerjee[1]. [1]*Perspectum Diagnostics Ltd, Oxford, United Kingdom*
Email: gary.woodward@perspectum-diagnostics.com

Background and aims: Magnetic resonance cholangiopancreatography (MRCP) is a non-invasive imaging technique for the evaluation of biliary disease. Despite its widespread use there remain limitations, including variable quality bile duct depiction and subjective assessment. We report the first, groundbreaking, application of quantitative MRCP imaging and demonstrate the robust performance profile for its application to a cohort of healthy and liver disease subjects.
Method: For *in vivo* performance assessment, liver disease patients (n = 10 biliary disease, n = 10 parenchymal disease) and health subjects (n = 20) were recruited for repeated heavily T2-weighted MRCP imaging on Siemens Prisma 3 T, Siemens Avantofit 1.5 T, GE Discover 3 T and GE Optima 1.5 T scanners, followed by processing with MRCP+, that combines multi-scale Hessian analysis, gradient vector flow analysis, an intelligent path search algorithm and novel duct modelling algorithms. Accuracy was assessed using digital synthetic 3D printed phantoms. Reference intervals were calculated for all reported metrics to inform interpretation.
Results: Performance profiles were demonstrated for tree volume (95% LoA for repeatability of –3.5-3.4 ml and reproducibility of –1.5-2.8 ml), gallbladder volume (95% LoA for repeatability of –9.4-4.4 ml and reproducibility of –8.0-12.0 ml), and duct diameter measures for the common hepatic (CBD), left-hepatic (LHBD), right hepatic (RHBD), pancreatic (PD) and cystic ducts (CD) with a CoV of 13%, representative. MRCP+ duct measurement accuracy was within ± 0.8 mm of ground-truth. Normal reference intervals were estimated at 1-9 ml and 7-40 ml for tree and gallbladder volumes, and 2.6-6.4 mm, 1.3-4.7 mm, 2.3-5.2 mm, 1.4-4.2 mm, 2.3-5.3 mm for CBD, CD, LHBD, PD and RHBD median diameter, respectively.



Conclusion: We report the inaugural assessment of biliary tree measures and performance profile charateristics determined using groundbreaking quantitative MRCP imaging. MRCP+ provides reliable measures with significant potential for applications in biliary disease diagnosis, stratification and monitoring in clinical practice.

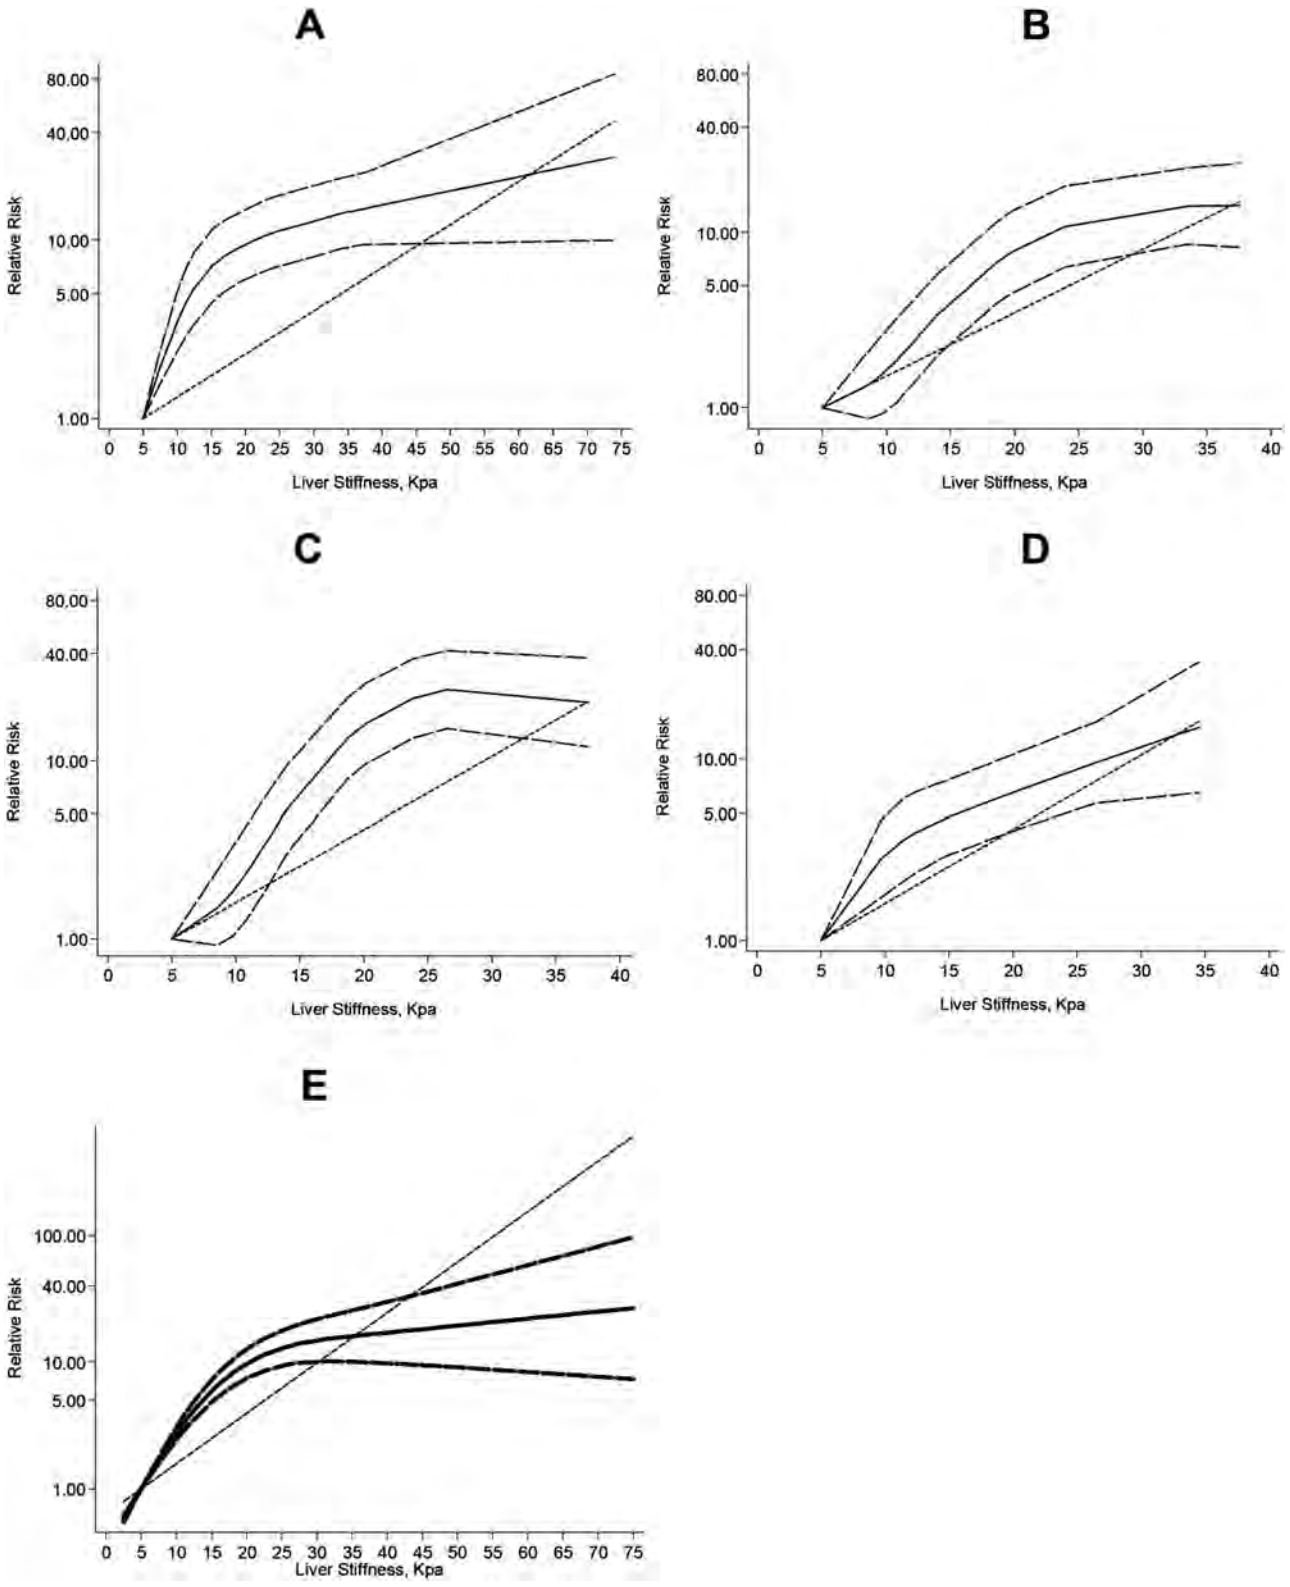


Figure: (abstract: SAT-434): Dose-Response Analysis. The dose-response relationship between baseline LS and risk of (A) hepatic carcinoma, (B) all-cause mortality, (C) hepatic decompensation, (D) liver-related events, (E) composite outcomes. The short dash line represents the linear relationship. The solid line and the long dash line represent the estimated RR and its 95% CI for the spline model. The value of 5 kPa served as referent.

Liver transplantation and hepatobiliary surgery: Experimental

SAT-436

Inhibition of autophagy prolongs recipient survival through accelerating CD8+ T-cell apoptosis in a rat liver transplantation model

Xiaolong Chen[1], Qing Yang[1], Xuejiao Li[2], Yinan Deng[1], Guihua Wang[1], Genshu Chen[1]. [1]*The Third Affiliated Hospital of Sun Yat-Sen University, Department of Hepatic Surgery, Liver Transplantation, Guangzhou, China;* [2]*The Third Affiliated Hospital of Sun Yat-Sen University, Guangdong Key Laboratory of Liver Disease Research, Guangzhou, China*
Email: wgsh168@163.com

Background and aims: In liver transplantation (LT), acute rejection (AR) remains a common complication that significantly shortens recipient survival although various immunosuppressors have been used in clinical practice. In recent years, manipulating immune tolerance has been regarded as one of the promising solutions. Autophagy, an evolutionarily conserved protein degrading system, has been reported to be involved in the immune rejection and may become a target to establish immune tolerance. However, its role in AR after LT has not been elucidated.
Method: Human liver tissues from patients with AR and control individuals were obtained to evaluate autophagy specific protein LC3 expression. Acute rejection model was established in rats to analyze the exact role of autophagy in AR. In addition, the underlying mechanism of autophagy participated in AR were further explored by ex vivo study.
Results: The autophagy of $CD8^+$ T cell was strongly enhanced in patients with AR and autophagy level was positively correlated with the severity of rejection. Similar findings were observed in the acute rejection rat model. Furthermore, administration of autophagy inhibitor 3-methyladenine (3-MA) significantly prolonged graft survival through inhibiting autophagy of $CD8^+$ T cell, which resulted in decreased viability and function of $CD8^+$ T cell. In addition, inhibition of autophagy of activated CD8+ T cells largely reduced the stabilization of intact mitochondria and subsequently increased the production of mitochondrial superoxide (MitoSOX) in vitro.
Conclusion: We firstly showed inhibiting autophagy significantly prolongs liver allograft survival by accelerating apoptosis of CD8+ T cells, which will provide a novel strategy for immune tolerance induction.

SAT-437

An mTor-based immunosuppression reduces the antiviral efficacy of NS3/4A and NS5A inhibitors for HCV genotype 1b treatment in vitro

Alexandra Frey[1], Andreas Walker[2], Jörg Timm[2], Guido Gerken[1], Heiner Wedemeyer[1], Kerstin Herzer[1]. [1]*University Hospital Essen, Gastroenterology and Hepatology, Essen, Germany;* [2]*University Hospital Düsseldorf, Virology, Düsseldorf, Germany*
Email: alexandra.frey@uk-essen.de

Background and aims: With the approval of direct-acting antivirals (DAAs), the success of HCV therapy has been considerably improved. However, in the context of HCV therapy after LT, the influence of mTOR Inhibitors for immunosuppressive therapy (IS) after LT on the efficacy of DAAs is not thoroughly investigated.
Method: Subgenomic HCV replicons of different genotypes (GT) were treated with different IS (mTOR Inhibitors: Everolimus (EVR), Sirolimus (SRL); Calcineurin Inhibitors (CNI): Cyclosporin A, Tacrolimus) alone and in combination with Daclatasvir (DAC), Elbasvir (ELB), Ledipasvir (LDV), Simeprevir (SIM) and Grazoprevir (GRZ). The HCV replication activity was determined by qRT PCR (GT1b) or luciferase assay (GT2a/GT3a/GT4a).
Results: The combination of NS3/4A inhibitors with mTOR inhibitors does significantly reduce antiviral efficiency against HCV GT1b. The efficacy of the Protease Inhibitor (PI) GRZ, is reduced by 14% (EVR: $p \leq 0.05$) or 20% (SRL: $p \leq 0.005$), whereas mTOR inhibitors completely eliminate the antiviral effect of the PI SIM (EVR: $p \leq 0.005$; SRL: $p \leq 0.01$). The combination of NS5A inhibitors (DAC, ELB, LDV) with EVR or SRL also results in a 10-20% lower antiviral effect in GT1b compared to DAA treatment alone ($p \leq 0.05$). In contrast, HCV GT2a and 3a replication activity does significantly decrease upon combination of NS3/4A and NS5A inhibitors with EVR/SRL ($p \leq 0.01$). Upon administration of Calcineurin Inhibitors antiviral activity of DAAs was not compromised in either genotype.
Conclusion: The combination of an NS3/4A or NS5A inhibitor with an mTOR inhibitor-based IS leads to a significant reduction of DAA efficiency in GT1b, suggesting that post LT, IS should abandon mTOR inhibitors during antiviral treatment. In GT1b patients, CNI-based IS appears to be more suitable, whereas mTOR-based IS would be a rather beneficial treatment option in patients with GT2a or GT3a.

SAT-438

Effect of chondroitin sulfate in the rat liver cold ischemia and warm reperfusion injury

Background and aims: Liver transplantation is the effective treatment for severe liver disease. The primary dysfunction and initial malfunction of the graft is related to the ischemia-reperfusion injury (IRI). IRI is characterized by an initial event of sinusoidal endothelial cell necrosis followed by a late phase of hepatocyte apoptosis. Strategies have been done to minimize cell death. We recently verified that chondroitin sulfate (CS) increased cell regeneration and decreased apoptosis in the bile duct ligation model. So, the aim was to investigate the effect of CS in the cold ischemia and warm reperfusion injury model.
Method: Wistar rats (6-8 weeks) were submitted to cold liver ischemia (4°C) in University of Wisconsin solution for 24h and warm reperfusion (37°C) with Krebs solution for 20 or 40 min. CS (120 mg/kg body weight) was added at ischemia (I) and/or reperfusion (R) period; none was added in the control. Liver viability was evaluated by glucose production, BSP clearance and bile secretion. Trypan blue-positive cells (necrosis) and apoptotic bodies were counted on hematoxylin–eosin stained liver slides. Cathepsin B (CB), catalase (CAT) and superoxide dismutase (SOD) activity were measured in liver homogenate. Nitric oxide (NO) was measured using NO analyzer (Sievers). Results were analyzed by GraphPad Prism and expressed as mean ± SEM.
Results: CS did not change all the liver viability parameters studied. In the 20 min-R groups, CS decreased (ANOVA, $p < 0.0001$) the number of necrotic cells (cells.$10^{-3}/\mu m^2$) when added in R (2.2 ± 0.1) or IR (2.2 ± 0.1), but not in I (3.2 ± 0.1) compared to the control group (2.6 ± 0.2). In the 40 min-R group, CS did not affect the necrosis level. In relation to apoptosis, we found more apoptotic bodies and an increased CB activity in the 40 min-R group when CS was added in the R compared to control and to the CS added to IR. We did not observe any difference in CAT and SOD activity level in all groups. However, CS decreased (ANOVA, $p = 0.0259$) the concentration of NO (µM) when added in the I (13.4 ± 0.8) compared to control group (17.5 ± 0.2).

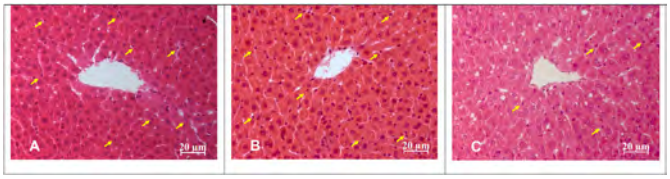

Figure: Hematoxylin-eosin liver specimens (40x total magnification) of control (A), Chondroitin sulfate added to ischemia (B) and to the reperfusion period (C).

Conclusion: Our data suggest that CS protects liver from necrosis in the early stage of IRI. However, at the late stage, it seems that CS did not have effect in relation to apoptosis.

SAT-439

Identification of new drug targets to prevent ischemia-induced bile toxicity using a human biliary organoid model

Floris Roos[1], Marcel Bijvelds[2], Hugo de Jonge[2], Herold Metselaar[2], Ksenia Burka[1], Jan Ijzermans[1], Monique Verstegen[1], Luc van der Laan[1]. *[1]Erasmus MC, Surgery, Rotterdam, Netherlands; [2]Erasmus MC, Gastroenterology and Hepatology, Rotterdam, Netherlands*
Email: f.roos@erasmusmc.nl

Background and aims: The study of bile duct biology and disease has been hampered by the lack of a good cell culture model of cholangiocytes. With the establishment of the human liver-derived organoid (LDOs) culture platform, it has become possible to long-term expand cells which exhibit cholangiocyte-like properties. The aim of this study is to investigate the role of cystic fibrosis transmembrane conductance regulator (CFTR) in hypoxia induced bile duct injury. It has been hypothesized that (transplantation-related) liver hypoxia leaves cholangiocytes vulnerable for bile toxicity due to an insufficient protection by CFTR-related bicarbonate (NH_3) secretion. There for we investigated if liver-derived organoids have functional cholangiocyte-transport channels and can be used for drug-discovery purposes.
Method: LDOs, cultured from donor livers reserved for LT, were analyzed on the genetic and protein level for cholangiocyte-specific transporters (CFTR and AE2). Functionality of these channels was analyzed using an Ussing-chamber assay in 2D-grown organoids (n = 42). Forskolin (cAMP-activator) added to the apical side of the cells, initiated CFTR activation which was specifically inhibited by GlyH. Hypoxic conditions were achieved by nitrogen gas ($95\%N_2/5\%CO_2$) exposure. To study bile-related toxicity, undiluted bile was added under oxygen and hypoxic conditions and cell death was analyzed. Finally, compounds were tested for the ability to abrogate the hypoxic-induced inhibition of CFTR.
Results: CFTR was expressed in all liver organoid cultures on both gene (qPCR) and protein (Western blot) level. Moreover CFTR could be functionally activated by Forskolin in the Ussing chamber set-up. CFTR activity was significantly lower when measured under hypoxic conditions compared to oxygenated conditions (1.66 ± 0.45 vs. 4.18 ± 0.48, p = 0.005). Furthermore, a significant decrease in activity was observed when the same 2D-organoids were switched from oxygenated to hypoxic conditions (8.00 ± 1.19 vs. 5.89 ± 1.26, p = 0.02). Further experiments showed that bicarbonate is the driving factor when CFTR is activated in LDOs, suggesting that under hypoxic conditions less bicarbonate is excreted into the bile. When 2D-grown LDO were exposed to bile, it resulted in more cell death in hypoxic versus oxygen conditions (31.2% ± 4.32 vs. 19.18 ± 4.81, p = 0.04). Most importantly, addition of compound C (cAMP-inhibitor) was able to rescue transporter activity under hypoxic conditions.
Conclusion: LDOs provide an excellent model to study cholangiocyte-transporters. We demonstrate that hypoxia inhibits CFTR-related bicarbonate secretion and cAMP-inhibitor compound C can restore this. This encourages further clinical studies to test whether cAMP-inhibitors can prevent hypoxia-related biliary injury during graft preservation and after LT.

Manns[2], Elmar Jaeckel[1,2], Richard Taubert[1,2]. *[1]Hannover Medical School, Integrated Research and Treatment Center Transplantation (IFB-Tx), Hannover, Germany; [2]Hannover Medical School, Gastroenterology, Hepatology and Endocrinology, Hannover, Germany; [3]Hannover Medical School, Pathology, Hannover, Germany; [4]Helmholtz Centre for Infection Research, Genome Analytics, Braunschweig, Germany; [5]Hannover Medical School, Transfusion Medicine, Hannover, Germany; [6]Queen Elizabeth Hospital, Cellular Pathology, Birmingham, United Kingdom; [7]University of Birmingham, Immunology and Immunotherapy, Birmingham, United Kingdom*
Email: taubert.richard@mh-hannover.de

Background and aims: The long-term outcome of patients after liver transplantation has not been improved over the past three decades. Up to 50% of patients show refibrosis in 5 year biopsies and side effects of chronic immunosuppression determine the morbidity and quality of life after liver transplantation. As histology long-term after liver transplantation is less precise in distinguishing between harmful and non-harmful findings, we employed molecular analysis to better characterize various rejection types (molecular microscope).
Method: We conducted next generation sequencing of mRNA isolated from 71 cryo-conserved liver allograft biopsies with no histological rejection (NHR; n = 20), subclinical TCMR (subTCMR; n = 25), clinical TCMR (cTCMR; n = 10) or possible cAMR (pcAMR; n = 16). Pathway analysis was performed with Ingenuity Pathway Analysis (IPA, QIAGEN) for transcripts with $p < 0.05$, false discovery rate < 0.05 and with > 2fold change in expression.
Results: In the principal component analysis NHR and subTCMR exhibited quite similar intrahepatic gene expression patterns indicating no major inflammation in the graft. In contrast cTCMR and pcAMR were quite different from NHR on the molecular level. Next, each rejection type (subTCMR, cTCMR, pcAMR) was compared pairwise to NHR and the overlap of these three comparisons was determined. Only two transcripts, PRDM1 and RGCC, were consistently regulated in all three rejection types compared to NHR. On the other hand cTCMR and pcAMR were significantly different from NHR. Both rejection types shared 200 transcripts mostly involved in regulation of the T cell compartment, dendritic cell maturation, leucocyte migration and cell cycle control including proliferation and DNA repair. However, not all of these 200 transcripts were homogenously up or down regulated in cTCMR and pcAMR: 516 pcAMR specific transcripts were mostly involved in similar pathways as those shared by cTCMR. 341 cTCMR specific transcripts were mostly involved in cell cycle control, potentially reflecting tissue response to more severe and more acute tissue damage during cTCMR compared to subTCMR and pcAMR. There was only a minimal overlap between our 341 cTCMR specific transcripts and the published 13 TCMR specific transcripts (two of 13 transcripts: CCL19, TOP2A) that were determined by microarray.
Conclusion: On the molecular level subTCMR is nearly indistinguishable from NHR ruling out any relevant graft inflammation. In contrast pcAMR is rather a resembling TCMR thereby showing substantial graft injury and tissue repair. Molecular profiling will help to identify patients with relevant graft inflammation thereby potentially providing a chance for individualized immunosuppression.

Gallbladder disease in the absence of cirrhosis is a significant risk factor for hepatocellular carcinoma

Kenda Al-Assi[1,2], Rikita Hatia[1], Vijayashri Rallapalli[1], Yehia Abugabal[3], Ahmed Abdelhakeem[1,3], Reham Abdel-Wahab[3,4], Kanwal Raghav[3], Prasun Jalal[5], Ahmed Kaseb[3], Asif Rashid[6], Donghui Li[3], Manal Hassan[1]. *[1]The University of Texas MD Anderson Cancer Center, Department of Epidemiology and Cancer Prevention, Houston, United States; [2]The Royal College of Surgeons in Ireland-Medical University of Bahrain, Bahrain, Bahrain; [3]The University of Texas MD Anderson Cancer Center, Department of Gastrointestinal Medical Oncology, Houston, United States; [4]Assiut University Hospitals-Assiut Faculty of Medicine, Department of Clinical Oncology, Assiut, Egypt; [5]Baylor College of Medicine, Division of Abdominal Transplantation, Houston, United States; [6]The University of Texas MD Anderson Cancer Center, Department of Pathology, Division of Pathology and Laboratory Medicine, Houston, United States*
Email: mhassan@mdanderson.org

Background and aims: Hepatocellular carcinoma (HCC) is the most common primary Liver cancer with a five-year survival rate of less than 5%. Gallbladder disease (GBD) is defined as the presence of cholelithiasis or cholecystitis. Both cholelithiasis and cholecystitis have been reported as risk factors in the development of gastrointestinal cancers, such as biliary tract and pancreatic cancers. Moreover, patients with GBD tend to develop chronic liver diseases which may progress to cirrhosis. However, the role of GBD in the development of non-cirrhotic related HCC has not been elucidated. We aimed to investigate the role of GBD and the risk of HCC development in absence of cirrhosis and after adjustment for potential confounders.
Method: We conducted a case-control study at The University of Texas M.D. Anderson Cancer Center. Cases were defined as pathologically confirmed HCC. Controls were healthy individuals without prior history of cancer, who are spouses of other cancer patients seen at MD Anderson. All subjects are USA residents. Participants were personally interviewed for prior history of GBD and for several HCC risk factors (environmental, behavioral, chronic medical conditions, and family history of cancer). Blood samples of all participants were tested for markers of hepatitis B and C viruses. We reviewed the pathology and radiology records of HCC patients to assess presence and absence of cirrhosis. Multivariable logistic regression analysis was conducted to estimate the adjusted odds ratio (AOR) and 95% confidence interval (CI) for the association between GBD and HCC in absence of cirrhosis and adjustment for potential confounders.
Results: Between 2000 and 2017 a total of 1333 cases and 1104 controls were enrolled in the study; 347 HCC patients showed no evidence of cirrhosis and were eligible for this analysis. The prevalence of GBD based on the participants' recall during personal interview was 22.7% in the cases. Upon further assessment by review of medical records, the prevalence of GBD was 40.3% in the cases. Individuals with GBD were two times more likely to develop HCC than individuals with no history of GBD (AOR = 2.0; 95% CI: 1.4–2.8). The estimated AOR did not meaningfully change when we rely on the prevalence of GBD recalled by cases (27%) versus the prevalence of GBD obtained from medical records. The association between GBD and HCC continue to be significant in absence of viral hepatitis, through a restricted analysis among non-viral non-cirrhotic population after controlling for age, sex race, alcohol use, cigarette smoking, diabetes and family history of cancer.
Conclusion: We conclude that GBD is a significant risk factor for HCC development in absence of cirrhosis. Future research aiming at investigating the underlying mechanism of GBD-induced HCC in absence of cirrhosis should be warranted. In addition, patients with GBD should be screened for evidence of cirrhosis.

SAT-452

Analysis of intrahepatic sarcomatoid cholangiocarcinoma compared with intrahepatic adenocarcinoma

Yanghyon Baek[1], Jin-Sook Jeong[2], Dong-Kyun Kim[1], Sung-Wook Lee[1]. *[1]DongA University College of Medicine, Department of Internal Medicine, Busan, Korea, Rep. of South; [2]DongA University College of Medicine, Department of Pathology, Busan, Korea, Rep. of South*
Email: p100100@dau.ac.kr

Background and aims: Most malignant tumors in the intrahepatic bile duct are adenocarcinoma which are commonly referred to as cholangiocellular carcinoma (CCC). In contrast, intrahepatic sarcomatoid cholangiocarcinoma (s-CCC) is an extremely rare, accounting for less than 1% of hepatobiliary malignancies. In this study, we investigated the clinical, imaging, and histopathologic features of s-CCC compared with those of CCC.
Method: From January 2001 to June 2018, a total of 228 patients with intrahepatic cholangiocarcinoma (IHCC) diagnosed via surgery or US-guided liver biopsy at Dong-A University Hospital were screened. Among them, 11 patients were diagnosed with s-CCC and 2 patients showed mixed histopathologic features of HCC and s-CCC.

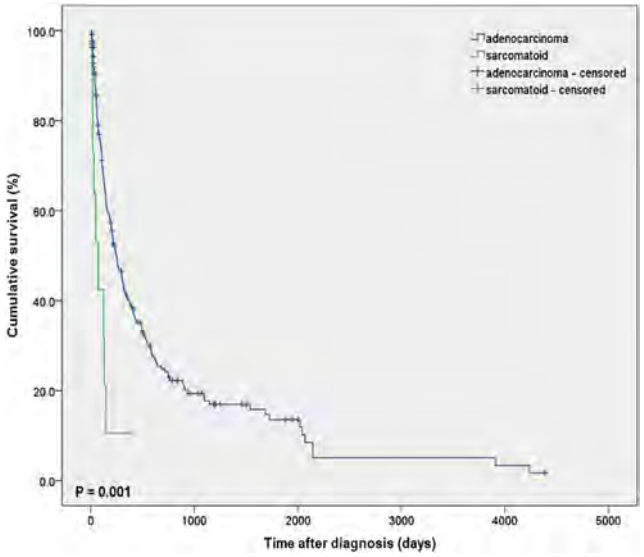

Figure: Comparison of cumulative survival rates

Results: Among 11 patients diagnosed with s-CCC, 9 (81.8%) were men and 2 (18.2%) were women. The median age was 61 years. Compared with 216 patients with CCC, fever, past history of chronic viral hepatitis, and LC were more common in patients with s-CCC. The incidence of abdominal pain was more likely to be significantly high in patients with s-CCC (10 cases, 90.9%). CEA and AFP levels were with normal range in most cases, which were not helpful in the diagnosis of s-CCC. The initial radiologic impression obtained via abdominal US and CT scan was very variable as IHCC, HCC, lymphoma, and hepatic abscess. None of the 11 patients were not clearly diagnosed with s-CCC at the first imaging study. In immunohistochemical findings, IHC study had shown that cancer cells expressed CK8, CK19 and vimentin, but not HSA and AFP. A larger mass size, more frequent distant metastasis, and more advanced stage were more likely to be observed in patients with s-CCC than those with CCC. The mean survival time of patients with s-CCC was significantly shorter than that of patients with CCC. (Figure 1)
Conclusion: Intrahepatic s-CCC of the liver is an extremely rare disease, and it characterized by non-specific symptoms and commonly diagnosed at an advanced stage. In addition, the prognosis is

extremely poor due to the rapid progression of the disease. Early diagnosis and appropriate treatment are important. Because clinical, serologic, and imaging findings are not helpful in distinguishing s-CCC from CCC, biopsy should be performed to accurately diagnose and predict prognosis. There has been no fully established treatment thus far, but, surgical resection is usually prioritized.

SAT-453

Effects of sorafenib on pancreatic volume and their clinical implications in patients with hepatocellular carcinoma

Francesca Benevento[1], Luca Ielasi[1], Francesco Tovoli[1], Luigi Bolondi[1], Alessandro Granito[1], Matteo Renzulli[2]. Email: francesca.benevento@aosp.bo.it

Background and aims: Sorafenib is the frontline therapy for advanced hepatocellular carcinoma (HCC). Pancreatic toxicity, from asymptomatic elevation of pancreatic enzymes to overt acute pancreatitis, is a common adverse even. Pancreatic atrophy has been reported as a relatively infrequent event. However, the actual prevalence of sorafenib-induced pancreatic atrophy, its clinical impact and its possible prognostic role remain elusive. Our aim to prospectively asses the pancreatic volume at the baseline and six months after the start of sorafenib. We also looked for correlations between pancreatic volume reduction, prevalence of sorafenib-related diarrhoea, and overall survival (OS).
Method: We evaluated 52 consecutive patients who started sorafenib for hepatocellurar carcinoma in our outpatient clinic. As part of the routine clinical examinations, these patients underwent a thorax-abdomen-pelvis computed tomography: a) within 2 weeks before the start of sorafenib; b) every two months after the first dose (± 2 weeks). Pancreatic volume and response to sorafenib were evaluated at each examination. Clinical evaluations were performed a week after each CT. Clinicians were blinded to the results of pancreatic volume assessment.
Results: Pancreatic volume was significantly lower 6 months after the start of sorafenib compared to the baseline ($p < 0.01$). In detail, 29 patients (55.8%) had a volume loss > 10%. The prevalence of diarrhoea was similar in patients with and without volume loss > 10% (48.2 vs 30.7%, $p = 0.403$). A significant volume loss was not associated with an higher rate of lipase elvation (34.5 vs 34.6%, $p = 1.000$). Either, there were no correlation with the median average daily dose of sorafenib or with the OS (median 9.6 vs 9.0 months, $p = 0.435$).
Conclusion: Reduction of pancreatic volume is a relatively common event in sorafenib-treated patiens, however it has no significant clinical implications.

Email: lmalahias@targetpharmasolutions.com

Background and aims: Over the past two years, there has been an expansion of systemic therapy options including tyrosine kinase inhibitors and immune checkpoint inhibitors for hepatocellular carcinoma (HCC). The aim of this study was to characterize clinical characteristics and HCC treatments in a contemporary cohort of HCC patients across diverse practice settings.
Method: TARGET-HCC, a multinational observational study, includes participants followed by hepatology and oncology investigators from academic and community sites in the US and Europe. In a combined retrospective/prospective design, medical records including provider narratives, laboratory, pathology, and imaging data are abstracted into a centralized database. Interventions for HCC, adverse events, and disease progression are longitudinally assessed.
Results: We identified 1198 pts enrolled across 47 sites who were diagnosed with HCC within 3 years of enrollment (median time from diagnosis to enrollment = 7 months). Most pts (76%) were male; white (73%), had underlying hepatitis C (61%), and most had Child Turcotte Pugh A (63%) or B (29%) cirrhosis. Distribution of Barcelona Clinic Liver Cancer (BCLC) tumor stage at diagnosis and initial treatment within 6 months of diagnosis are shown in Table 1. Only 38% of BCLC 0-A pts (n = 674) underwent curative treatment with ablation, resection, or transplant, with many (37%) instead undergoing non-curative locoregional therapy (LRT) and 3% undergoing systemic therapy (ST). Non-curative LRT was the most common type of treatment (63%) for BCLC-B pts (n = 258), although 24% were able to undergo curative treatment approaches whereas 9% were treated with ST. Surprisingly, only 23% of BCLC-C pts (n = 101) underwent ST with a large proportion (42%) still undergoing non-curative LRT. BCLC-C pts treated with LRT had less vascular invasion than those without LRT (31% vs 49%, respectively). For BCLC-C pts with follow-up of ≥ 6 months (n = 30), 11% received ST (primarily kinase inhibitors and/or immunotherapies) and 3% had radiation as second line treatment.

Figure: First Line Therapy Within 6 Months of Initial HCC Diagnosis by BCLC Stage at Diagnosis

First Line Therapy	BCLC-0 (N = 114)	BCLC-A (N = 560)	BCLC-B (N = 258)	BCLC-C (N = 101)	BCLC-D (N = 10)
LRT	67%	64%	72%	48%	40%
Ablation	42%	22%	16%	6%	10%
TACE	25%	36%	48%	26%	30%
Other Embol.	7%	13%	14%	18%	0%
Other LRT	2%	1%	0%	0%	0%
Resection	4%	15%	9%	13%	0%
Transplant	1%	0%	0%	0%	0%
External Radiation	2%	5%	3%	11%	20%
Systemic	1%	4%	10%	23%	10%
Treatment pending	29%	20%	14%	19%	30%

During a median follow-up of 11 months from diagnosis, 12% of all pts (n = 143) have died. Long-term follow-up is ongoing.

Conclusion: In a diverse cohort of patients with HCC in clinical practice, LRTs are frequently applied to pts with late stage disease, which may be discordant with current guidelines. Further evaluation of treatment paradigms and long-term outcomes is ongoing.

SAT-455

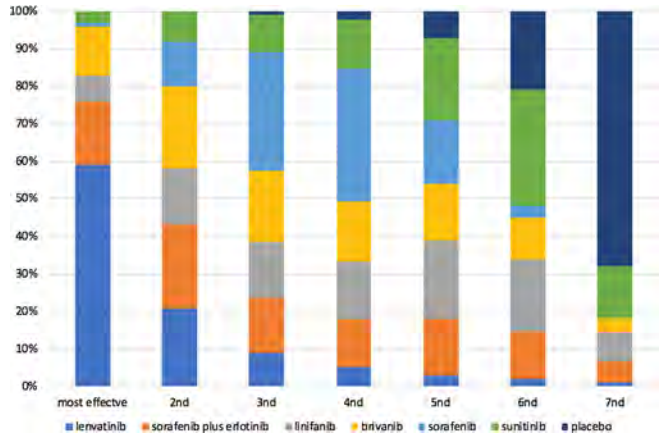
Efficacy of sorafenib and lenvatinib for hepatitis status: a network meta-analysis of phase III trial

Andrea Casadei Gardini[1]. [1]*IRST-IRCCS, Meldola, Italy*
Email: andrea.casadei@irst.emr.it

Background and aims: To date, there are no validated prognostic nor predictive markers of response to sorafenib in HCC, although hepatitis status seems to be a potential candidate.
For this reason, we conducted an NMA to evaluate whether the virus etiology could be used to determine which patients may benefit from either lenvatinib or sorafenib.
Method: Data were extracted from the publications or estimated as proposed by Parmar et al.[28]. Treatment effects were estimated by posterior means and 95% credible intervals (CrIs) using random

effect, identity link function and non-informative prior distributions (uniform and normal). We performed 25, 000 iterations with burn-in number of 5, 000 iterations and a thin interval of 20 to obtain the posterior distributions of model parameters. Convergence was assessed using the Brooks-Gelman-Rubin method. Posterior distributions were used to assess the probability of each treatment to be the best, second best and so on. Inconsistency and heterogeneity were assessed using node-split models, I2 and Cochran Q tests. Significant heterogeneity was considered to be present for I2 > 50% or p value > 0.10. Der Simonian and Laird method and random effect were used. All the analyses were made with the R packages "Metaphor" and "Gemtc" (https://www.r-project.org/).

Results: The NMA was performed on a total of 1, 788 patients on six study, of these 1160 patients were HCV-positive or HBV-positive. Of these, 251 (21.6%)HBV-positive patients and 91 (7.8%) HCV-positive patients received lenvatinib, whereas 390 (33.6%)HBV-positive patients and 229 (19.7%) HCV-positive patients received sorafenib. A total of 114 (9.8%)HBV-positive patients and 85 7.3%) HCV-positive patients received placebo. In the overall population no difference was observed between lenvatinib and sorafenib, despite if a slight trend towards a greater efficacy of lenvatinib (HR 0.92, 95% CrI0.61-1.36). Both lenvatinib and sorafenib were significantly better than placebo. When we restricted the analysis to HBV-positive patients, a significant benefit in terms of OS was estimated for sorafenib (HR 0.78 95% CrI 0.62-0.97) with respect to placebo; for HBV-positive patients there was a clear trend in favor of lenvatinib over sorafenib (HR 0.82 95% CrI 0.60-1.15).



For HCV-positive no differences between lenvatinib and sorafenib were observed (HR 0.91 95% CrI 0.41-2.01). I2, Cocran's Q and node-split models showed no evidence of heterogeneity nor inconsistence, strengthening the results of the NMA.

The rankogram in Fig. 1 reports the probably best approach for these patients. The rankogram show that Lenvatinib was probably the best approach for HBV-positive patients

Conclusion: Our data from NMA highlighted that lenvatinib has a greater activity in HBV-positive patients.

SAT-456

New multi inflammation indicators in advanced hepatocellular carcinoma patients receiving sorafenib

Andrea Casadei Gardini[1], Francesca Garuti[2], Andrea Neri[2], Franco Trevisani[3], Stefano Cascinu[4]. *[1]IRST, Meldola, Italy; [2]UNIBO, Bologna, Italy; [3]UNIBO, Meldola, Italy; [4]UNIMORE, Modena, Italy*
Email: andrea.casadei@irst.emr.it

Background and aims: Several inflammation and immune-based prognostic scores, such as lymphocyte count, neutrophil-lymphocyte ratio (NLR), and systemic immune-inflammation index (SII), have been developed to predict survival and recurrence in cancers, including HCC.

We evaluated the potential role of new multi inflammation indicators (MII) as predictors of outcome in HCC patients treated with sorafenib.

Method: 170 patients with HCC (24 BCLC B and 146 BCLC C) consecutively treated with sorafenib between March 2008 and August 2018 were enrolled. Information on neutrophil, lymphocyte and platelet counts was obtained from blood tests carried out the week before the start of treatment. The MII-1 was calculated as the ratio between the absolute neutrophil count and the lymphocyte count (NLR) x high sensitivity protein C reactive (hs-PCR); MII-2 was calculated as the ratio between the absolute platelet count and the lymphocyte count (PLR) x hs-PCR; MII-3 was calculated as platelet count × NLR (SII) x hs-PCR.

PFS and OS were estimated by the Kaplan-Meier method and curves were compared by the log-rank test. Unadjusted and adjusted hazard ratios (HRs) by baseline characteristics (age, gender, etiology, ECOG performance status) were calculated using the Cox proportional hazards model.

We also conducted landmark analyses to reduce possible confounding by time on treatment by assessing the impact of change in SII; NLR and PLR at 1 month landmark time on survival outcomes. X-tile 3.6.1 software (Yale University, New Haven, CT) was used to determine the cutoff value for baseline levels of each II.

Results: Median overall survival (OS) was 12.4 months (95% CI 9.6-15.4) and 8.9 months (95% CI 6.9-9.7) for patients with low (< 25) and high (≥ 25) MII-1 values, respectively (HR = 1.74, 95% CI 1.21-2.51, p = 0.003).

Median OS was 12.6 months (95% CI 9.6-16.2) and 8.9 months (95% CI 6.9-9.7) for patients with low (< 1424) and high (≥ 1424) MII-2 values, respectively (HR = 2.14, 95% CI 1.44-3.20, p = 0.0004).

Median OS was 12.6 months (95% CI 9.8-16.0) and 8.9 months (95% CI 6.9-9.6) for patients with low (< 6068) and high (≥ 6068) MII-3 values, respectively (HR = 1.91, 95% CI 1.98-2.90, p = 0.0005).

Multivariate analysis showed that MII-1, MII-2 and MII-3 were the only independent prognostic factors for OS and they outperformed NLR.

Conclusion: These news immune inflammation indicators represent potential prognostic indicator in patients with advanced HCC treated with sorafenib.

SAT-457

Sarcopenia determines post-progression outcomes in advanced hepatocellular carcinoma after sorafenib failure

Tsung-Yi Cheng[1], Pei-Chang Lee[1,2,3], Yi-Tzen Chen[4], Ming-Chih Hou[1], Yi-Hsiang Huang[1,2,5]. *[1]Taipei Veterans General Hospital, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei City, Taiwan; [2]National Yang-Ming University, Faculty of Medicine, School of Medicine, Taipei City, Taiwan; [3]National Yang-Ming University, Institute of Pharmacology, School of Medicine, Taipei City, Taiwan; [4]Taipei Veterans General Hospital, Department of Nursing, Department of Medicine, Taipei City, Taiwan; [5]National ang-Ming University, Institute of Clinical Medicine, School of Medicine, Taipei City, Taiwan*
Email: yhhuang@vghtpe.gov.tw

Background and aims: Sarcopenia, an objective surrogate for performance status, is associated with the degree of liver fibrosis, outcomes of patients with cirrhosis and hepatocellular carcinoma (HCC). In patients with advanced HCC after sorafenib treatment, most of the patients had poor ECOG performance status. Whether muscle mass still a prognostic factor after sorafenib failure was unclear. In this study, we aimed to determine the role of sarcopenia in advanced HCC patient after sorafenib treatment.

Method: From August 2012 to March 2017, 515 consecutive patients who received sorafenib treatment for advanced HCC in Taipei Veterans General Hospital were retrospectively reviewed. Among them, 381 patients who experienced radiology-proved progressive diseases (PD) and had complete clinical data were enrolled into the

analyses. Sarcopenia was defined as transverse psoas muscle thickness per height less than 16.8 mm/m.
Results: The prevalence of sarcopenia was 64.8% (247/381) at the time of PD after sorafenib treatment. Sarcopenia was female predominant and was associated with lower body mass index, chronic hepatitis C infection, larger tumor size, prolonged prothrombin time, lower serum albumin level, more ascites formation, and higher grade of albumin-bilirubin (ALBI) grade. Patients with sarcopenia had significantly shorter post-progression survival (PPS) compared with the counterparts (median PPS 3.9 vs 5.8 months, p = 0.005). In multivariate analyses, large tumor size (> 10 cm), high alpha-fetoprotein level (> 400 ng/ml), ALBI grade, early progression within 4 months, presence of new extrahepatic metastasis, and sarcopenia were independent risk factors to post-progression mortality. After adjustment of other factors, sarcopenia remained a significant predictor to a poor PPS in sorafenib-failed HCC (hazard ratio [HR] = 1.30, p = 0.029).
Conclusion: Sarcopenia significantly differentiates PPS and is an independent prognostic factor to determine mortality in sorafenib-failed HCC. Building muscle mass is important for advanced HCC patients after sorafenib failure before entry into second-line systemic therapy to prolong survival.

SAT-458

Subtraction arterial images of hepatocyte-specific contrast-enhanced MRI: Added value for the diagnosis of hepatocellular carcinoma in the liver imaging reporting and data system v2018

Sang Hyun Choi[1], Dong Hwan Kim[1], Jae Ho Byun[1], So Jung Lee[1], So Yeon Kim[1], Hyung Jin Won[1], Yong Moon Shin[1], Pyo-Nyun Kim[1].
[1]*Asan Medical Center, Radiology, Seoul, Korea, Rep. of South*
Email: jhbyun@amc.seoul.kr

Background and aims: Arterial-phase image of hepatocyte-specific contrast-enhanced magnetic resonance image (MRI) has not been satisfactory due to weak arterial hyperenhancement, despite its higher sensitivity for diagnosing hepatocellular carcinoma (HCC). We investigated the clinical effect of arterial subtraction images of gadoxetate-enhanced MRI in diagnosing HCC using natural history cohort.
Method: We retrospectively analyzed 372 hepatic nodules (273 HCCs, 18 other malignancies, and 81 benign nodules) 3.0 cm or smaller of 258 patients at risk of HCC who underwent hepatocyte-specific contrast-enhanced MRI in 2016. Final diagnosis was assessed histopathologically or clinically (marginal recurrence after treatment or change in lesion size on follow-up imaging). We compared the detection rate of arterial hyperenhancement between ordinary arterial-phase image and subtraction arterial image and assessed effect of subtraction arterial images in diagnosing HCC using the Liver Imaging Reporting and Data System (LI-RADS) v2018.

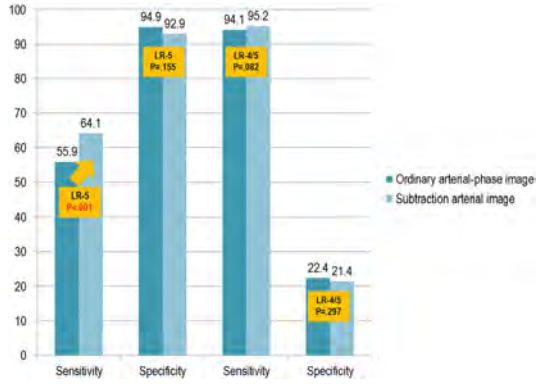


Figure 1: Comparison of Diagnostic Performance for HCC According to the LI-RADS between the Ordinary Arterial-Phase Image and Arterial Subtraction Image for 368 Hepatic Nodules. NOTE. After excluding four LR-TIV nodules from whole 372 nodules, 368 hepatic nodules were used for the analysis.

Results: Subtraction arterial images had a significantly higher detection rate of arterial hyperenhancement than ordinary arterial-phase images for all hepatic nodules (72.3% vs. 62.4%, p <.001) and HCCs (91.9% vs. 80.6%, p <.001; Fig. 1). Compared with ordinary arterial-phase images, subtraction arterial images significantly increased sensitivity of LI-RADS category 5 for diagnosing HCC (64.1% vs. 55.9%, p <.001, Fig. 1), without a significantly decreasing specificity (92.9% vs. 94.9%, p = .155). For histopathologically confirmed lesions, subtraction arterial images significantly increased sensitivity to 68.8% from 61.3% of ordinary arterial-phase images (p <.001) with a minimal decrease in specificity to 84.8% from 89.1% (p = .151).
Conclusion: Subtraction arterial images of hepatocyte-specific contrast-enhanced MRI can significantly improve sensitivity for diagnosing HCC, without a significantly decreasing specificity.

SAT-459

NASH as a risk factor for intrahepatic cholangiocarcinoma and its prognostic role: Case-control study

Stefania De Lorenzo[1], Francesco Tovoli[2], Francesco Vasuri[3], Deborah Malvi[3], Maria Antonietta D'errico[3], Giovanni Brandi[1]. [1]*Sant'Orsola-Malpighi Hospital, University of Bologna, Department of Experimental, Diagnostic and Specialty Medicine, Bologna, Italy;* [2]*Sant'Orsola-Malpighi Hospital, University of Bologna, Department of Medical and Surgical Sciences, Bologna, Italy;* [3]*Sant'Orsola-Malpighi Hospital, Bologna University, "F Addarii" Institute of Oncology and Transplantation Pathology, Bologna, Italy*
Email: stefania.delorenzo@libero.it

Background and aims: The prevalence of intrahepatic cholangiocarcinoma (ICC) is rising worldwide. The current epidemics of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) might be partly responsible for this trend.
Method: Case control study investigating the prevalence of histology-confirmed NASH in peritumoral liver of resected ICC patients and controls (pre-explant biopsies of liver donors). Controls were matched for age and sex in a 2:1 fashion. Correlates between NASH, tumor characteristics and overall survival (OS) were also explored in the ICC cohort.
Results: Between 2006 and 2017, 84 ICCs were resected in our Institution. Sixty-two (74%) had no apparent risk factors for ICC. Amongst this group, the prevalence of NAFLD and NASH was 45.2% and 24.2%, respectively, compared to 44.3 and 8.9% in the 124 matched liver donors ($p = 1.000$ and $p = 0.007$, respectively). The 5-year OS rate was 20.0% in NASH and 57.4% in ICC without either NASH and other risk factors ($p = 0.017$). Main tumor size, sex and NASH (hazard ratio 2.618, 95% confidence interval 1.140-6.013, $p = 0.023$) were independent predictors of the OS at the multivariate Cox regression.
Conclusion: NASH (but not NAFLD) acts as a risk factor for ICC and may affect its long-term outcome. A collaborative multicenter approach could confirm and strengthen these data.

SAT-460

Influence of sustained virological response in diagnostic performance of alpha-fetoprotein for hepatocellular carcinoma in patients with HCV-cirrhosis

Ana Gomez[1,1], Carmen Álvarez-Navascués[1], Valle Cadahía-Rodrigo[1], María Torner[1], Maria Luisa Gonzalez Dieguez[1], Maria Varela[1], Manuel Rodríguez[1]. [1]*Hospital Universitario Central de Asturias, Liver Unit. Division of Gastroenterology and Hepatology, Oviedo, Spain*
Email: canavascues99@movistar.es

Background and aims: The usefulness of alpha-fetoprotein (AFP) for hepatocellular carcinoma (HCC) surveillance has been limited by its low sensitivity (sen.) and specificity (spe.), mainly in patients with viral cirrhosis. The aim of this study was to know AFP behavior in patients with HCV-cirrhosis included in an HCC surveillance program, comparing patients with sustained virological response (SVR) and viremic patients (VIR).
Method: 349 patients with HCV-cirrhosis, without HCC, follow-up ≥ 18 months and > 3 AFP determinations (det.) (223 SVR/126 VIR), enrolled in a surveillance program based in biannual US/AFP were analyzed. 105 additional patients with HCV-cirrhosis who developed HCC within the program were also included (with AFP at HCC diagnosis and 6 months earlier). 2141 AFP det. in patients without HCC were collected (median: 6/patient; 1305 in SVR and 836 in VIR). ROC curves were used for the analysis of sen./esp., considering the first AFP det. in patients without HCC and the one at diagnosis in those with HCC.
Results: Most patients without HCC were male (65.3%), age 54 years, genotype 1 (79.3%) and CHILD-Pugh A (91.1%). In 83% SVR was obtained with DAA. The proportion of AFP det. > 10, > 15 y > 20 ng/ml in SVR and VIR patients was 4.3% vs 45%, 0.45% vs 28.7% y 0.22% vs 21.1% ($p < 0.001$). No SVR patient had det. > 20 ng/ml and more than twice the previous det., while this fact was present in 2, 75% in VIR patients ($p < 0.001$). Patients with HCC were mainly male (75.2%), genotype 1 (69.5%). Among them, 18 (17%) had developed HCC after SVR. The proportion of patients with AFp > 10, > 15 y > 20 ng/ml at HCC diagnosis was 60, 9%, 59% y 49, 5% respectively, without differences between SVR and VIR patients ($p > 0.5$). 28, 5% of patients had AFp > 20 ng/ml and more than twice the previous det. Area under the ROC curve of AFP for HCC diagnosis was 0, 77 (IC95%:0.71-0.83) in the global series, 0.65 (IC95%:0.57-0.73) in VIR patients and 0.75 (IC95%:0.59-0.92) in SVR. The value with higher diagnostic efficacy was 15 ng/ml in VIR patients (sen.58.6%; spe.73.4%) and 10 ng/ml in those SVR (sen.66.7%; spe.94.2%; VPP 48%, VPN 97.2%).
Conclusion: In HCV-cirrhosis, SVR leads to a normalization of AFP value, lowering the proportion of false positives. SVR also allows to reduce the value with most discriminative ability, increasing sensibility. As a consequence, diagnostic performance of AFP substantially improves after SVR. These results open the door to re-evaluate AFP role in HCC screening in patients with HCV-cirrhosis.

SAT-461

HCC recurrence after DAA treatment in HCV patients

Maria Guarino[1], Dario Bruzzese[2], Giovan Giuseppe Di Costanzo[3], Marco Guarracino[3], Federica Morando[1], Anna Sessa[1], Luca Rinaldi[4], Marcello Persico[5], Angelo Salomone Megna[6], Coppola Nicola[7], Valentina Cossiga[1], Nicola Caporaso[1], Filomena Morisco[1]. Email: maria.guarino86@gmail.com

Background and aims: The present real-life multicenter, prospective study aims to investigate the effects of DAAs IFN-free therapies in HCV patients with a previous successfully treated HCC, in terms of neoplastic recurrence and SVR rates.
Method: From March 2015 to March 2017, all consecutive HCV patients with a previous successfully treated HCC and underwent to DAAs therapy were enrolled. The baseline clinical, biochemical and radiological data were registered. The assessment of neoplastic recurrence was used as primary outcome, while a secondary outcome was the evaluation of patients characteristics predicting HCC recurrence. Cumulative probabilities of recurrence were extracted from time-to-event curves based on Kaplan-Meier product limit method Hazard ratios (HRs) with 95% confidence intervals (95% CIs) were estimated using univariate and multivariable Cox regressions.
Results: Eighty-three percent of patients were in Child-Pugh class A, and 89% had a history of HCC BCLC stage 0/A, while 35% of patients had a prior HCC recurrence. Ninety-one percent of the patients achieved SVR. The median time between the HCC 1st diagnosis and DAAs-starting was 17.2 months (range 10.1-37.2), while the median time from the last successful HCC treatment to DAAs starting was 10 months (range 5.8-16.6). Thirty-one HCC recurrences were observed from DAAs-starting in a median observational follow-up of 31.7 months. The incidence rate of recurrence was 20.5/100 person-year (95% C.I. 13.9-29.0). The 6-, 12- and 24-months HCC recurrence rates from the last HCC treatment were 1%, 8.9% and 25.6%, respectively. Higher BMI (HR 1.20, 95% C.I. 1.01-1.42, $p = 0.020$), higher levels of Total Bilirubin (HR 2.54, 95% C.I. 1.04 to 6.19, $p = 0.041$) and of AFP (HR 1.02, 95% C.I. 1.001-1.03, $p = 0.019$) and DAA treatment failure (HR 5.68, 95% C.I. 1.63 to 19.80) (fig. 1) were significantly associated with

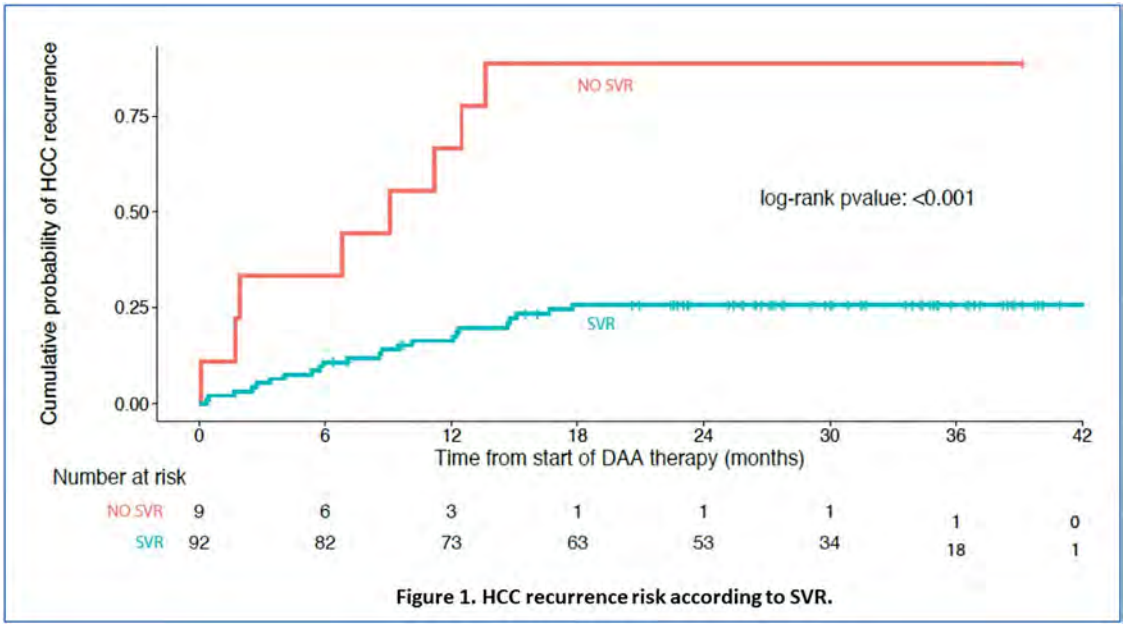

Figure 1. HCC recurrence risk according to SVR.

Figure: (abstract: SAT-461)

higher risk of HCC recurrence, both at univariate and at Cox multivariable analysis.

Conclusion: Patients with lower risk of HCC recurrence are characterized by lower BMI, lower bilirubin and AFP levels and higher SVR rate. These data suggest that the absence of well-known HCC risk factors reduces the HCC recurrence rate also in patients underwent DAAs.

SAT-462

Current non-invasive liver reserve models do not predict histological fibrosis severity in hepatocellular carcinoma

Teh-Ia Huo[1], Shu Yein Ho[1], Po-Hong Liu[1], Chia-Yang Hsu[1], Chien-Wei Su[1], Yi-Hsaing Huang[1], Ming-Chih Hou[1]. *[1]Taipei Veterans General Hospital, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan*
Email: tihuo@vghtpe.gov.tw

Background and aims: The Ishak scoring system has been used to stage liver fibrosis. Ten non-invasive liver reserve models were proposed to assess the severity of liver fibrosis, but their performance in hepatocellular carcinoma (HCC) is unknown. We aimed to evaluate the correlation between these models and severity of fibrosis in patients with HCC.

PALBI	-0.113	0.105	0.186	0.109

Method: A total 464 patients with HCC undergoing surgical resection were retrospectively analyzed. Multivariate logistic regression analysis was performed to determine independent factors associated with advanced fibrosis (Ishak score 4 or higher).

Results: There were no significant correlations between all non-invasive models and severity of fibrosis in HCC (p for trend all > 0.1). In subgroup analysis, cirrhosis discriminant index (CDS) and Lok's index in hepatitis B-, and fibrosis index based on 4 factors (FIB-4), CDS and Lok's index in hepatitis C-associated HCC, best correlated with the severity of liver fibrosis. Low platelet count, prolonged prothrombin time, hepatitis C and multiple tumors were independently associated with advanced fibrosis. Among the 10 models, CDS was the best model to predict cirrhosis.

Conclusion: Currently used non-invasive liver reserve models do not well correlate with severity of histological fibrosis in HCC. New non-invasive models are required to improve the predictive accuracy of liver fibrosis in HCC.

Albumin-bilirubin grade-based nomogram to predict tumor recurrence in patients with hepatocellular carcinoma

Teh-Ia Huo[1], Shu Yein Ho[1], Po-Hong Liu[1], Chia-Yang Hsu[1], Yi-Hsaing Huang[1], Chien-Wei Su[1], Ming-Chih Hou[1]. [1]*Taipei Veterans General Hospital, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan*
Email: tihuo@vghtpe.gov.tw

Background and aims: Tumor recurrence after curative resection is common in hepatocellular carcinoma (HCC), but large-scale long-term prediction on an individual basis has seldom been reported. We aimed to construct an albumin-bilirubin (ALBI) grade-based nomogram to predict tumor recurrence in patients with HCC undergoing surgical resection.

Method: A total 1, 038 patients with newly diagnosed HCC undergoing curative resection between 2002 and 2016 were enrolled. Baseline characteristics, tumor status and severity of liver functional reserve were collected. The Cox proportional hazards model was used to predict tumor recurrence and construct the nomogram. The performance of the nomogram was evaluated by the discrimination and calibration tests.

Results: After a mean follow-up time of 30 months, 510 (49%) patients developed tumor recurrence. The cumulative recurrence-free survival at 1, 3, 5, and 10 years were 79%, 51%, 38% and 26%, respectively. In the Cox multivariate model, ALBI grade 2-3, multiple tumors, tumor size equal or large than 2 cm, serum α-fetoprotein level equal or greater than 20 ng/ml and total tumor volume equal or larger than 227 cm^3 were independent risk factors associated with tumor recurrence. A nomogram was constructed based on these five variables. Internal validation with 10, 380 bootstrapped sample sets had a good concordance of 0.607 (95% of confidence interval: 0.587-0.627). The calibration plots for 1-, 3- and 5-year recurrence-free survival well matched the idealized 45-degree line.
Conclusion: ALBI is a feasible marker for tumor recurrence. This easy-to-use ALBI grade-based nomogram may predict tumor recurrence for individual HCC patient undergoing surgical resection.

Predictive value of pretreatment neutrophil-to-lymphocyte ratio in survival of patients with hepatocellular carcinoma

Young Mi Hong[1], Mong Cho[1], Ki Tae yoon[1]. [1]*Pusan National University Yangsan Hospital, Gastroenterology, yangsan, Korea, Rep. of South*
Email: mcho@pusan.ac.kr

Background and aims: Hepatocellular carcinoma (HCC) is inflammation-related cancer because nonresolving inflammation contributes to the development and progression of HCC. The neutrophil-to-lymphocyte ratio (NLR) has been shown to be associated with prognosis in various types of cancer. The present study aimed to investigate the utility of NLR in the prognosis after diagnosis of HCC.
Method: We retrospectively analyzed data regarding peripheral blood inflammatory cells, patient and tumor characteristics from HCC patients who diagnosed with HCC between November 2008 and December 2017. Baseline data were recorded before treatment. The relationships between overall survival (OS) and the variables including the NLR were assessed.
Results: A total of 1, 688 patients who diagnosed with HCC were included. In multivariate analysis elevated NLR, multiple tumors, large tumor size, underlying liver cirrhosis, vascular invasion, extrahepatic metastases, high tumor markers, low albumin and high bilirubin were found as independent indicators of poor overall survival. The NLR rose in association with advancing the BCLC stage ($p < 0.001$). An NLR ≥ 1.9 was a significant predictor of poor overall survival ($p < 0.0001$).
Conclusion: We have demonstrated that an elevated pretreatment NLR is associated with a poor overall survival in patients for HCC.

SAT-465

The NIACE Score: A prognostic indicator in Hepatocellular carcinoma

Julien Nithianandan[1], Stuart Roberts[2], Ammar Majeed[2], Gauri Mishra[3], William Kemp[2]. [1]*Alfred Hospital, Melbourne, Australia;* [2]*Alfred Hospital, Department of Gastroenterology, Melbourne, Australia;* [3]*Monash Medical Centre, Gastroenterology Department, Melbourne, Australia*
Email: w.kemp@alfred.org.au

Background and aims: The Barcelona Clinic Liver Cancer (BCLC) classification is the reference system to stage and prognosticate hepatocellular carcinoma (HCC). The NIACE (tumour nodularity, infiltrative nature of the tumour, serum alpha-fetoprotein level, Child-Pugh score, and ECOG performance status) score uniquely considers tumour characteristics, although is yet to be validated in an Australian context. It is suggested that the NIACE score may offer prognostic clarity in some BCLC classes, which encompass heterogenous tumours matched with single management options. We aimed to compare the prognostic value of the NIACE score within the BCLC staging system

Method: We retrospectively analysed data from a cohort of 2202 patients with HCC, across six metropolitan hospitals in Victoria, Australia from the period January 2000-August 2018. Patients were included in the study if all markers were available to calculate prognostic scores including: tumour nodularity (0 if < 3, 1 if ≥ 3), tumour infiltration (0 if no, 1.5 if yes), serum AFP (0 if < 200, 1.5 if ≥ 200 ng/ml), Child-Pugh score (0 if A, 1.5 if B) and ECOG status (0 if 0, 1.5 if ≥ 1). Baseline characteristics including age, sex, country of birth, ethnicity, aetiology of chronic liver disease, and presence cirrhosis were recorded. Survival time was measured from date of diagnosis to date of death (or censored at last follow-up). Transplant-free survival (TFS) was used as the end point for analysis.

Results: A total of 366 patients (M/F = 86%/14%; median age at diagnosis = 63 ± 12 yrs; Australian born 103 (28.1%)) were included in the analysis. Aetiology of liver disease was HBV = 64 (17.4%), HCV = 157 (42.8%), alcohol = 143 (39.0%), and other = 108 (29.4%). The mean serum AFP level for the cohort was 7839 ng/ml. During a median follow-up time of 16 mths, 185 patients (50.4%) had deceased. The median TFS for BCLC 0 (n = 21), A (n = 108), B (n = 82), C (n = 113) and D (n = 39) were; 64, 29, 24, 12 and 4 months respectively (p < 0.001). The Transplant-free survival for NIACE score < 2.5 (n = 169) vs ≥ 2.5 (197) was 34 ± 3mths vs 12 ± 2mths, p < 0.001. Furthermore, NIACE had prognostic value within BCLC subclasses with the TFS of patients within BCLC-A (36 ± 7mths vs 20 ± 3mths, p < 0.01) and BCLC-B (31 ± 7mths vs 19 ± 4mths, p < 0.005) being significantly different for scores of < 2.5 vs ≥ 2.5 respectively. There was no significant discriminating ability amongst later stage BCLC C or D.

Conclusion: The NIACE score is a relatively easy-to-calculate prognostic score that distinguishes 2 subgroups with different prognosis within BCLC A and B stage HCC. This is the first validation of the score in an Australian population. Further prospective validation of the NIACE score in HCC patients and comparison with other simple scores such as ALBI grade is warranted to confirm its prognostic value and use in guiding decision making in conjunction with the BCLC staging system.

SAT-466

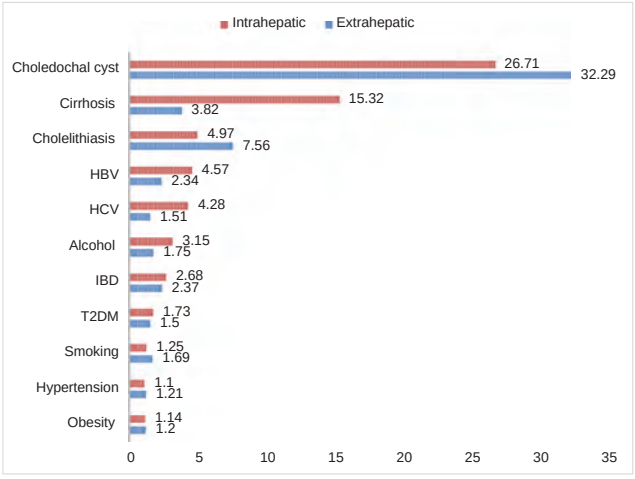
A meta-analysis of risk factors for intrahepatic and extrahepatic cholangiocarcinoma

Shahid Khan[1], Oliver Clements[1]. [1]*Imperial College London, Hepatology, London, United Kingdom*
Email: shahid.khan@imperial.ac.uk

Background and aims: Cholangiocarcinoma (CCA) carries a poor prognosis. Multiple studies report an increasing incidence of CCA, particularly intrahepatic CCA, globally. This systematic review and meta-analysis analysed the association of previously inconclusive or unexplored risk factors, as well as those previously reported, for both iCCA and extrahepatic CCA (eCCA).

Method: A literature search of case-control studies was performed to identify potential risk factors for CCA. Revman 5.3 was used to calculate pooled odds ratios (OR) with 95% confidence intervals. Heterogeneity was assessed with the Cochrane Q test. A random effects model was utilised when there was significant heterogeneity. Funnel plots were used to assess for publication bias.

Results: 25 studies were identified from seven countries and 11 risk factors selected for meta-analysis. Choledochal cysts infer the greatest risk of both ICC and ECC: pooled ORs 26.71 (95% CI, 15.80-45.16) and 32.29 (95% CI, 26.90-38.78), respectively. Cirrhosis inferred significant risk, stronger for ICC than ECC (OR 15.32 and 3.82, respectively). Hypertension was associated with least risk of ICC with a pooled OR of 1.10 (95% CI, 0.89-1.37) and obesity was found to infer the least risk of ECC with a pooled OR of 1.20 (95% CI, 0.84-1.70). There was no evidence of publication bias.



Conclusion: This is the most comprehensive meta-analysis of risk factors for CCA to date. Multiple studies report increasing trends in some of these risk factors which may partially explain the increasing incidence of iCCA.

SAT-467

Pathologic identity of indeterminate hepatic nodules on dynamic computed tomography images of cirrhotic patients undergoing liver transplantation: A potential bias in evaluating suitability for transplantation

Ha Il Kim[1], Jihye Lim[2], Ju Hyun Shim[1], Han Chu Lee[1]. [1]*Asan medical center, Gastroenterology, Seoul, Korea, Rep. of South;* [2]*Asan medical center, Internal medicine, Seoul, Korea, Rep. of South*
Email: s5854@amc.seoul.kr

Background and aims: There has been no consistent practical guidance on whether to do biopsy or to wait and see for indeterminate hepatic nodules (IDNs) not meeting diagnostic criteria for hepatocellular carcinoma (HCC) by the combination of arterial hyper-enhancement and portal/delayed wash-out in cirrhotic patients. The aim of this study based on explant pathology of cirrhotic patients is to investigate histological identities for differently-enhanced lesions considered to be IDNs on dynamic computed tomography (CT) images before liver transplantation (LT).

Method: This study included 239 cirrhotic patients who primarily underwent LT and had dynamic CT images within two months before LT at Asan Medical Center. All patients had at least one hepatic nodule ≥ 1 cm in diameter on CT, which were definitely not benign lesions such as hemangioma and cyst; and ≤ 4 measurable nodules. IDNs on CT were histologically classified by correlating with corresponding

explant pathology. Parameters predicting malignant potential of IDN were examined.
Results: Most of included patients were infected with hepatitis B (68%) with a median age of 54 years. A total of 316 nodules in all 239 patients were identified: 112 classified as HCC and 204 as IDN by CT. Eighty-seven percent of IDNs were measured ≤ 3 cm in size. Analyses of radio-pathological correlation of IDNs revealed that 123 out of 204 IDNs (60%) were proved to be malignant tumors with 115 HCCs, 1 cholangiocarcinoma (CCA), and 1 combined HCC-CCA. Non-malignant IDNs in the explant livers were mostly dysplastic nodules (75%). Arterial iso- and portal/delayed hypo-attenuation was the enhancement pattern with the highest possibility of malignant IDNs (73%:43/59), followed by hyper- and iso- (60%:59/99), hyper- and hyper- (57%:8/14), hypo- and hypo- (48%:12/25), and iso- and hyper-attenuation (25%:1/4). There were no malignant IDNs with hypo- and hyper-attenuation or hypo- and iso-attenuation. Most of radiological HCCs (90.2%) were correctly confirmed on explant examination. No clinical, radiological, and temporal factors including serum alpha-fetoprotein level, size of nodule, arterial and portal/delayed patterns, and interval change of the nodule were significantly associated with malignant IDNs (Ps < 0.05). In our series, 43 patients within Milan by pre-LT CT turned out to be beyond Milan by explant pathology in which malignant IDNs could be calculated.
Conclusion: Our study indicates that a considerable number (60%) of small hepatic nodules considered indeterminate on dynamic CT images of LT patients with cirrhosis contained primary malignancies, mostly HCC in a HBV-endemic country. Biopsy-based evaluation of IDNs may be preferred in clinical practice, and careful assessment of the eligibility for LT is required in cirrhotics with IDNs.

SAT-468
Prognostic value of post-treatment liver stiffness in hepatocellular carinoma with histologically confirmed cirrhosis
Jung Il Lee[1], Kwan Sik Lee[1], Hyun Woong Lee[1], Hye Young Chang[2].
[1]*Yonsei University College of Medicine, Seoul, Korea, Rep. of South;* [2]*Gangnam Severance Hosptial, Yonsei University College of Medicine, Seoul, Korea, Rep. of South*
Email: mdflorence@yuhs.ac

Background and aims: Severity of liver fibrosis can be non-invasively evaluated by measuring liver stiffness (LS) using transient elastography, and patients with cirrhosis may undergo dynamic changes in LS measurements (LSM) after antiviral therapy. This study aimed to evaluate the value of achieving low LSM after curative resection in hepatocellular carcinoma (HCC) patients with histologically proven liver cirrhosis.
Method: Total 192 (n = 146, newly started antiviral therapy [AVT]; n = 46, previously started AVT) patients that received curative surgery for HBV related HCC at Barcelona Clinic Liver Cancer stage 0-A, and had METAVIR fibrosis 4, were investigated.
Results: The follow-up LSM significantly decreased in newly started AVT group (New AVT) (p = 0.002) whereas no significant changes were noticed in previous AVT (Previous AVT) group (p = 0.062). Achieving low LSM (≤ 8 kiloPascal [kPa]) had no predictive value in early recurrence in both groups (p = 0.520 and *P* = 0.898, respectively). However, low LSM (≤ 8 kPa) during the follow-up suggested reduced risk of late recurrence (> 12 months) (Hazard Ratio [HR], 0.519; 95% Confidence Interval [CI], 0.307-0.877; *P* = 0.014) in New AVT group whereas no predictive value was found for in Previous AVT group (p = 0.375). Late recurrence suggested increased risk of mortality in New AVT group (HR, 14.80, 1.894-115.718; *P* = 0.010) along with having low APRI score during the follow-up (HR, 0.234, 0.066-0.831; *P* = 0.025). No significant predictors were detected in Previous AVT group.
Conclusion: Among those with HCC occurred without concomitant antiviral therapy, achieving low LSM (≤ 8 kPa) after antiviral therapy might be a good prognostic marker for late recurrence after surgery even with histologically confirmed cirrhosis.

SAT-469
Frequency of TP53, CTNNB1, and TERT promoter mutations in patients with hepatocellular carcinoma from Southern Italy
Daniele Lombardo[1], Carlo Saitta[2], Cristina Musolino[1], Giuseppe Navarra[3], Giovanni Raimondo[2], Teresa Pollicino[3].
[1]*University of Messina, Department of Clinical and Experimental Medicine, Messina, Italy;* [2]*University Hospital of Messina, Department of Internal Medicine, Messina, Italy;* [3]*University Hospital of Messina, Department of Human Pathology, Messina, Italy*
Email: tpollicino@unime.it

Background and aims: Mutations in TP53 and CTNNB1 genes as well as in TERT promoter are considered drivers for hepatocellular carcinoma (HCC) development. They show variable frequencies in different geographic areas, possibly depending on liver disease etiology and environmental factors.
Method: We investigated TP53, CTNNB1, and TERT genetic mutations using direct Sanger sequencing technique in tumor and non-tumor liver tissues from 67 patients with HCC (43 HCV or HBV related; 24 non-virus related) as well as in liver tissue specimens from 30 subjects with non-alcoholic fatty liver as control. All studied subjects were from Southern Italy. TERT expression was assessed by quantitative RT-PCR in duplicate using TaqMan (Applied Biosystems) gene expression assay.
Results: No CTNNB1 mutation or TP53 R249S substitution were detected in any case. The homo- or heterozygous TP53 R72P polymorphism was found in 10/67 (14.9%) tumors, in 0/67 (0%) non-tumor tissues (p = 0.001), and in 0/30 controls (p = 0.02) analyzed. Two TERT gene promoter mutations were found in 33/67 (49.2%) tumor tissues examined. None of the non-tumor tissues and of the liver specimens from control subjects carried these mutations. The most frequent mutation was the known hot spot located at −124 bp from the ATG start site of TERT (−124G > A, 28 cases, 41.8%; P < 0.001). The other mutation-never described before-was located in the promoter at −300 bp from the ATG (−300G > C, 5 cases, 7.5%; P = 0.02). This mutation creates a typical TFII-I binding sequence (CTGTCC), and was found alone (2 cases) or in combination (3 cases) with the −124 bp mutation. Neither TP53 R72P polymorphism nor the two TERT gene promoter mutations were associated with viral or non-viral etiology.
Real-time PCR experiments showed that mutations at −124 bp and −300 bp induced a 20-fold and 4-fold increase of TERT expression, respectively. When both mutations were present in the promoter, expression of TERT was increased more than 100-fold.
Conclusion: CTNNB1 mutations are uncommon in patients with HCC in our geographic area, whereas the TP53 R72P substitution and TERT promoter mutations at −124 bp and −300 bp are significantly associated with HCC. The combination of mutations at −124 bp and at −300 bp strongly induces TERT promoter activity.

SAT-470
Circulating levels of soluble urokinase plasminogen activator receptor (suPAR) predict outcome after resection of cholangiocarcinoma
Sven Loosen[1], Frank Tacke[1], Annemarie Breuer[1], Jakob Kather[1], Thomas Longerich[2], Alexander Koch[1], Christian Trautwein[1], Christoph RODERBURG[1], Ulf Neumann[1], Tom Lüdde[1]. [1]*University Hospital RWTH Aachen, Aachen, Germany;* [2]*University Hospital Heidelberg, Heidelberg, Germany*
Email: sloosen@ukaachen.de

Background and aims: While surgical resection has remained the only potentially curative therapy for patients with cholangiocarcinoma (CCA), 5-year survival rates after tumor resection are still below 30%, corroborating the urgent need for better preoperative stratification tools to identify the ideal surgical candidates. The soluble urokinase plasminogen activator receptor (suPAR) has evolved as a prognostic marker for various clinical conditions but its role in the context of CCA has remained unknown. In this study, we evaluated

circulating levels of suPAR as novel biomarker in patients undergoing resection of CCA.
Method: Tumor expression of uPAR, the membrane bound source of circulating suPAR, was analysed by IHC in 108 CCA samples. Serum levels of suPAR were measured by ELISA in a trainings and validation cohort comprising a total of 117 CCA patients as well as 76 healthy controls and 11 patients with primary sclerosing cholangitis (PSC).
Results: High tumoral uPAR expression was associated with an impaired outcome after CCA resection. Moreover, circulating levels of suPAR were significantly elevated in CCA patients compared to PSC patients and healthy controls. Importantly, patients with initial suPAR levels above the ideal prognostic cut-off value of 3.72 ng/ml had a significantly impaired long-term survival in the trainings and validation cohort. The prognostic relevance of circulating suPAR was further confirmed by uni- and multivariate Cox regression analysis. Finally, high pre-operative suPAR levels were indicative for acute kidney injury after tumor resection.

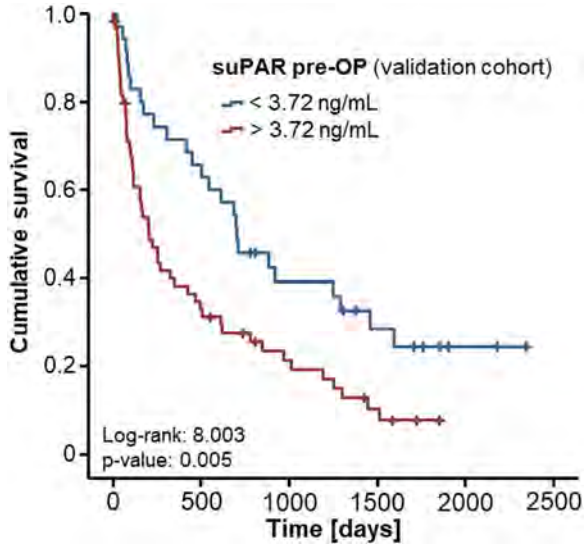


Figure 1: **Overall survival after tumor resection**. Patients with preoperative suPAR serum levels above the optimal cut-off value of 3.72 ng/ml show a significantly impaired long-term survival after tumor resection.

Conclusion: Circulating suPAR represents a previously unrecognized biomarker in patients with resectable CCA which might help to preoperatively identify the ideal candidates for extended liver resection.

SAT-471

Hepatic adenomatosis increases risk of hepatic adenoma bleeding

Chelsea Mcdermott[1], Christine Cho-Shing Hsu, MD[2], Sameer Desale[3], Stephen Fernandez, MPH[3], Marco Ertreo, MD[4], Reena C. Jha, MD[4], Rohit S. Satoskar, MD[2], Alexander T. Lalos, MD[2], Amol S. Rangnekar, MD[2], Arul M. Thomas, MD[2], Coleman I. Smith, MD[2], Thomas W. Faust, MD[2]. *[1]Georgetown University School of Medicine, Washington, United States; [2]MedStar Georgetown University Hospital Transplant Institute, Washington, United States; [3]MedStar Health Research Institute, Biostatistics and Biomedical Informatics, Washington, United States; [4]MedStar Georgetown University Hospital, Radiology, Washington, United States*
Email: cmm474@georgetown.edu

Background and aims: Known risk factors for hepatic adenoma (HA) bleeding are size > 5 cm, Beta-catenin mutated and Sonic hedgehog activated adenomas. The objective of this study is to determine additional clinical risk factors for HA bleeding.
Method: Retrospective analysis of patients diagnosed with HA by MRI at a single-center academic hospital. Demographics, clinical data, and data from initial and latest MRIs were collected. Number of lesions and largest three lesion sizes were recorded for patients with multiple HAs. Complications and treatments delivered were followed.
Results: 187 patients were reviewed. 94% were women, the mean age was 47.7 ± 13.7 years and median follow-up time was 386 days (IQR 172, 1142). Of the 132 patients who had clinical follow-up and follow-up MRIs, 17.6% (all women) experienced bleeding from HA. Bleeding was not significantly higher in patients with specific race, ethnicity, type 2 diabetes, obesity, or tobacco and alcohol use. In univariate analysis, risk of bleeding was increased in patients with oral contraception (OCP) use (OR = 2.38; CI: 0.97-5.8, p = 0.057), larger HAs (OR = 1.48 per 1 mm increase; CI: 1.2-1.8, p < 0.0001), and multiple HAs (> 10 lesions) (OR = 4.03; CI: 1.4-11.9, p = 0.058). In the multivariate adjusted analysis, only size remained statistically significant (OR = 1.44, CI: 1.4-1.2, p < 0.0001).
Most patients who had HA bleeding were resected (88%), but some underwent multiple embolizations (4%), embolization followed by resection (12%), radiofrequency ablation (4%) and liver transplant (6%). The median size of unifocal lesions in bleeding patients was 7.50 cm (IQR 5.30, 11.8) compared to 2.30 cm (IQR 1.2, 4.10) in non-bleeding patients. The smallest lesion that bled was 1.8 cm. In patients with > 10 lesions who bled, the median lesion size for the largest three lesions was 6.5 cm (IQR 4.7, 9.05), 4.4 cm (IQR 2.2, 5.6) and 1.45 cm (IQR 1.3, 1.6) compared to 3.60 cm (IQR 2.3, 5.4), 2.70 cm (IQR 2, 3.1) and 2.20 cm (IQR 1.7, 2.8) in non-bleeding HA patients. In patients with > 10 HAs, 40% of patients did not bleed from their largest lesion.
Conclusion: There is an increased risk of bleeding with larger HA, multiple HAs, and OCP use. In the adjusted multivariate analysis, size was more predictive of HA bleeding, but this could be related to a smaller population of patients with multiple HAs. Patients with > 10 HAs should be considered for prophylactic therapy. Larger multi-center prospective studies are needed to confirm these observations.

SAT-472

Massive sequencing of circulating DNA as a potential tool for diagnosis and follow-up in patients with hepatocellular carcinoma

Monica Higuera[1], Elena Vargas-Accarino[1], María Eugenia Soria[1], Josep Gregori[1,2,3], Maria Torrens[1], María Teresa Salcedo[4], Itxarone Bilbao[5], Francisco Rodríguez-Frías[1,6], Josep Quer[1,2], Beatriz Minguez[1,2,7]. *[1]Vall d'Hebron Institute of Research (VHIR), Hospital Universitari Vall d'Hebron, Universitat Autònoma de Barcelona, Liver Diseases, Barcelona, Spain; [2]Centro de Investigación Biomédica en Red de enfermedades Hepáticas y Digestivas (CIBERehd) del Instituto Carlos III, Madrid, Spain; [3]Roche Diagnostics S.L., Sant Cugat del Vallés, Barcelona, Spain; [4]Hospital Universitari Vall d'Hebron, Universitat Autònoma de Barcelona, Department of Pathology, Barcelona, Spain; [5]Hospital Universitari Vall d'Hebron, Universitat Autònoma de Barcelona, Department of Hepatobiliopancretic Surgery, Barcelona, Spain; [6]Hospital Universitari Vall d'Hebron, Universitat Autònoma de Barcelona, Biochemistry Unit, Barcelona, Spain; [7]Hospital Universitari Vall d'Hebron, Universitat Autònoma de Barcelona, Department of Internal Medicine II, Barcelona, Spain*
Email: bminguez@vhebron.net

Background and aims: Tumor biopsy is the usual source of molecular information in cancer. Analysis of plasma cell free DNA (cfDNA) could be a non-invasive tool, having clinical applications in terms of diagnosis and prognostic estimation in patients with hepatocellular carcinoma (HCC). We aim to evaluate correlation between mutations detected in HCC and those detected in cfDNA, and the prognostic value of their evolutive changes.
Method: Patients undergoing surgical resection for HCC in our center were prospectively included in the study. 4 samples were analyzed on each: 1) fresh frozen tumor tissue (HCC), 2) adjacent non-tumoral tissue (NT), 3) peripheral blood mononuclear cells (PBMC) and 4) plasma. cfDNA was extracted from 1 ml of plasma using the MagMAX Cell-Free DNA Isolation kit from Thermo fisher. Samples were

subjected to high-depth sequencing for the detection of mutations in 5 of the most relevant/prevalent genes in HCC on the Illumina MiSeq platform. Sequences with coverage of more than 10, 000 readings were analyzed and only mutations with a frequency higher than 1% were accounted for

Results: 12 patients have been analyzed to date. 75% men (9/12), average age of 62 years. 100% had single HCC, median size of 4.05 cm. 50% (6/12) were HCV positive. 18 mutations were detected in HCC tissue: TERT (11/12), TP53 (2/12) and CTNNB1 (5/12) and 16 mutations in the cfDNA: TERT (10/12), TP53 (3/12) and CTNNB1 (3/12). 12/18 mutations detected in HCC, were detected in the corresponding sample of cfDNA, (75% agreement). 4 mutations detected in cfDNA were not in their tumor tissue, suggesting that cfDNA captures information not obtained by conventional biopsy due to tumor heterogeneity. Follow-up samples after more of 20 months from resection in 2 patients with no evidence of recurrence, did not detect mutations in cfDNA. Analysis of samples collected 10 months before HCC diagnosis in one patient, detected a TERT mutation at 8% of frequency (10% at the time of resection)

Conclusion: Analysis of mutations in cfDNA by massive sequencing identifies most of tumor somatic mutations of HCC patients; moreover, other mutations detected in cfDNA were not present in the tumor, suggesting it could overcome tumor heterogeneity. Its detection could have relevant implications in early diagnosis and its follow-up over time, could have prognostic implications in early detection of recurrence, optimizing clinical management of HCC.

SAT-473

Transition to the era of direct-acting antiviral changes in the prognosis of patients with hepatitis C virus-related hepatocellular carcinoma

Yoshifumi Miura[1], Sadahisa Ogasawara[1], Yoshihiko Ooka[1], Kazufumi Kobayashi[1], Susumu Maruta[1], Hiroaki Kanzaki[1], Kengo Kanayama[1], Takahiro Maeda[1], Soichiro Kiyono[1], Yuko Kusakabe[1], Masato Nakamura[1], Eiichiro Suzuki[1], Tomoko Saito[1], Shingo Nakamoto[1], Shin Yasui[1], Akinobu Tawada[1], Tetsuhiro Chiba[1], Makoto Arai[1], Tatsuo Kanda[1], Hitoshi Maruyama[1], Naoya Kato[1]. [1]*Chiba University, Graduate School of Medicine, Department of Gastroenteology, Chiba, Japan*
Email: sadahisa@me.com

Background and aims: Since the usage of direct-acting antivirals (DAAs) in the Japanese field practice in 2014, the numbers of patients whose hepatitis C virus (HCV) was eradicated not only before the occurrence of HCC but also after receiving curative therapies have dramatically increased. In this study, we evaluated the impact of DAAs in patients with HCV-related HCC using 3 different time-period cohorts.

Method: Between 2003 and 2016, we retrospectively identified HCV-related early stage HCC patients who received curative therapies (either resection, percutaneous ethanol injection [PEI], or radio-frequency ablation [RFA]) from the database of our institution and divided them into 3 cohorts (group A: 2003-2006, group B: 2007-2011, and group C: 2012-2016).

Results: Of the 453 HCV-related early stage HCC patients, 128, 161, and 164 patients belonged to groups A, B, and C, respectively. The median ages of groups A, B, and C patients were 68 years [range: 46-84], 71 years [range: 39-86], and 71 years [range: 45-85], respectively. The resection rates were similar in all 3 groups (group A: 23.4%, group B: 21.7%, and group: 23.1%). Of the 128 patients in group A, 4.7% and 4.7% patients achieved sustained virological response (SVR) before and after the occurrence of HCC, respectively. Both the rates were significantly increased in groups B and C (9.3% and 13.0% in group B and 20.7% and 36.5% in group C, respectively; $p < 0.0001$). The 5-year survival rate in group C were significantly higher than in groups A and B (group A: 55.6%, group B: 61.7%, group C: 73.6%; $p = 0.0015$). Similarly, of the 400 patients who did not eradicate HCV at the time of occurrence, the 5-year survival rate of group C was significantly higher than that of groups B and C (group A: 55.0%, group B: 58.7%, group C: 71.4%; $p = 0.0070$).

Conclusion: The prognosis of HCV-related HCC receiving curative therapies significantly improved during the era of "DAAs."

SAT-474

Misdiagnosis of focal liver lesions by means of CEUS

Tudor-Voicu Moga[1], Roxana Sirli[1], Alina Popescu[1], Mirela Danila[1], Ana-Maria Ghiuchici[1], Ioan Sporea[1]. [1]*"Victor Babes" University of Medicin and Pharmacy, Gastroenterology and Hepatology, Timisoara, Romania*
Email: moga.tudor@gmail.com

Background and aims: Contrast Enhanced Ultrasound (CEUS) has become the method of choice for many practitioners for the evaluation of Focal Liver Lesions (FLL) detected by standard ultrasound. In real life though some lesions may not follow the classical enhancement pattern described by EFSUMB guidelines. The **aim** of this paper is to assess the FLL's that were misdiagnosed or inconclusive in CEUS in our monocentric cohort.

Method: The analysis was performed on 979 FLL's that were evaluated by CEUS by 4 ultrasound experts. All FLL's were judged according to EFSUMB-CEUS guide lines (1) and had a second line imaging method (CT, MRI) or histology as a refference method. Using the refference method for the final diagnosis we highlighted the most frequent lesions that were misdiagnosed or inconclusive and the issues that may lead to misdiagnosis in CEUS.

Results: from the 979 FLLs, 123 (12.5%) FLL's were misdiagnosed and 227 (23.1%) inconclusive for the CEUS final diagnosis. From the misdiagnosed lesions the most frequent were: 31.7% HCC; 24.3% Metastasis; 17.8% Hemangioma; 8.9% FNH; From the 227 inconclusive lesions, 115 were classified as benign or malignant, the rest of 112 lesions were considered fully inconclusive at CEUS. The most frequent inconclusive lesions were: 37% HCC, 5.2% dysplastic nodules, 4.8% cholangiocarcinoma, 13.6% metastasis, 11.8% hemangioma. The size of the lesions and the age of the patients did not influenced the correct CEUS diagnosis [size: 4.3 ± 3.2 cm (350 lesions) vs. 4.5 ± 3 cm (629 lesions) P = **0.3293**], [age: 59.1 ± 13 years vs. 60 ± 12.3 years, **p = 0.2902**]. From the 350 FLL's (misdiagnosed or inconclusive), 42.8% (150/350) were present on advance liver fibrosis while only 29.4% (185/629) from the FLL's that were corectlly diagnosed by CEUS were detected on advance liver fibrosis. (**p < 0.0001**)

Conclusion: In our cohort, 12.5% of the FLL's were misdiagnosed by CEUS. The misdiagnosis was not influenced by the size of the lesions or by the age of the patient but was influenced by advance liver fibrosis.

SAT-475

Clinical validation of the role of contrast-enhanced ultrasound in the EASL guidelines for the diagnosis of hepatocellular carcinoma

Lorenzo Mulazzani[1], Vito Sansone[1], Luca Giordano[1], Chiara Di Bonaventura[1], Alice Giamperoli[1], Angelo Cimino[1], Fabio Piscaglia[1]. [1]*S. Orsola-Malpighi Hospital, University of Bologna, Unit of Internal Medicine, Bologna, Italy*
Email: lorenzo.mulazzani2@studio.unibo.it

Background and aims: Contrast-enhanced ultrasound (CEUS) of liver nodules after an inconclusive CT/MRI was endorsed in the 2018 EASL guidelines for the management of hepatocellular carcinoma (HCC), but no validation of this flowchart exists to verify whether using CEUS as second diagnostic line is useful or a waste of resources. Thus, this observational study aims to validate the role of CEUS in the diagnosis of HCC in real clinical practice.

Method: During a 6 months period, we prospectively enrolled patients at risk of HCC with liver nodules submitted to CEUS for the characterization of liver lesions. Exclusion criteria: CEUS performed to study treatment outcome, portal vein thrombosis or to choose target lesion, CT/MRI performed ≥ 3 months apart from CEUS. The theoretical impact of CEUS on the clinical decision was then assessed.

Results: A total of 43 patients (mean age 64y) with conditions at risk for HCC underwent CEUS to characterize 64 liver nodules (median diameter 19 mm, range 6-91 mm). A total of 12 lesions were excluded as not receiving CT/MRI within < 3months from CEUS (none with a pattern of HCC). A total of 20 of the 52 remaining nodules received a diagnosis of HCC by CT/MRI. CEUS showed no case of LRM class (which would suggest a non-hepatocellular malignancy prompting biopsy), thus provided no additional benefit in this setting (in keeping with the guidelines). Conversely CEUS showed an HCC pattern in 4/32 (12.5%) nodules (4/16 patients, 25%) without a diagnosis of HCC at first CT/MRI. Of the remaining 28 cases one was LRM (and confirmed metastasis at histology), while no other showed the HCC pattern. Of these 4 typical HCC nodules 1 was diagnosed as such by biopsy, 1 by MRI after an inconclusive CT, 1 by repeating MRI in 2 months, 1 was not biopsied because of poor clinical conditions with ascites, but exams showed AFp > 250.000 ng/ml.
Conclusion: The present observational prospective study validates the effectiveness of CEUS according to the diagnostic flowchart of the 2018 EASL guidelines for HCC. In particular using CEUS in second line after an inconclusive CT or MRI investigation was shown to be able to provide a correct diagnosis of HCC in 12.5% of cases missed by CT or MRI.

SAT-476
Discordance between clinical judgement and genetic differentiation of intrahepatic metastasis and multicentric occurrence in multinodular HCC

Yuji Iimuro[1], Atsushi Takano[1], Kenji Amemiya[2,3], Yosuke Hirotsu[2], Hitoshi Mochizuki[2,4], Toshio Oyama[3], Masao Omata[4,5]. *[1]Yamanashi Cenral Hospital, Department of Surgery, Kofu, Japan; [2]Yamanashi Central Hospital, Genome Analysis Center, Kofu, Japan; [3]Yamanashi Central Hospital, Department of Pathology, Kofu, Japan; [4]Yamanashi Central Hospital, Department of Medicine, Kofu, Japan; [5]The University of Tokyo, Tokyo, Japan*
Email: siimuro@hyo-med.ac.jp

Background and aims: It is important to differentiate between IM and MC in multinodular HCC for its treatment strategy. The differentiation has been dependent on image finding or pathological observation of each tumor, while the criteria remains obscure. The **AIMs** of the present study were to elucidate genetic alterations in multinodular HCCs for differentiation between IM and MC, and to examine the accuracy of conventional criteria.
Method: Forty HCC patients (30 solitary and 10 multinodular, 99 lesions) were genetically investigated. Microdissected samples were analyzed employing a next generation sequencer (NGS). We performed targeted sequencing covering 72 SMGs reported to be associated with HCC in TCGA or ICGC. **Intra nodules analysis:** As a validation analysis, genetic clonality among pathologically distinct components within each HCC nodule (13 nodules, 33 lesions) was analyzed. **Inter nodules analysis:** Multinodular HCCs were tested whether each tumor possesses common genetic alterations (IM) or not (MC) (10 patients; 27 nodules). The results of genetic differentiation were compared with conventional clinical judgement.
Results: Intra nodular validation analysis revealed that pathologically distinct components within HCC nodule possessed common trunk mutations, such as *TERT* promoter, *TP53*, or *CTNNB1*, implying their monoclonal origin despite pathological heterogeneity. In inter nodular analysis, MC was identified in 2 cases without common genetic alterations, and IM was diagnosed in 7 cases. In a case with 4 nodules, 2 nodules had common mutations, while others not, being mixture of IM and MC. Intriguingly, in a MC case with 3 neighboring nodules, who was diagnosed as IM on image analysis, no common genetic mutation was detected among those moderately differentiated HCCs. The concordance rate between genetic differentiation and conventional clinical judgement was about 50%.
Conclusion: There is limitations in conventional diagnosis criteria for IM or MC in multinodular HCCs. Elucidation of genetic clonality in each tumor is critical for better understanding of pathophysiological features of multinodular HCCs.

SAT-477
Impact of skeletal muscle quality and quantity on outcomes following curative therapy of hepatocellular carcinoma

Tomoaki Nakajima[1], Hirokazu Suii[1], Ryoji Tatsumi[1], Masakatsu Yamaguchi[1], Mutsuumi Kimura[1], Tomohiro Arakawa[1], Yasuaki Kuwata[1], Itaru Ozeki[1], Takumi Ohmura[1], Shuhei Hige[1], Yoshiyasu Karino[1], Joji Toyota[1]. *[1]Sapporo Kosei General Hospital, Sapporo, Japan*
Email: t.nakajima@ja-hokkaidoukouseiren.or.jp

Background and aims: The quality and quantity of skeletal muscle are important in patients with malignant tumors to predict prognosis. In this study, we investigated the impact of skeletal muscle quality and quantity on outcomes after curative therapy in patients with Hepatitis C Virus (HCV)-related hepatocellular carcinoma (HCC).
Method: We investigated 223 patients (mean age 72 years, 131 liver cirrhosis) who underwent first hepatic resection or radiofrequency ablation for HCV-related HCC between January 2004 and December 2013. The quantity and quality of skeletal muscle, indicated by psoas muscle mass index (PMI) and intramuscular adipose tissue content (IMAC), were measured in pre-therapeutic computed tomography images at the L3 level by manual tracing. Overall survival (OS) and recurrence-free survival (RFS) rates were compared according to PMI and IMAC, and prognostic factors were assessed.
Results: The OS rate in patients with low PMI and high IMAC was lesser than in those with high PMI and low IMAC ($p = 0.010$), with a mean survival time of 6.0 and 9.8 years, respectively. The RFS rate in patients with high IMAC was lesser than in those with low IMAC ($p = 0.036$). In multivariate Cox hazard analysis, liver cirrhosis (hazard ratio, 3.336; $P < 0.001$), low PMI and high IMAC (hazard ratio, 2.088; $P = 0.007$) and des-γ-carboxy prothrombin level (≥ 40 mAU/ml) (hazard ratio, 1.880; $P = 0.016$) were significant prognostic factors of poor OS, and hepatic resection (hazard ratio, 1.844; $P = 0.016$) and high IMAC (hazard ratio, 1.656; $P = 0.042$) were significant prognostic factors of poor RFS.
Conclusion: Loss in the quality and quantity of skeletal muscle is closely related to mortality and recurrence in patients with hepatocellular carcinoma.

Background and aims: There are various predictiction models for hepatocellular carcinoma (HCC) in patients with chronic hepatitis B (CHB), but the prediction model for HCC in treatment naïve CHB patients is insufficient. Moreover, there's lack of studies on cirrhotic patients.
Method: This study enrolled 602 treatment naïve chronic hepatitis B patients with cirrhosis, who were treated with nucleoside/nucleotide (NUC : Entecavir or Tenofovir disoproxil fumarate). To identify the most favorable model for predicting the HCC development, we compared the areas under the receiver operating characteristic curve (AUROCs) of previous HCC prediction models and non-invasive predictive scores. And then we used the method of Delong et al. for the calculation of the standard error of the AUROC and of the difference between two AUROCs.
Results: After excluding patients developed HCC within 1 year NUC treatment or have missing data, 582 patients were enrolled. FIB-4 and modified PAGE-B showed higher predictive value than others (CU-HCC: 0.604, GAG-HCC: 0.612, REACH-B: 0.577, PAGE-B: 0.619, modified PAGE-B : 0.678, APA-B: 0.553, THRI : 0.58, FIB-4 : 0.61, FIB-4 after 1year treatment : 0.648, GPR : 0.608, APRI : 0.461).
Conclusion: In treatment naïve cirrhotic CHB patients, modified PAGE-B model and FIB-4 showed the highest predictive power, but their accuracy was poor. A new model for patients with cirrhosis is needed.

Analysis of the relationship between serum creatinine/cystatin C ratio and muscle mass in patients with hepatocellular carcinoma

Hirotaka Oura[1], Sadahisa Ogasawara[1], Yoshihiko Ooka[1], Kazufumi Kobayashi[1], Susumu Maruta[1], Hiroaki Kanzaki[1], Kengo Kanayama[1], Takahiro Maeda[1], Yuko Kusakabe[1], Soichiro Kiyono[1], Masato Nakamura[1], Tomoko Saito[1], Eiichiro Suzuki[1], Shingo Nakamoto[1], Shin Yasui[1], Akinobu Tawada[1], Tetsuhiro Chiba[1], Makoto Arai[1], Tatsuo Kanda[1], Hitoshi Maruyama[1], Naoya Kato[1]. *[1]Chiba University, Graduate School of Medecine, Department of Gastroenterology, Chiba, Japan*
Email: ahma4627@chiba-u.jp

Background and aims: Sarcopenia is defined as a loss of skeletal muscle mass and strength, and its influences on various diseases has been one of the latest controversial research topics. It is strongly correlated with prognosis of patients with hepatocellular carcinoma (HCC). The ratio between blood creatinine (Cre) and cystatin C (CysC) values has been recently determined to have a potential role in screening sarcopenia. Therefore, this study aimed to investigate the relationship between serum Cre/CsyC ratio and muscle mass in patients with HCC using a large cohort.
Method: Among patients who underwent treatment for newly diagnosed HCC in our hospital from June 2009 to December 2016, those with available data for both Cre and CysC at the same time were identified. The skeletal muscle index at L3 level (L3-SMI) (cm^2/m^2) was calculated to evaluate muscle mass using CT imaging in patients with HCC. A correlation between Cre/CysC and L3-SMI was analyzed.
Results: Among the 622 patients with available Cre and CysC data, 435 (69.9%) were men, the median age was 71 years, and the mean body mass index was 23.9 ± 4.0. The number of each Child-Pugh classification was 496 (79.7%) in A, 121 (19.5%) in B, and 5 (0.8%) in C. Regarding HCC staging based on the Barcelona Clinic Liver Cancer stage, 376 (60.5%) were in the early, 144 (23.2%) in the intermediate, and 102 (16.4%) in the advanced stage. Cre/CysC was 0.66 ± 0.21, and L3-SMI was 42.35 ± 9.09, showing that Cre/CysC was significantly correlated with L3-SMI ($r = 0.186$, $p < 0.001$). A total of 522 patients had serum Cre level lower than the normal upper limit, indicating a stronger correlation between Cre/CysC and L3-SMI ($r = 0.352$, $p < 0.0001$); however, no significant correlation was observed in patients with serum Cre level higher than the normal upper limit ($r = -0.026$, $p = 0.788$).
Conclusion: This study confirmed that Cre/CysC can potentially be used as a simple marker associated with muscle volume. Additional validation studies should be conducted.

SAT-480

Long-term survivors in patients with hepatocellular carcinoma: An ITA.LI.CA report

Filippo Pelizzaro[1], Andrea Vieno[1], Giulia Peserico[1], Angela Imondi[1], Anna Sartori[1], Barbara Penzo[1], Franco Trevisani[2], Alessandro Vitale[1], Fabio Farinati[1]. *[1]University of Padua, Department of Surgery, Oncology and Gastroenterology, Padua, Italy; [2]Alma Mater Studiorum-University of Bologna, Department of Medical and Surgical Sciences Division of Semeiotics, Bologna, Italy*
Email: filippo.pelizzaro@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) is characterized by a poor prognosis but some patients reach a quite long survival, the predictors of the event not being fully elucidated. The aim of our study was to compare a long-term survival group (≥ 5 yrs) to a control group (< 5 yrs) to identify parameters associated with good prognosis.
Method: To conduct this retrospective case-control study a group of HCC patients with survival ≥ 5 years (cases, n = 568) and a control group of equal size (n = 568) with survival < 5 years were selected from the ITA.LI.CA. database, now including 6991 patients.
Results: Compared to controls, cases were less frequently cirrhotics (89.8% vs. 93%, $p = 0.04$) with less frequent portal hypertension (36.8% vs. 53.9%, $p < 0.0001$) and had at diagnosis better residual liver function (Child A in 82.7% vs. 69.5%, $p < 0.0001$). Moreover, they had their diagnosis more frequently during surveillance (80.1% vs. 71.4%, $p = 0.0007$), with less advanced HCC (in the majority of cases monofocal, whit a diameter ≤ 3 cm and in stage BCLC 0-A). The long-term survivors had been treated in 80.8% of cases with at least one curative therapy (resection or ablation) in their clinical history, against 56.6% of controls ($p < 0.0001$). At a multiple logistic regression analysis, variables significantly associated with survival were: surveillance, ECOG-PS, portal hypertension, tumor aspect (monofocal/multifocal), diameter of the largest liver lesion, AFP levels and BCLC stage. The discriminant analysis identified diagnosis under surveillance, main treatment and BCLC stage as the variables with better discriminant capacity between the two groups, correctly classifying 77.2% of the cases, overall.
Conclusion: Preserved liver function, early stage at diagnosis and radical treatment are associated with good prognosis. Surveillance confirms its usefulness being in this study a sound predictive factor of long-term survival.

SAT-481

Intratumoral mast cell infiltration and recurrence of hepatocellular carcinoma in patients undergoing orthotopic liver transplantation

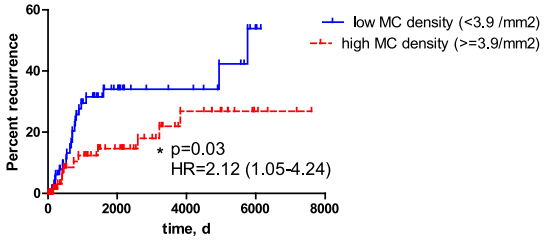
Email: nataliya.rohr-udilova@meduniwien.ac.at

Background and aims: Tumor-infiltrating immune cells are highly relevant for prognosis as well as for discovery of immunotherapy targets in hepatocellular carcinoma (HCC). Recently, we provided evidence for altered mast cell infiltration and activation in tumor tissue of HCC patients by CIBERSORT immune cell profiling in combination with immunohistochemical (IHC) staining for the mast cell marker tryptase. Here, we retrospectively investigated the relevance of mast cells for HCC recurrence in an Austrian cohort of patients who underwent orthotopic liver transplantation (OLT).
Method: The Austrian HCC patient cohort included 172 patients (21 females, 151 males, 55.2+7.9 years, tumor staging 28/121/23 T1/T2/T3) who underwent OLT at the Medical University of Vienna. The underlying HCC etiologies comprised HCV infection (n = 70), alcoholic liver disease (n = 49), HBV (n = 16), and others (n = 22). Tissue microarrays (TMAs) from tumors and corresponding surrounding tissues were IHC-stained for tryptase. The TMA core diameter was 2 mm. Two cores per tumor and one core per surrounding tissue were analyzed for each patient. Tryptase-positive cells were quantified by tissue morphometric analysis and correlated with HCC recurrence.
Results: Mast cells were detected in 93% of HCC tumors (160/172) and in 100% of available surrounding liver tissues (n = 149). A low density of intratumoral mast cells (median mast cell density cut-off: 3.9 cells/mm^2) correlated significantly with a higher HCC recurrence rate (Fig.1, hazard ratio: 2.12, 95% confidence interval: 1.1-4.2; log-rank Mantel-Cox test p = 0.03) and was associated with a larger tumor size (Spearman correlation coefficient $r^2 = 0.237$, p = 0.001). Moreover, the mean number of tumors was significantly increased in patients with low density of intratumoral mast cells (2.7+0.2 cm vs. 2.2 +0.1 cm; p = 0.04 unpaired t-test, Welch correction).

Fig. 1. Intratumoral mast cell density and HCC recurrence (172 patients)



Conclusion: OLT-HCC patients with low mast cell density in tumor tissue have a higher risk for HCC recurrence, which is of prognostic importance. The underlying mechanisms and the impact of MCs on HCC biology require further investigation.

SAT-482

Incidence of hepatocellular carcinoma after hepatitis C cure with DAA in a cohort of patients with advanced liver disease: Results from a prospective screening program

Marco Sanduzzi Zamparelli[1], Sabela Lens[2], Víctor Sapena[1], Neus Llarch[1], Anna Pla[2], Gemma Iserte[1], Concepció Bartres[2], Ramón Vilana[3], Luis Bianchi[3], Nuñez Isabel[4], Anna Darnell[3], Ernest Belmonte[3], Carmen Ayuso[3], Maria Ángeles García-Criado[3], Alba Díaz[5], Carla Fuster[5], Ferran Torres[6], Jordi Bruix[1], Xavier Forns[2], María Reig[1], Zoe Mariño[2]. *[1] Barcelona Clinic Liver Cancer (BCLC) Group, Liver Unit, Hospital Clinic Barcelona, CIBERehd, IDIBAPS, University of Barcelona, Barcelona, Spain; [2]Liver Unit, Hospital Clinic Barcelona, CIBERehd, IDIBAPS, University of Barcelona, Barcelona., Barcelona, Spain; [3]Barcelona Clinic Liver Cancer (BCLC) Group. Email: zmarino@clinic.cat

Background and aims: Although HCV cure with DAA (> 95%) is associated with a reduced risk of disease progression, the impact of DAA on hepatocellular carcinoma (HCC) occurrence is controversial. The aim of this study was to estimate HCC incidence after DAA in a cohort of patients with advanced liver disease by a prospective screening program.
Method: Prospective study including HCV-infected patients with cirrhosis or advanced fibrosis (F3, TE ≥ 9.5Kpa), without previous history of HCC, cured after DAA; patients should have a US imaging in < 30 days from inclusion excluding the presence of HCC or non-characterized nodules. All patients were evaluated every 6 months. Follow-up (FU) time was censored at the moment of event (HCC) or September 2018. HCC incidence was expressed in 100/patients-year (100PY) (IC95%). Adherence to screening was assessed.
Results: 275 patients signed inform consent; 90 patients were excluded (mainly due the absence of pre-DAA US in < 30 days); 185 patients were analysed: 52.4% men, age 65.1 [55.1-72] years. 34% (n = 63) patients were F3 (TE 11.5[10.1-12.1] KPa) vs 122 (65.9%) patients with cirrhosis (TE 18[14.3-26.6] Kpa): 87.7% Child-A, 17.2% history of decompensation, 40.9% varices in endoscopy, 39.3% TE ≥ 21Kpa. Adherence to screening program was 98.4% and 7 incident HCC were detected after a median clinical and radiological time of 27.5[24.7-33.9] and 23.9[23.4-24] months, respectively. Median time from SVR to HCC diagnosis was 24.5[17.3-30.7] months. Overall incidence of HCC was 2.01/100PY [IC95%: 0.9-4.2]. All HCC cases occurred in cirrhotic patients (incidence: 3.04/100PY [IC95%: 1.4-6.3]) with TE ≥ 21KPa (incidence in subgroup: 5, 93/100PY [IC95%: 2.9-11.8]. The 7 HCC cases [BCLC-0 (n = 3)/A (n = 3)/C (n = 1)] received specific treatment [percutaneous (n = 4), surgery (n = 1), TACE (n = 1); sorafenib (n = 1)]; 2 patients presented recurrence/HCC progression after 2.3 and 2.04 months of oncologic treatment. During FU, 7 patients died (3.78%), one due to HCC progression.
Conclusion: Risk of HCC persists in cirrhosis even if SVR is achieved with DAA (3.04/100PY). In this cohort, we did not identify any HCC in F3 patients (although the number of patients is limited). Moreover, in this specific cohort of patient without non-characterized nodules at baseline we did not find a time-association of HCC and DAA. Altogether, screening programs to rule out HCC are necessary in patients with cirrhosis achieving SVR; this risk should be further investigated in larger cohorts of F3 patients.

Email: mreig1@clinic.cat

Background and aims: Hepatic epithelioid hemangioendothelioma (HEHE) is a vascular neoplasm, more frequent in women than in man and usually arises in a non-cirrhotic liver. This is a very rare tumor (0.1-1/100, 000 person) and no prospective study on this population is available until today. The aim of this study is to describe the HEHE patients profile and the treatment of patients with this orphan condition.
Method: We performed an international (Sao Paulo, Salvador de Bahia and Barcelona-Clínic), retrospective and multicentric study which registered the baseline clinical, biochemical radiological and pathological features and all the evolutionary events that were available in the patient file. The images were centralized and pathologic samples were revised by three pathologists (MS, VA and CM) with more than 10 years of experience in liver cancer.
Results: From 1994 to 2016 we identified 27 patients with HEHE diagnosis in the patient reports but complete baseline clinical and laboratory data were available in 25 patients. One patient was diagnosed of a hepatic angiosarcoma at the moment of liver transplantation (LT) and finally excluded from this analysis. Median age was 38.7 years, the majority of patients were females (64%), without underlying chronic liver disease (76%). In 17 patients the diagnosis was incidental while 7 patients were symptomatic. Of the 24 included patients, 66.7% had multinodular disease and 50% presented extrahepatic disease at the diagnosis, all of them presenting at least lung involvement. Interestingly, 71% of the patients received a specific treatment such as chemotherapy (n:6), resection (n:7) or LT (n:4). The pathology revision was possible in 20 patients and the central radiologic evaluation only in 13 patients. The most frequent radiologic pattern, was a progressive central contrast uptake in 6 patients, followed by stable nperipheral enhancement without changes through the phases and persistent minimal uptake through all phases in 4 and 3 patients in each pattern, respectively. Median follow-up in the whole cohort was 80.2 months [IQR; 51.7 to 154.3], survival rate at 5- and 10-years were 91.5% and 51.9%, respectively. Eleven patients of the whole cohort developed progression and 7 died.
Conclusion: This multicentric study reflects the need of a better characterization and understanding of the natural history of this hepatic neoplasm. Active research through larger international consortia should define the molecular pathways involved in its development and allow an optimal treatment approach.

SAT-484

CEUS pattern of hepatocellular carcinoma: Prognostic implication

Eleonora Terzi[1], Alice Giamperoli[1], Vito Sansone[2], Simona Leoni[1], Ludovico De Bonis[1], Alessandro Granito[1], Fabio Piscaglia[1].
[1]Sant'Orsola-Malpighi General and University Hospital, Unit of Internal Medicine, Department of Digestive Disease and Internal Medicine, Bologna, Italy; [2]Sant'Orsola-Malpighi General and University Hospital, Unit of Gastroenterology, Department of Surgical Sciences, Bologna, Italy
Email: fabio.piscaglia@unibo.it

Background and aims: American College of Radiology (ACR) has released the Liver Imaging Report And Data System (LI-RADS) scheme, which categorizes nodules in patients at risk for hepatocellular carcinoma (HCC) according to the degree of risk of nodules to be HCC as LR-3, LR-4, LR-5 (definitely HCC) and LR-M (probable malignancy not specific for HCC). EASL guidelines recommend biopsy for nodules not meeting the LR-5 class whereas LI-RADS policy, adopted by AASLD, largely include only imaging follow-up.
Aim of this study was to test whether HCC showing the CEUS pattern of indeterminate nodules (LR-3 and LR-4) are associated with better prognosis in terms of *Overall Survival* (OS) and *Recurrence-Free Survival* (RFS) than LR-5 (which could support LI-RADS/AASLD policy) or not (which would mandate EASL policy).
Method: Among 472 consecutive cirrhotic patients with liver nodules referred to our Centre (January 2005-December 2016), we retrospectively enrolled 98 patients with first diagnosis of single HCC according to 2012 AASLD guidelines (CT/MRI if typical or histology if CT/MRI were inconclusive) for whom a complete CEUS pattern, categorized according to the CEUS LI-RADS policy, was available.
Results: Median size of HCC lesions was 2.5 cm (range 1-7.2 cm). According to CEUS LI-RADS classification, 8 (8%) patients were in LR-3, 31 (32%) in LR-4, 54 (55%) in LR-5 and 5 (5%) in LR-M. Patient and nodule characteristics were not statistically different between LI-RADS classes. At univariate analysis CEUS LI-RADS class was not found to be a predictor of survival but statistically related to RFS (p = *0.029)*, since LR-M had shorter RFS than other classes. Also the LR-4 had shorter RFS than LR-5.
Conclusion: HCC showing the CEUS LI-RADS classes LR-3 and LR-4 have no better clinical outcome than typical HCC, therefore conclusive diagnostic investigation of indeterminate nodules up to liver biopsy is promptly requested to avoid leaving aggressive HCC not timely treated.

Background and aims: Cholangiocarcinomas (CCAs) are classified into intrahepatic (iCCA), perihilar (pCCA) or distal (dCCA). Their etiologies are mostly unknown and their pathogenesis is poorly understood. Large international registries of CCA patients with demographic, biochemical, clinical and histopathological information are missing and necessary to better understand this disease and improve its management.
Method: The European CCA Registry is an international multicenter initiative supported by EASL (Registry Award 2016) that includes patients with CCA from 8 institutions and 4 countries in the secure online platform REDCap. Clinical data was retrospectively (2010) and prospectively (2016) collected by experts in the field.
Results: A total of 1, 011 records are entered, including 48% iCCAs, 23% pCCAs, 28% dCCAs and 1% CCA-HCC mixed tumors. Mean age at diagnosis was 65.6, and the male/female ratio 1:0.76. The most

common known risk factors were cirrhosis (6.4%), viral hepatitis (3.1% HCV; 1.8% HBV), diabetes (20.5%), obesity (15.2%), alcohol (17.2%) and presence of primary sclerosing cholangitis (PSC: 1.3%). Serum levels (mean; IU/L) of biochemical markers of cholestasis (GGT: 417; ALP: 313) and liver injury (ALT: 74.1; AST: 60.8), as well as non-specific tumor markers (CA19.9: 5, 138 UI/ml; CEA: 163 ng/ml) were altered. These biomarkers were considered for diagnosis together with imaging (53.1%: MRI, CT, USG, ERPC) and pathological (34.5%: biopsy/cytology) approaches. Tumor staging (TNM; AJCC 7th Edition) at diagnosis revealed that 39.7% of cases had stages I-III, 39.9% stage IV, and 20.4% unknown. Moreover, 38.9% of patients underwent surgical resection (R0-R1) (81.0% I-III; 12.2% IV; 6.8% unknown) with an overall survival (OS) of 18 months (IC95: 16-22). On the other hand, 61.1% of the tumors were unresectable: 70% (16.8% I-III; 59.7% IV; 23.5% unknown) received chemo- or locoregional therapies, and 30% did not receive treatment (10.2% I-III; 57.2% IV; 32.5% unknown). Chemo- or locoregional therapies provided an OS of 10 months (IC95: 9-11), whereas non-treated patients exhibited an OS of 4 months (IC95: 3-6).

Conclusion: This international initiative shows the current management of patients with CCA, and demonstrates the need of international collaborations to improve diagnosis, staging and treatment. The European CCA Registry, which also includes biological samples, emerges as a unique and extraordinary platform for future collaborative studies.

SAT-486

Short- and long-term effects of transarterial chemoembolization on portal hypertension in patients with hepatocellular carcinoma

Bernhard Scheiner[1], Gregor Ulbrich[1], Mattias Mandorfer[1], Thomas Reiberger[1], Christian Müller[1], Fredrik Waneck[2], Michael Trauner[1], Claus Kölblinger[2], Prof. Dr. Arnulf Ferlitsch[1], Wolfgang Sieghart[1], Markus Peck[1], Matthias Pinter[1]. *[1]Medical University of Vienna, Department of Internal Medicine III, Division of Gastroenterology and Hepatology, Vienna, Austria; [2]Medical University of Vienna, Department of Biomedical Imaging and Image-guided Therapy, Division of Cardiovascular and Interventional Radiology, Vienna, Austria*
Email: matthias.pinter@meduniwien.ac.at

Background and aims: Transarterial chemoembolization (TACE) affects hepatic perfusion, and might impact on portal pressure in patients with hepatocellular carcinoma (HCC). However, the significance of these transient changes is unclear, since data on the impact of TACE on portal hypertension (PHT) and associated complications is limited.

Method: We report the secondary outcome "hepatic hemodynamics" from the AVATACE trial, a prospective randomized, placebo-controlled trial on the efficacy of TACE in combination with bevacizumab or placebo. Hepatic venous pressure gradient (HVPG) was measured at baseline (prior to 1st TACE), within 9 days ("acute effects"), 2 months ("intermediate effects"), and 6 months ("long-term effects") after 1st TACE.

Results: 28 patients with mainly intermediate stage HCC (BCLC B: n = 24, 86%) were included. N = 20 (71%) had clinically significant portal hypertension (CSPH, HVPG ≥ 10mmHg) at baseline (median HVPG 12 (IQR 9-19) mmHg). TACE neither had "acute effects" on HVPG (median after 2 days: 16 (IQR 7-20) mmHg p = 0.822) nor "intermediate effects" (median after 2 months/3 TACE, HVPG: 14 (IQR 6-18) mmHg, p = 0.223). However, in 13 patients with available HVPG measurement at month 6, there was a significant increase in HVPG (10 (IQR: 5-12) mmHg vs. 16 (IQR: 11-19) mmHg, p = 0.007). Changes in HVPG did not correlate with changes in MELD (Spearman's ρ = 0.305, p = 0.310). PHT-related complications exclusively occurred in patients with CSPH (8 (40%) vs. 0). Survival was not statistically significantly different between patients with vs. without CSPH at baseline (10 (95%CI: 4-16) vs. 15 (0-43) months, p = 0.201).

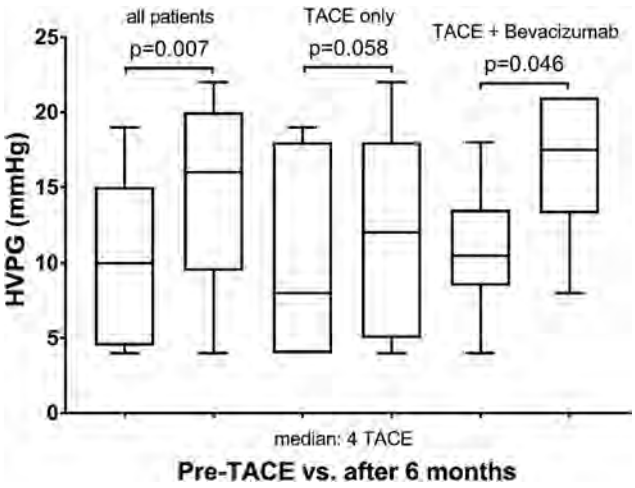

Figure: Long-term effects of repeated TACE (median: 4 procedures) on hepatic venous pressure gradient

Conclusion: Repeated TACE was associated with a significant long-term increase in HVPG. This finding should be considered when deciding whether to continue with TACE or switch to systemic treatment, since CSPH drives the development of complications.

SAT-487

Reliability of a single biopsy in evaluating immune tumor microenvironment of hepatocellular carcinoma

Ying-Chun Shen[1,2,3], Chia-Lang Hsu[4], Yung-Ming Jeng[5], Ming-Chih Ho[6], Cheng-Maw Ho[6], Ching-Ping Yeh[2], Chia-Yu Yeh[2], Meng-Chi Hsu[2], Ray-Heng Hu[6], Ann-Lii Cheng[1,2,3]. *[1]National Taiwan University Cancer Center, Taipei, Taiwan; [2]National Taiwan University Hospital, Department of Oncology, Taipei, Taiwan; [3]National Taiwan University, Graduate Institute of Oncology, School of Medicine, Taipei, Taiwan; [4]National Taiwan University Hospital, Department of Medical Research, Taipei, Taiwan; [5]National Taiwan University Hospital, Department of Pathology, Taipei, Taiwan; [6]National Taiwan University Hospital, Department of Surgery, Taipei, Taiwan*
Email: ycshen.daisy@gmail.com

Background and aims: Tumor heterogeneity has been repeatedly reported in hepatocellular carcinoma (HCC). Therefore, the reliability of a single tumor biopsy in evaluating immune tumor microenvironment (ITME) is often questioned. We conducted a prospective study to analyze the similarity of ITME from different parts of a single tumor.

Method: With patients' consent, multi-region random sampling was done from freshly resected tumors. The ITME was evaluated by conventional immunohistochemical staining as the composition of 8 immune cell types (CD4+ T, CD8+ T, CD20+ B, Foxp3+ Treg, CD68+ macrophage, MPO+ myeloid, DC-LAMP+ dendritic and NKp46+ NK cells). The density of immune cells (number/mm^2) was determined by whole-slide counting under 100X-fields. The similarity of ITME within a single tumor was evaluated by a multivariate Mahalanobis distance analysis, which measured the distance of a given point to the center of the dataset by taking both variance and covariance into account. Similarity in ITME of random samples within a tumor was defined as a distribution of distance within 0-10.

Results: Thirteen tumors were collected from 12 patients. The median diameter of tumor is 9 cm (range: 3-16 cm). A median of 6 samples (range: 3-12) were obtained from each tumor. Seventy-three samples were adequate for IHC analysis. The mean (range) immune cell densities per sample (/mm^2) were 175.9 (0.2-1213) for CD8+ T cells, 72.5 (0-326.7) for CD4+ T cells, 10.0 (0-58.2) for D20+ B cells, 30.8 (0-190.8) for Foxp3+ regulatory T cells, 286.1 (7.0-778.6) for CD68+ macrophages, 38.5 (0-420.7) for MPO+ myeloid cells, 1.4 (0-7.7) for DC-LAMP+ dendritic cells and 1.1 (0.1-6.6) for NKp46+ NK

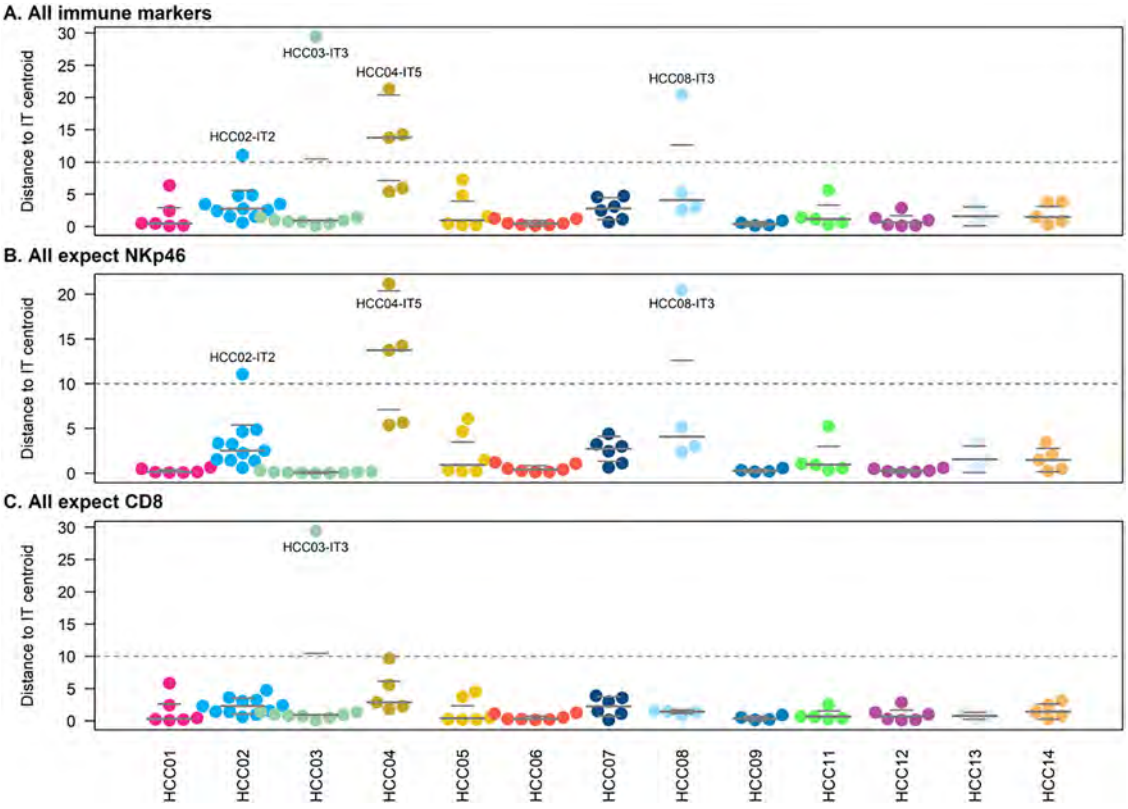

Figure: (abstract: SAT-487): Multivariate analysis of ITME of HCC by using Mahalanobis distance.

cells. Ignoring the rarest NKp46+ subpopulation, 10 out of 13 tumors (77%) showed similarity in ITME of the random samples within the tumor. The CD8+ T cell is the major contributor of dissimilarity in ITME of the rest 3 tumors (No. 2, 4, 8).
Conclusion: Random biopsy from a given HCC for quantification of tumor-infiltrating immune cells is adequate in the majority of patients.

SAT-488
Both ALBI/delta ALBI grade are good predictive parameters for prognosis in chc/hcc patients with transarterial chemoembolization treatment

Wei Teng[1], Rachel Wen-Juei Jeng[1], Yi-Chung Hsieh[1], Chien-Hao Huang[1], Chun-yen Lin[1], I-Shyan Sheen[1]. [1]*Chang Gung Memorial Hospital, Linkou Medical Center, Gastroenterology and Hepatology, Taoyuan, Taiwan*
Email: chunyenlin@gmail.com

Background and aims: The prognosis of patients with hepatocellular carcinoma (HCC) is influenced by both the anatomic extent of cancer and liver reserve function. The Albumin-Bilirubin (ALBI) grade is a new index for liver function evaluation using only albumin and total bilirubin level. Its predictive role on outcome of HCC patients undergoing TACE is still undetermined. This study aimed to investigate the application of ALBI grade and dynamic change of ALBI grade (delta ALBI grade) after first TACE for prognosis prediction in CHC-HCC patients.
Method: From January 2005 to December 2015, freshly diagnosed naïve CHC-HCC patients that were treated with TACE as the initial treatment at the Chang Gung Memorial Hospital, Linkou Medical Center were retrospectively recruited. The pre-treatment host factors, tumor status and non-invasive markers were collected. The Cox regression model was used to identify independent predictors of overall survival.
Results: Among 613 treatment-naïve CHC-HCC patients, most (74.9%) were grade II/III at baseline. The median follow-up duration was 31.7 (range 3.0-129.0) months. 430 patients died after repeated TACE that more than half due to liver failure (n = 241, 56.0%) during median follow-up 26.9 months. Complete remission after repeated TACE occurred in 46.2% patients. 208 patients (33.9%) had tumor recurrence after complete remission with median recurrence free interval 8.5 months. By Cox regression analysis, ALBI grade II/III (aHR: 1.451, p = 0.005) and increased delta ALBI grade during treatment (aHR: 1.436, p = 0.006) were predictive factors while achieving complete response after repeated TACE (aHR: 0.373, p < 0.001) was a protective factor of mortality. The 2- and 5-year survival rate was lower in ALBI grade II/III (67.3%, 34.2% vs. 77.2%, 46.8%) and in increase delta ALBI grade patients (67.8%, 20.0% vs. 73.4%, 39.6%) (Log rank test, p = 0.023 and 0.039 respectively). Furthermore, ALBI grade II/III (aHR: 1.088, p = 0.035) and increased delta ALBI grade (aHR: 1.456, p = 0.029) were independent predictive factors related to tumor recurrence. The 1- and 2-year HCC recurrence rate was higher in ALBI grade II/III (54.3%, 74.3% vs. 43.9%, 61.7%) and in increase delta ALBI grade patients (71.1%, 86.8% vs. 52.0%, 72.0%) (Log rank test, p = 0.042 and 0.026 respectively).
Conclusion: Both ALBI and delta ALBI grade are independent parameters to predict survival and tumor recurrence of CHC-HCC patients receiving TACE treatment.

SAT-489
Efficacy and safety of thermal ablation in patients with hepatocellular carcinoma and high comorbidity

Maria Torner[1], Paola Rueda[2], Ana Gomez[3], Andrés Castano-Garcia[3], Carmen Álvarez-Navascués[3], Maria Luisa Gonzalez Dieguez[3], Valle Cadahía-Rodrigo[3], Amador Prieto[2], Alicia Mesa[2], Manuel Rodríguez[3], Maria Varela[3]. Universitario Central De Asturias, Gastroenterology and Hepatology, Oviedo, Spain
Email: mariatrnrsm@gmail.com

Background and aims: Radiofrequency (RF) is the ablative method of choice in HCC BCLC-0/A not candidates for resection or transplantation. Microwave ablation (MW) is potentially more effective by avoiding the heat sink effect and achieving greater ablation volume. There is little evidence comparing RF vs MW (specially in Caucasian patients) and also about the prognosis in patients (pat.) with high comorbidity (hc). Describe the efficacy and safety of thermal ablation in pat. with hc (Charlson index > 3) with HCC.
Method: This is a retrospective observational unicentric study on pat. with HCC and high comorbidity who received RF/MW as initial treatment, decided on a multidisciplinary committee (MC). Visits were made at baseline, one more post-RF/MW and every 4 months if evidence of a complete response (mRECIST criteria), deciding the follow-up schedule in MC. Baseline variables (comorbidity, liver function, tumour burden), type of treatment, adverse effects, and clinical-analytical-radiological changes of each visit were recorded. RF was performed with cool-tip RF Ablation System (Medtronic) and MW with Solero MTA System (AngioDynamics) under deep sedoanalgesia.
Results: From Jan 2014 to July 2018, 163 pat. were treated and 86 met the inclusion criteria (44 RF/42 MW): 70 males, median age 69, range 50-85 years; 74 cirrhosis (66 Child-A, 8 Child-B7); Charlson index: median 8, range 4-14. Etiology: 39 alcoholic, 34 HCV, 6 NAFLD. Staging: 19 BCLC-0/67 BCLC-A; 70 uninodular, 50 subcapsular, median tumour diameter 25 mm (P25- P75 19-33). Complete response to the first ablation was observed in a 65.9%, being the most frequent recurrence adjacent to the ablation margin (73, 04%). There were 14% complications (decompensation of cirrhosis 2.3%), 1 death after colon perforation. Baseline characteristics, tumour burden and evolution were similar in RF vs MW, except basal platelets (RF: $128x10^3$vs MW: $131x10^3$, p = 0.006) and n° nodules [RF: 1 (n = 29), 2 (n = 11), 3 (n = 2) vs MW: 1 (n = 41), 2 (n = 3), 3 (n = 0), p = 0.012]. No differences were found in the complete response rate (p = 0.203) or in complications (p = 0.412). Median follow-up was 19 months, 12 transplanted, 16 deceased (10 due to comorbidity). The median overall survival, OS (n = 86) was 40 months, 95% CI 37.4-42.6, without differences between RF/MW (p = 0.234). The baseline factors associated with OS in the univariate analysis were age (p = 0.024), platelets (p < 0.01), serum creatinine (p < 0.01), Charlson index (p = 0.008), BCLC (p = 0.096) and AFP (p < 0.01); and in the multivariate BCLC (p = 0.022, HR 4.090, 95% CI 1.230-13.597), the Charlson index (p = 0.014, HR 0.104, 95% CI 0.017-0.635) and the AFP value (p = 0.012; HR 1.005; 95% CI 1.001-1.009).
Conclusion: Thermal ablative treatments are safe and effective in patients with high Charlson index. In our series, there were no differences in the complete radiological response rate or in the adverse events between RF and MW.

SAT-490

No impact of direct-acting antivirals on recurrent hepatocellular carcinoma tumour growth in the ANRS CO22 Hepather Cohort

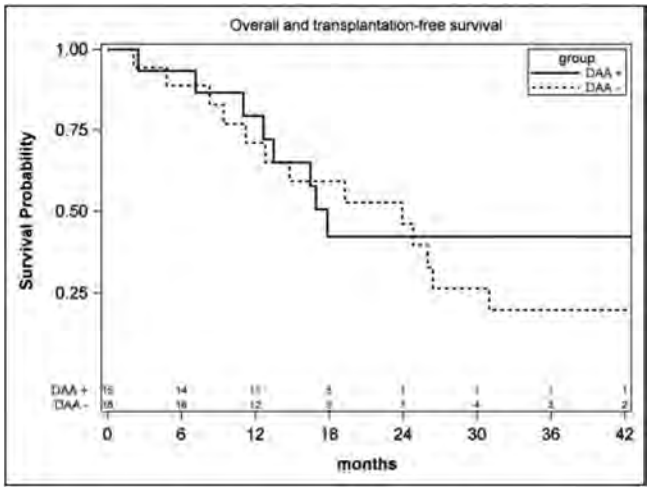
Email: anais.vallet-pichard@aphp.fr

Background and aims: If a significant risk of hepatocellular carcinoma (HCC) associated with direct-acting antiviral (DAA) in HCV-infected patients has now been excluded, a putative effect of DAAs on tumor growth is still debated. We performed a blinded comparison of the kinetics of HCC recurrence after HCV treatment with DAAs (DAA+) or no treatment (DAA-).
Method: Blinded radiological re-evaluations (CT scan and/or MRI) of the 40 HCV-infected patients with HCC recurrence (J Hepatol 2016), 6 months before the HCC recurrence, at the time of recurrence and in the follow-up. Seven patients (17.5%) were excluded because the "curative" treatment was not confirmed (incomplete hepatic response in 6 and parietal HCC spreading). Thirty of the 33 patients were Interferon-experienced.
Fifteen DAA^+ patients (3 with PEG-IFN) before HCC recurrence (occurring 9 (0.3-33) months after treatment) were compared to the 18 DAA^- patients among whom 4 initiated DAA after HCC recurrence. The median (IQR) follow-up was 17 (13-23) in DAA^+ and 28 months in DAA^- (11-51) (p = 0.11).
Results: They were 24 men, with a median age of 62 (57-71) years and 31 (94%) had cirrhosis. The DAA^+ in comparison with DAA^- patients had a lower MELD score (7.5 vs 10.1, p = 0.03). The median delay of HCC recurrence (time between the date of curative treatment and diagnosis of recurrence) was not different (21 vs 17 months) (p = 0.28) between DAA^+ and DAA^-. There was no difference in the rate of unifocal recurrence (47 vs 33%, p = 0.85), of nodular (vs infiltrative) form (93 vs 100%, p = 0.45), in the median diameter of the largest nodule (14 vs 19 mm, p = 0.40), in the rate of portal invasion (6.7 vs 5.6%, p = 0.99).
Seven patients died in each group; 1 and 7 liver transplantations were performed in the DAA^+ and DAA^- groups, respectively without difference of the overall survival and (/or) transplantation-free survival (median 17.8 vs 23.9 months, respectively, p = 0.98) (Figure). There was no difference between the groups for the occurrence of new hepatic nodules (p = 0.78), and RECIST time to progression (p = 0.81).



Conclusion: This blinded analysis of HCC recurrence after curative treatment does not evidence a significant impact of DAA therapy on the delay, severity or progression of HCC. Despite it does not impact overall survival, it suggests that DAA treatment should be initiated in all cirrhotic patients, including those with prior history of HCC.

SAT-491

Assessment of liver function by 13C methacetin breath test may help to predict liver function deterioration after selective transarterial chemoembolisation of hepatocellular carcinomas

Florian Van Bömmel[1], Stella Wellhöner[1], Rhea Veelken[1], Florian Gerhardt[1], Tim-Ole Petersen[2], Bettina Maiwald[2], Steffen Strocka[2], Albrecht Boehlig[1], Thomas Berg[1]. *[1]University Hospital Leipzig, Department of Gastroenterology and Rheumatology, Section of Hepatology, Leipzig, Germany; [2]University Hospital Leipzig, Department of Diagnostic and Interventional Radiology, Leipzig, Germany*
Email: florian.vanboemmel@medizin.uni-leipzig.de

Background and aims: Transarterial chemoembolization (TACE) for the treatment of hepatocellular carcinoma (HCC) is associated with a risk of deterioration of liver function. The maximum liver function capacity test (LiMAx®) is a dynamic breath tests based on ^{13}C methacetin metabolism that reflects the hepatic functional mass. The aim of our study was to assess the potential of LiMAx to give more accurate information on decrease of liver function following TACE as compared to currently used routine parameters.
Method: Transarterial chemoembolization (TACE) for the treatment of hepatocellular carcinoma (HCC) is associated with a risk of deterioration of liver function. The maximum liver function capacity test (LiMAx®) is a dynamic breath tests based on ^{13}C methacetin metabolism that reflects the hepatic functional mass. The aim of our study was to assess the potential of LiMAx to give more accurate information on decrease of liver function following TACE as compared to currently used routine parameters.
Results: Before the first TACE, LiMAx results revealed normal liver function, limited hepatic or significant hepatic impairment in 9, 18 and 10 patients. LiMAx results correlated intermediately with CPS (r = -0.54) and weakly with BCLC (r = 0.13) scores. At day 14 after TACE, all patients were still under observation including two with newly developed and one with shift from mild to moderate ascites, 3 with increase in CPS score, 3 and one with newly developed fatigue or pruritus, respectively, all of which had shown either limited or severe hepatic impairment by LiMAx ($^{13}CO2$ < 275 µg/kg/h) before TACE. Four patients with previously normal liver function by LiMAx had shifted to limited hepatic and one from limited to severe hepatic impairment.
Conclusion: Assessing liver function by ^{13}C methacetin metabolism may represent a novel tool for the early identification of patients developing deterioration of liver function after TACE. Our results need to be confirmed in larger cohorts and for different interventional treatments for HCC.

SAT-492

Associating spleen volume and liver stiffness measurements improves prediction of persistent post-hepatectomy decompensation after resection of hepatocellular carcinoma

Ramiro Fernandez[1], Audrey Coilly[1], Luis Cano[2], Daniel Cherqui[1], nicolas golse[1], Marc-Antoine Allard[1], Antonio Sa Cunha[1], René Adam[1], Cyrille Feray[1], Didier SAMUEL[1], Eric Vibert[1]. *[1]AP-HP Hôpital Paul-Brousse, Centre Hépato-Biliaire, Villejuif, France; [2]INSERM, Univ. Rennes, CHU Rennes, INRA, Univ. Bretagne Loire, Nutrition Metabolisms and Cancer, Rennes, France., Rennes, France*
Email: ramirofp02@gmail.com

Background and aims: Liver Stiffness Measurement (LSM) by Transient Elastography (TE) could be useful for predicting persistent post-hepatectomy decompensation (PHD) with thresholds around 22kPa (ref). However, there is a so-called "gray zone" (15 to 22kPa) where prediction of outcomes remains challenging and this might condition the use a composite score including another factor. Spleen volume, a parameter associated to portal hypertension, could improve patient selection in association with LSM.
Method: Patients who underwent hepatectomy at our tertiary center were included in a prospective database, all patients operated for HCC between august 2014 to December 2017 were considered for inclusion in the study. Follow-up results were analyzed beyond three months. Spleen volume was measured using dedicated software and Liver Stiffness Measurements were obtained with Transient Elastography. Morbidity/Mortality was defined accoding to Clavien-Dindo classification. Post-hepatectomy liver failure was defined by the "50:50 criteria" and PHD if ascites, jaundice or encephalopathy were present after three-month follow-up.
Significant preoperative variables were included for multivariate analysis and bootstrapped at 1, 000 to determine independent factors for PHD. ROC curves were performed to determine LSM and SV cut-off points and diagnostic ability. Thereafter, a theoretical decision tree model was created and compared the diagnostic ability with and without the presence of SV in the algorithm.
Results: One hundred and sixteen patients were analyzed. The median of number of lesions was 1 (1-9) and the tumor size was 3.5 cm (0.7-45). Laparoscopic resections were made in 35% of patients. PHD was found in 9.5% (n = 11). Mortality rate was 4.3% (n = 5). LSM had a cut-off point of 11.6kPa (AUROC 0.71 CI 95% 0.71-0.88) with a sensitivity of 89%, specificity of 47% with a PPV of 14% and a NPV of 98%. The SV showed a cut-off point of 380 cm^3 (AUROC 0.77 CI 95% 0.77-0.93) with a S: 55%, Sp: 91%, PPV 38.5% and NPV 96%. SV and LSM did not have a correlation above the threshold of 11.6kPa (r = 0.156 p = 0.152).
A theoretical decision tree model was created using LSM with or without SV. ROC curves were obtained. If SV was retained, there was an increase in Sensitivity (from 61.5% to 96.7%) and NPV (from 96.4 to 100%) but also a decrease in Specificity (From 96.7 to 93.4) and PPV (from 64 to 59.1%) (p = 0.0034).
In the cohort, 8.6% of the patients with LSM > 11.6kPa developed PHD; however 36% of patients with both LSM > 11.6 and SV > 380cm^3 presented it. None of the patients without any of the conditions had PHD.
Conclusion: Associating SV to LSM improves prediction of PHD. Given the non-invasive nature of these tests, they can be used for selection of patients with HCC who are fit for liver resection.

SAT-493

Prevalence and clinical significance of intrahepatic cholangiocellular carcinoma with radiological enhancement pattern mimicking hepatocellular carcinoma

Luca Vigano[1], Ana Lleo[2], Riccardo Muglia[3], Nicolo Gennaro[3], Laura Sama[1], Francesca Colapietro[2], Luca Di Tommaso[4], Alessio Aghemo[2], Massimo Roncalli[4], Luigi Solbiati[3], massimo colombo[2], Guido Torzilli[1]. *[1]Humanitas Clinical and Research Center, Hepatobiliary and General Surgery, Rozzano, Italy; [2]Humanitas Clinical and Research Center, Internal Medicine and Hepatology, Rozzano, Italy; [3]Humanitas Clinical and Research Center, Radiology, Rozzano, Italy; [4]Humanitas Clinical and Research Center, Pathology Unit, Rozzano, Italy*
Email: luca.vigano@humanitas.it

Background and aims: Non-invasive diagnosis of hepatocellular carcinoma (HCC) in patients with cirrhosis requires demonstration of wash-in and wash-out on contrast imaging. Recent studies reported misclassification with intrahepatic cholangiocarcinoma (ICC). To analyze the radiological enhancement patterns of ICC and their association with prognosis, with particular interest to lesions mimicking HCC.
Method: We retrospectively evaluated all consecutive patients affected by ICC undergoing surgery between 2007 and 2017. Patients with mixed HCC-ICC were excluded. Two expert radiologists reviewed the arterial and portal/late phases of preoperative CT and

MRI. Full-nodule hyper-enhancement in arterial phase and hypo-enhancement in portal/late phase was classified as "HCC-like pattern." Imaging of ICCs with HCC-like pattern was reviewed by an additional radiologist blinded to clinical data.

Results: We reviewed imaging of 92 patients (mean age 68 years; males 49%; cirrhosis 18%) including multiphase CT in all and MRI in 85 (92%). Sixty-six (72%) tumors showed arterial hyper-enhancement, categorized as: full-nodule (12/66, 13%), > 25% of nodule (20/66, 22%) and peripheral (34/66, 37%). The remaining ICCs were either iso-enhancing (4%) or hypo-enhancing (24%). Among 12 ICCs with full-nodule arterial enhancement, 4 were hypo-enhancing in portal/late phase (HCC-like pattern), including 1 cirrhotic patient.

Overall, 4/92 (4%) ICCs (4/45 cirrhosis/hepatitis, 9%) showed a HCC-like pattern accounting for misclassification as HCC on imaging review. HCC-like ICCs accounted for 9% of single tumors ≤ 50 mm. All HCC-like ICCs arose on liver cirrhosis or hepatitis (100% vs. 47% for non-HCC-like ICCs, p = 0.053).

After a median follow-up of 29 months, 3-year survival was 62%. All patients with HCC-like ICCs are alive and disease-free (median 64 months), whereas peripheral rim enhancement was associated with a shorter 3-year survival (48% versus 70%).

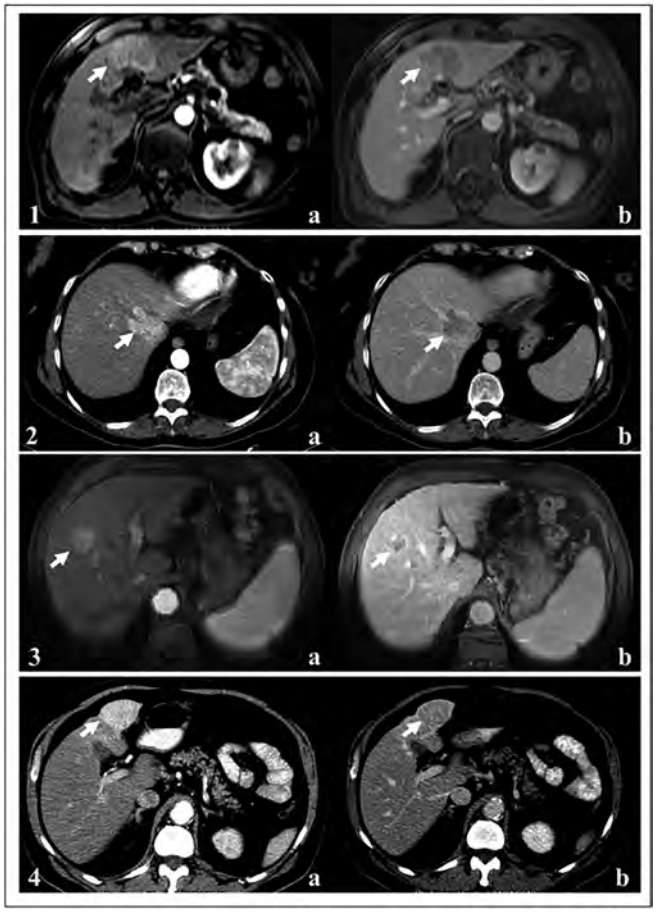


Figure: ICC with a full-nodule wash-in (a) and wash-out (b) pattern at CT or MRI contrast-enhanced imaging, mimicking typical features of HCC.

Conclusion: ICC can be misdiagnosed as typical HCC in 4% of cases, 9% of single tumors ≤ 50 mm or of tumors on cirrhosis/hepatitis. HCC-like ICCs show a favorable survival compared to ICCs with peripheral rim enhancement. The risk for misdiagnosis should be considered before treatment planning.

SAT-494

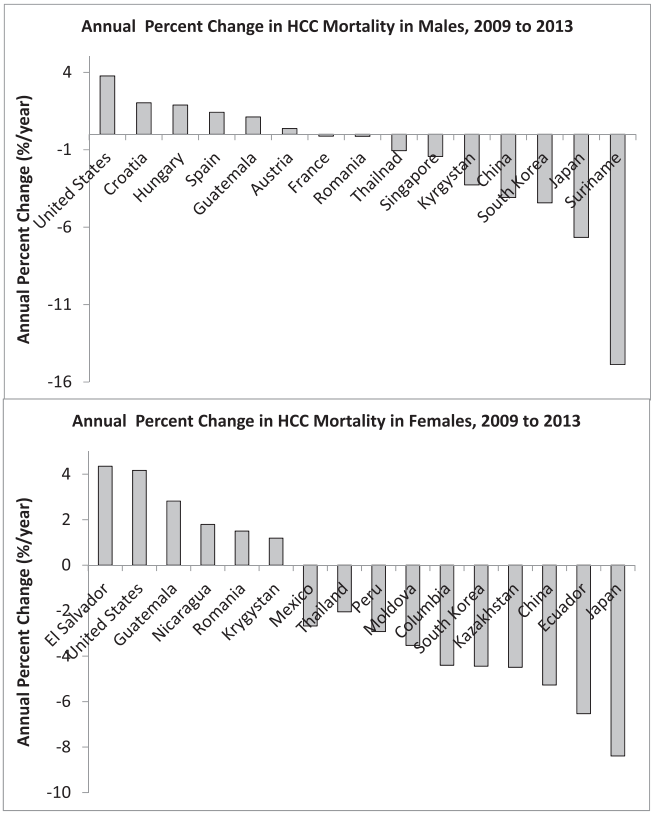
Global hepatocellular carcinoma mortality trends: An analysis of the world health organization cancer mortality database

Chuck Chan[1], Benny Liu[2], Taft Bhuket[2], Robert G. Gish[3,4], Robert Wong[2]. *[1]Western University of Health Sciences, Pomona, United States; [2]Alameda Health System-Highland Hospital, Gastroenterology and Hepatology, Oakland, United States; [3]Stanford Hospital, Palo Alto, United States; [4]Hepatitis B Foundation, Doylestown, United States*

Email: rowong@alamedahealthsystem.org

Background and aims: Hepatocellular carcinoma (HCC) is the second leading cause of cancer-related deaths worldwide. HCC mortality is influenced by multiple factors including etiology of liver disease, successful implementation of HCC surveillance, and access to HCC therapies, among which there is significant variation across world regions. Identifying regions with persistently high HCC mortality can help target public health resources to those in need. We aim to evaluate country-specific disparities in HCC mortality trends using World Health Organization's (WHO) Cancer Mortality Database.

Method: We retrospectively evaluated 2004-2013 WHO cancer mortality data to identify adults (age 35-74 years) with histologically confirmed HCC across 58 countries. Age-standardized sex-specific mortality rates were calculated based on country-specific population data and presented as mortality rate per 100, 000 persons. Annual percent change (APC) in HCC mortality was evaluated using a simple regression model to the log of the adult survival rate.



Results: Overall HCC mortality among men was highest in South Korea (63.56 per 100, 000 persons) and Thailand (63.31 per 100, 000 persons), both significantly higher than the country with the next highest HCC mortality, China (43.36 per 100, 000 persons, p < 0.001). HCC mortality in women was highest in Thailand (22.77 per 100, 000 persons) and Guatemala (22.39 per 100, 000 persons), both significantly higher than the country with the next highest mortality, South Korea (14.55 per 100, 000 persons). Within each country, HCC

mortality was significantly higher in men compared to women. For example, HCC mortality in men was nearly 4 times higher than women in a high HCC mortality region such as South Korea (63.56 vs. 14.55 per 100, 000 persons, p < 0.001), with similar observations in a lower HCC mortality region such as Spain (14.88 (men) vs. 3.83 (women) per 100, 000 persons, p < 0.001). While South Korea, Thailand, and China had the highest HCC mortality among men, all three countries reported overall declining mortality from 2009 to 2013 (APC: South Korea, 4.43% decline; Thailand, 1.06% decline; China, 4.08% decline). While Thailand, Guatemala, and South Korea had the highest HCC mortality rates among women, only Thailand (APC, 2.95% decline) and South Korea (APC, 4.44% decline) demonstrated decreasing mortality from 2009-2013, whereas HCC mortality increased in Guatemala (APC, 4.17% increase).

Conclusion: Significant country-specific and sex-specific disparities in worldwide HCC mortality were observed. While HCC mortality rates have declined in many world regions, countries with rising HCC mortality require greater attention to identify potential gaps in the HCC care cascade so that quality improvement programs can be implemented to improve global HCC outcomes.

SAT-495

Incidence and risk factors of hepatocellular carcinoma in patients with hepatitis C in China and the US

Ming Yang[1], Neehar D. Parikh[2], Huixin Liu[3], Elizabeth Wu[2], Sherry Fu[2], Huiying Rao[1], Bo Feng[1], Andy Lin[4], Ran Fei[1], Lai Wei[1], Anna S. Lok[2]. *[1]Peking University People's Hospital, Peking University Hepatology Institute, Peking University Health Science Center, Beijing, China; [2]Department of Internal Medicine, Division of Gastroenterology and Hepatology, University of Michigan, Ann Arbor, United States; [3]Department of Clinical Epidemiology and Biostatistics, Peking University People's Hospital, Beijing, China; [4]The Molecular and Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, United States*
Email: ymicecream@163.com

Background and aims: Hepatitis C virus (HCV) infection is the main cause of HCC in the US and an increasingly common cause of HCC in China. We aimed to evaluate the incidence and risk factors of HCC in HCV patients in China and the US.

Method: HCV RNA+, HBsAg- patients without HCC were prospectively recruited from 2 centers in China and 1 center in the US using a standardized protocol. Diagnosis of HCC was based on predefined criteria and radiology/pathology reports. Competing-risk Cox regression was used to identify risk factors for HCC with SVR as time-dependent covariate.

Results: 795 US and 854 Chinese patients followed for a median of 3.06 and 3.99 years, respectively were analyzed. US patients were significantly more likely to be men (57.4% vs. 48.2%), older (median 57 vs. 53 years), have cirrhosis (45.4% vs. 16.2%), diabetic, have current or past use of alcohol, cigarettes and coffee, and lower prevalence of anti-HBc. 45 US patients and 13 Chinese patients developed HCC. Cumulative incidence of HCC at 5 years was significantly higher in the US than in the Chinese cohort, 7.6% vs. 1.8% (p < 0.0001), which was driven by the higher prevalence of cirrhosis in the US patients. None of the patients with APRI < 0.5 or FIB-4 < 1.45 developed HCC. In the 10 patients without cirrhosis at enrollment who developed HCC, the median APRI was 2.03 and FIB-4 4.49 compared to 0.55 and 1.67, respectively in those who did not develop HCC. 53.7% of US and 50.6% of Chinese patients achieved SVR. HCC developed in 8 patients with cirrhosis but none of the patients without cirrhosis, after achieving SVR. Multivariate analysis showed that age, gender, cirrhosis and APRI were predictors of HCC while study site and SVR were not. SVR was associated with significantly lower incidence of HCC when analyzed as binary variable with hazard ratio of 0.16 (0.08-0.33) overall, and 0.22 (0.11-0.46) for cirrhosis patients.

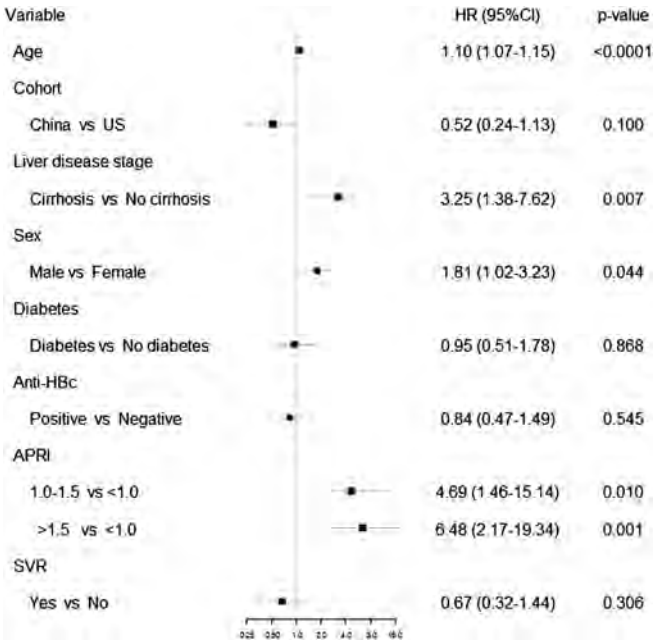


Figure: Multivariate Cox regression analysis of predictors of HCC

Conclusion: In this study of HCV patients, HCC incidence in the Chinese cohort was lower than in the US cohort, due to lower proportion of Chinese patients with cirrhosis. APRI and FIB-4 can identify risk of HCC among patients not diagnosed to have cirrhosis. Incidence of HCV-related HCC in China and the US will continue to increase unless patients are treated prior to cirrhosis development.

SAT-496

Circulating cell-free HBV-human chimera DNA as new marker for HCC recurrence and clonality after curative resection

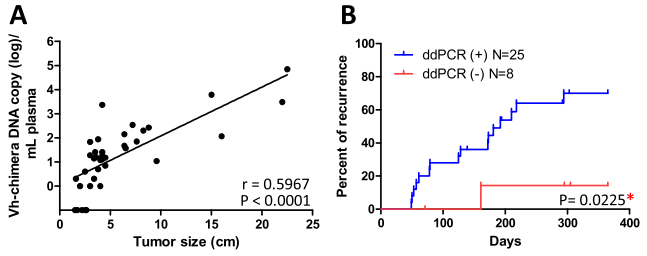
Chiao-Ling Li[1], Ming-Chih Ho[1], You-Yu Lin[1], Sheng-Tai Tzeng[2], Yun-Ju Chen[2], Hsin-Yung Pai[2], Ya-Chun Wang[2], Shiou-Hwei Yeh[1], Pei-Jer Chen[1]. *[1]National Taiwan University College of Medicine, Taipei, Taiwan; [2]TCM Biotech International Crop., Taipei, Taiwan*
Email: peijerchen@ntu.edu.tw

Background and aims: Early stage hepatocellular carcinoma (HCC) is treated by curative therapies, such as surgical resection or RFA. However, about 20-50% of patients develop tumor recurrence within the first year, indicating the frequent presence of minimal residual HCC after curative therapies. Alpha-fetoprotein (AFP) is the only biomarker currently used in clinical diagnosis for residual HCC but with limited sensitivity and specificity, and a better biomarker is an unmet need. This study examined the HBV-human chimera DNA (vh-DNA), generated from junctions of HBV integration in HCC chromosome and released into blood, as a potential circulating biomarker in HBV-related HCC. As more than 90% of HBV-related HCC contain integrated HBV DNAs which randomly distribute in chromosomes, the vh-DNA becomes a signature biomarker for monitoring the presence and clonality of recurrent HCC in majority of cases.

Method: We established a capture-next generation sequencing (NGS) platform to identify the HBV integration sites in 42 resected HCC tissues. For individual HCC, the most dominant junction of HBV integration was chosen to design specific primer pairs for droplet digital PCR (ddPCR). The ddPCR was used to detect and quantify the HCC specific vh-DNA in plasma samples collected just before surgery and 2 months after surgery. Levels of vh-DNA were then correlated with HCC recurrence in one-year follow-up.

Results: We succeeded in detecting HBV integrations in the HCC from 38 out of 42 HBV-related HCC patients (~91%), matching the performance of whole genomic sequencing. One specific signature vh-chimera was chosen from individual HCC of 38 cases, for detection

of circulating vh-DNA in the plasma (1 ml). The copy number of vh-DNA in plasma at surgery correlated well with the size of HCC, with the detection limit at 1-2 cm (Fig. 1A). Among the plasma collected at 2 months after surgery, two-thirds of samples contained the same signature vh-DNA as baseline plasma, indicating a possible residual HCC. Consistently, they suffered HCC recurrence more frequently than those without vh-DNA (Fig. 1B) in one year. The detection of same signature vh-DNA during HCC recurrence confirmed majority of recurrence within one year originated from the residual HCC escaping the surgical resection.



(A) Correlation between tumor size and plasma vh-DNA (copy number / mL plasma). (B) Recurrence analysis stratified by (+) or (-) of plasma vh-DNA detected by ddPCR.

Conclusion: This study supported vh-DNA as a new circulation marker for detecting minimal residual HCC in HBV-related HCC after surgery and for monitoring recurrence within one year of surgical resection. The marker warrants more investigations for clinical use.

SAT-497

Individual surveillance using PAGE-B score-based hepatocellular carcinoma risk in chronic hepatitis B patients under potent antiviral therapy

Minjong Lee[1], Ji Hyun Kim[1], Seong Hee Kang[2], Tae Suk Kim[1], Baek Gyu Jun[3], Ki Tae Suk[4], Moon Young Kim[2], Young Don Kim[3], Gab Jin Cheon[3], Soon Koo Baik[2], Dong Joon Kim[5], Dae Hee Choi[1].

Email: minjonglee2@naver.com

Background and aims: Current guidelines for chronic hepatitis B (CHB) patients are to undergo surveillance for hepatocellular carcinoma (HCC) with ultrasonography (US) every 6 months. However, sensitivities of US to detect early stage HCC are suboptimal in cirrhotic patients. We aimed to compare detection rates of very early stage HCC based on the Barcelona Clinic Liver Cancer stage (BCLC 0) between two groups: group A under 6-monthly US surveillance vs. group B under 6-monthly alternate dynamic 4-phase computed tomography (CT) and US surveillance. In low-risk patients, detection rates of HCC within BCLC 0 were compared between patients under 6-monthly US and 12-monthly US surveillance.

Method: We examined 2,151 CHB patients under entecavir/tenofovir therapy in multicenter cohorts from 2007 to 2016. In intermediate- and high-risk patients based on the PAGE-B score, detection rates of HCC within BCLC 0 were compared between group A and B. In low-risk patients, detection rates of HCC within BCLC 0 were compared between patients under 6-monthly US and 12-monthly US surveillance. Primary end point was proportion of HCC within BCLC 0 in each group. Cox proportional hazards model was used to assess effect of surveillance modality on detection of HCC within BCLC 0 after balancing between the comparison groups using frequency matching.

Results: During a median follow-up of 4.3 years in the high-risk group (n = 584), 5-year cumulative HCC incidence rates in group A were 15.0% not significantly different from 18.2% in group B (p = 0.17). However, detection rates of HCC within BCLC 0 were significantly higher in group B than those in group A (p < 0.001). In multivariable analysis for detection of HCC within BCLC 0, surveillance modality using CT showed a significant association with detection of HCC within BCLC 0 (adjusted hazard ratio [HR] 3.89, 95% confidence interval [CI] 2.03-7.44, P < 0.001). In intermediate-risk patients (n = 1,063), 5-year cumulative HCC incidence rates in group A were 5.3% not significantly different from 5.8% in group B (p = 0.30). Detection rates of HCC within BCLC 0 between A and B were not significantly different (p = 0.22). In multivariable analysis for detection of HCC within BCLC 0, surveillance modality using CT did not show a significant association (HR 1.61, 95% CI 0.75-3.47, P = 0.23). In low-risk patients (n = 504), 5-year cumulative HCC incidence rates in patients under 6-monthly US surveillance were 0.7% not significantly different from 0.5% in patients under 12-monthly US surveillance (p = 0.80). All of patients were diagnosed with HCC within BCLC 0 irrespective of surveillance intervals.

Conclusion: In CHB patients at high risk, surveillance using alternate dynamic CT and US resulted in significantly higher detection rates of very early HCC as compared to continuous US surveillance. The PAGE-B scores enable clinicians to provide more individualized surveillance recommendations.
